THE ABSOLUTE MEASUREMENT OF HIGH ELECTRICAL PRESSURES.

By Prof. W. M. THORNTON, O.B.E., D.Sc., D.Eng., Member, and W. G. THOMPSON, Ph.D., B.Sc., Graduate.

(*Paper first received* 30*th April, and in final form* 28*th July*, 1931; *read before* THE INSTITUTION 21*st January, and before the* NORTH-EASTERN CENTRE 11*th January*, 1932.)

SUMMARY.

There is at present no absolute standard method of measurement by which the high voltages now in common use may be compared. The paper gives an account of such a method in which the polarization of a metallic ellipsoid of revolution, suspended by an insulating fibre between vertical circular pole-plates, is observed. The dimensions and proportions of the ellipsoid and of the horizontal field were determined with high accuracy, and the magnitude of the electric gradient on the axis of symmetry of the instrument was calculated for given applied voltages. The working formula of the instrument is $F = k(n^2 - n_0^2)^{\frac{1}{2}}$, where F is the field strength, k a constant found from the dimensions, n the number of swings per second of the ellipsoid with the field on and n_0 with it off. The influence of the spacing of the plates, of shielding the ellipsoid, of gas pressure and temperature, was examined, and the readings of the instrument were compared with Whitehead and Castellain's sphere-gap determinations of voltage. As a combined check on the accuracy of their readings and those of this instrument, a value of the ratio c of the electromagnetic to the electrostatic units of quantity is obtained which agrees with the best previous results. It is concluded that continuous measurements of voltages up to 200 kV can be made with the precautions indicated in the paper, to an accuracy of at least 3 parts in 1 000, the constant of the instrument depending upon the value accepted for the ratio c.

(11) Determination of ratio of units.

(1) INTRODUCTION.

The accurate measurement of many physical constants depends upon the precise determination of the high potentials used to produce electrical discharge. There is at present no accepted standard of measurement with which instruments employed for this purpose can be compared. The Kelvin attracted-disc electrometer type, for so long the most convenient means of high-voltage measurement, is not made to deal as an instrument of precision with the pressures now common in electrical practice; its size becomes prohibitive and its factor of safety is low. Pérot and Fabry* showed that it is suitable for the absolute measurement of low voltages, but for the direct measurement of high voltages there is need of a standard comparable in accuracy with the present standards of current and resistance and the low-voltage cell. Sphere spark-gap measurement of very high voltages is probably the nearest approach to it.

The theory of the electric field in such gaps has been fully worked out,† but the experimental means of checking observation against calculation still leaves much to be desired. A difference of 2 per cent is possible even in accurate sphere-gap high-voltage determinations, and it is necessary to take the mean of many readings to obtain a result reliable to 1 part in 1 000.

One convenient method of measuring high voltage indirectly is by finding the charging current of a condenser of special construction, and in that case the capacitance, current, and frequency have to be measured. Another method is by making part of a sphere gap an exploring area from which current is led to earth through rectifying valves and direct-current instruments. In these latter measurements the calculation of the capacitance of a condenser in electromagnetic measure requires the ratio c of the units. This is known to an accuracy of 1 part in 1 000 and the voltage measurements are

* *Comptes Rendus*, 1897, vol. 124, p. 180.
† A. RUSSELL: *Journal I.E.E.*, 1919, Supplement to vol. 57, p. 223.

limited to this accuracy of statement, though they may be made to a higher degree of certainty.

One method of measuring high potentials that has not hitherto been fully explored offers advantages within the above restriction. An ellipsoid suspended between plane vertical metallic surfaces at different potentials is polarized by the field and, if placed at an angle to it, experiences a torque which brings it into line. The magnitude of this torque can be calculated when the material and dimensions of the ellipsoid and the intensity of the undisturbed field are known, and can be observed either by static deflections or by allowing the suspended body to make small swings about a position of rest in line with the field.

Measurements made for the purpose of finding the dielectric constants of solid insulators have shown that this method is capable of high accuracy which depends largely on the perfection of form of the ellipsoids.* As

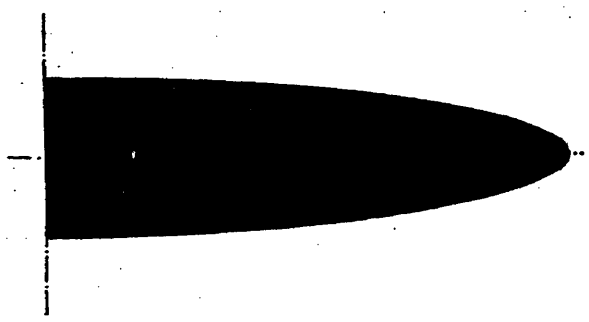

FIG. 1.—Enlarged image of ellipsoid.
Length = 3·9692 cm. Mass = 2·0496 grammes.
Diameter = 0·5970 cm. Moment of inertia = 1·65 g-cm².
Volume = 0·7388 cm³.

a matter of interest one of the ellipsoids in the above research was gilded and used to measure the intensity of the field. By a comparison of the value obtained with electromagnetic measurements of the voltage, values of c were found close enough to the accepted values to warrant a trial of the method as a means of measuring electric fields in electrostatic units.†

The method is only suitable for pressures high enough to maintain a field of several hundreds of volts per cm at the centre of the space between the plates, while at the same time the ratio of distance between plates to length of the ellipsoid should not be less than 25 if an accuracy above 1 in 1 000 is required. One advantage of such an instrument is that the calculations and working formulæ are simple and involve only the measurements of the dimensions of the ellipsoid and of its time of swing or deflection. The mechanical arrangement is also simple but, if it is to be used as a standard, the instrument must be large. In that to be described, for the measurement of voltages up to 200 000 with a desired accuracy of 1 in 1 000, the plates are 140 cm diameter and 100 cm apart.

The ellipsoids used in the previous work were made by Messrs. A. Hilger and Co. with such perfection that optical enlargement to 20 times or more the actual size failed to show a departure from the calculated ellipse of the same axial dimensions to as much as the thickness of a fine pencil line in an image 6 cm diameter and 40 cm long. It is the possibility of being able to rely on such workmanship that gives to the method, as it did to that of Pérot and Fabry, the first quality of an absolute standard instrument, an exact knowledge of the dimensions of the working part; in the present case this was a duralumin ellipsoid of revolution 0·59 cm diameter and 3·9 cm long (see Fig. 1).

* *Proceedings of the Royal Society*, A, 1909, vol. 82, p. 422.
† "A New Method of Measuring v," *Transactions of the University of Durham Philosophical Society*, 1908, vol. 3, p. 85.

(2) THEORY OF INSTRUMENT.*

The torque on the suspension of an insulated conducting ellipsoid, the longer axis of which makes an angle θ with the electric field F, is $B \sin\theta \cos\theta$, where $B = F^2V(L - N/LN)$, V is the volume of the body, and L and N are coefficients which depend only upon its shape. For a prolate ellipsoid of eccentricity e the longitudinal coefficient

$$N = 4\pi\left(\frac{1}{e^2} - 1\right)\left(\frac{1}{2e}\log\frac{1+e}{1-e} - 1\right)$$

and the transverse coefficient

$$L = 2\pi\left(\frac{1}{e^2} - \frac{1-e^2}{2e^3}\log\frac{1+e}{1-e}\right)$$

When the ellipsoid is held steadily in the position θ by torsion ϕ of the suspension the torque is a maximum at an angle of 45°. At smaller values of θ it is

$$2A\phi = B\sin 2\theta$$

$$= F^2V\frac{L-N}{LN}\cdot\sin 2\theta$$

or

$$F^2 = 2A\phi\frac{LN}{L-N}\cdot\frac{1}{V\sin 2\theta} \quad . \quad . \quad . \quad (1)$$

where A is found by experiment. The field is measured by observing the angle of torsion ϕ required to hold the ellipsoid steady at an angle θ to it.

When allowed to make small swings about the line of the field the motion of the ellipsoid is given by

$$\mathrm{I}\ddot{\theta} + A\theta + B\sin\theta\cos\theta = 0 \quad . \quad . \quad . \quad (2)$$

I being the moment of inertia about the axis of suspension.

A is then found from the free period T_0 with no field on, when B is zero and

$$T_0 = 2\pi\sqrt{\frac{\mathrm{I}}{A}}, \quad \text{or} \quad A = 4\pi^2n_0^2\mathrm{I} \quad . \quad . \quad (3)$$

n_0 being the number of free swings in a second.

For most of the work to be described the amplitude of swing was a few degrees and to a close approximation the equation of motion is

$$\mathrm{I}\ddot{\theta} + (A+B)\theta = 0 \quad . \quad . \quad . \quad . \quad (4)$$

The number of swings per second is then

$$n = \frac{1}{2\pi}\sqrt{\left(\frac{A+B}{\mathrm{I}}\right)}$$

$$A + B = 4\pi^2n^2\mathrm{I}$$

$$B = 4\pi^2(n^2 - n_0^2)\mathrm{I}$$

$$F^2 = \frac{B}{V}\cdot\frac{LN}{L-N} = 4\pi^2\frac{\mathrm{I}}{V}\cdot\frac{LN}{L-N}(n^2 - n_0^2)$$

* See *Proceedings of the Royal Society*, loc. cit., p. 422.

or $$F = k(n^2 - n_0^2)^{\frac{1}{2}} \quad . \quad . \quad . \quad . \quad . \quad (5)$$

where k (the constant of the instrument)

$$= 2\pi\left(\frac{\mathrm{I}}{V} \cdot \frac{LN}{L-N}\right)^{\frac{1}{2}}$$

For the measurement of high fields the difference between n and n_0 is so great that the latter may be neglected, and to an accuracy of 1 per cent the working formula is $F = kn$.

Swings of finite amplitude a modify the period, and the square of the frequency of swing reduced to an indefinitely small amplitude is

$$n_1^2 = \frac{n^2}{\frac{1}{2} + (\frac{1}{4} - \gamma\beta^{-2})^{\frac{1}{2}}} \cdot \left\{1 + \tfrac{1}{4} \cdot \frac{\frac{1}{2} - (\frac{1}{4} - \gamma\beta^{-2})}{\frac{1}{2} + (\frac{1}{4} - \gamma\beta^{-2})}\right\}^2 \quad (6)$$

or $$n_1^2 = n^2(1 + \tfrac{3}{2}\gamma\beta^{-2}) \text{ approx.}$$

in which $$\beta = 3\{(A/B) + 1\}$$

$$\gamma = 3\{(A/B)a^2 + \sin^2 a\}$$

The torque of the ellipsoid is proportional to the square of the field, and the instrument therefore gives true root-mean-square values. It is independent of the wave-form for pressures having the same R.M.S. value, and it is independent of temperature within possible ranges.

(3) The Ellipsoid.

In order that the difference $(n^2 - n_0^2)$ should be as large as possible in a given field the density of the ellipsoid should be small. Duralumin was used in preference to aluminium since it is more easily worked to a high finish and its density is nearly the same. No exact specification of size was given to Messrs. Hilger beyond the approximate dimensions, and the final measurements were 0·5970 cm diameter and 3·9694 cm long.

A platinum-iridium ellipsoid also made by Messrs. Hilger and measured at the National Physical Laboratory had a length of 2·4718 cm. This was enlarged optically to 26·5 cm and the duralumin ellipsoid when substituted for it gave an image of 42·55 cm. Its length deduced from these readings was (42·55/26·5) × 2·4718 = 3·9689. The mean of the two determinations, 3·9692 cm, was taken as its true length. The volume calculated from these figures, assuming true elliptical section, is 0·7408 cm³.

Measurements of the diameter of the ellipsoid along its axes gave the results compared in Table 1 with those calculated by taking the major axis 3·9692 and the minor 0·5970 and assuming that between these the section was truly elliptical.

Except at the tip the form is true to nearly 3 parts in 1 000. Higher accuracy is, of course, possible, but in ordering the ellipsoid the highest precision was not asked for. Fig. 2 shows a comparison between mathematical and actual form, the dimensions being enlarged many times.

The volume calculated from the observed form was 0·7388 cm³, which may be compared with that from the overall dimensions, viz. 0·7408 cm³.

Table 1.

Distance x from centre	Diameter		Ratio
	Observed	Calculated	
0	0·2985	0·2985	1·000
0·2799	0·2948	0·2954	0·999
0·5595	0·2844	0·2861	0·995
0·8397	0·2704	0·2704	1·000
1·1196	0·2453	0·2465	0·995
1·3995	0·2100	0·2114	0·998
1·6790	0·1577	0·1597	0·994
1·9593	0·0434	0·0515	0·840

An important factor determining the accuracy of the instrument is the moment of inertia of the ellipsoid. This was found from the geometrical moment of inertia and the density, which was obtained by careful weighing.

It was originally intended to suspend the ellipsoid in a rigid insulating saddle, but finally a hole was drilled through it and fitted with a tapered brass bush of density 8·44.

The change in the moment of inertia is

$$\pi\left(\frac{\rho_B - \rho_A}{10}\right)h[r_1^4 + r_2^4 + r_1^2 r_2^2 + r_1^3 r_2 + r_1 r_2^3]$$

The mass before bushing was 2·0496 grammes.
The final figures used were:—

Diameter:—0·5970 cm at 18° C.
Length:—3·9692 cm
Volume:—0·7388 cm³
Density:—2·7742
Original mass:—2·0496 grammes
Moment of inertia:—1·6509 g-cm² before bushing
1·6539 g-cm² after bushing

Ratio of enlargement = 10·72
Semi-major axis of enlarged image = 21·275 cm
Semi-minor axis of enlarged image = 3·2 cm
a^2 = 452·6 cm

The polarization coefficients L and N, the most important factors in the accuracy of the method, require the eccentricity e.

To determine this the enlarged image of the ellipsoid was divided into equal parts on either side of the centre and the ordinates were measured with as great accuracy as measurements on paper permit. y_1 and y_2 in Table 2 are on opposite sides of the axis.

regarded as the most probable value of e^2 to be us in calculating L and N.

Taking $e = 0{\cdot}9893$, $e^2 = 0{\cdot}9787$ and $e^3 = 0{\cdot}96$ the longitudinal coefficient $N = 0{\cdot}4489$, and the tra verse coefficient $L = 6{\cdot}0625$, whence

$$\sqrt{\left(\frac{LN}{L-N}\right)} = 0{\cdot}6967$$

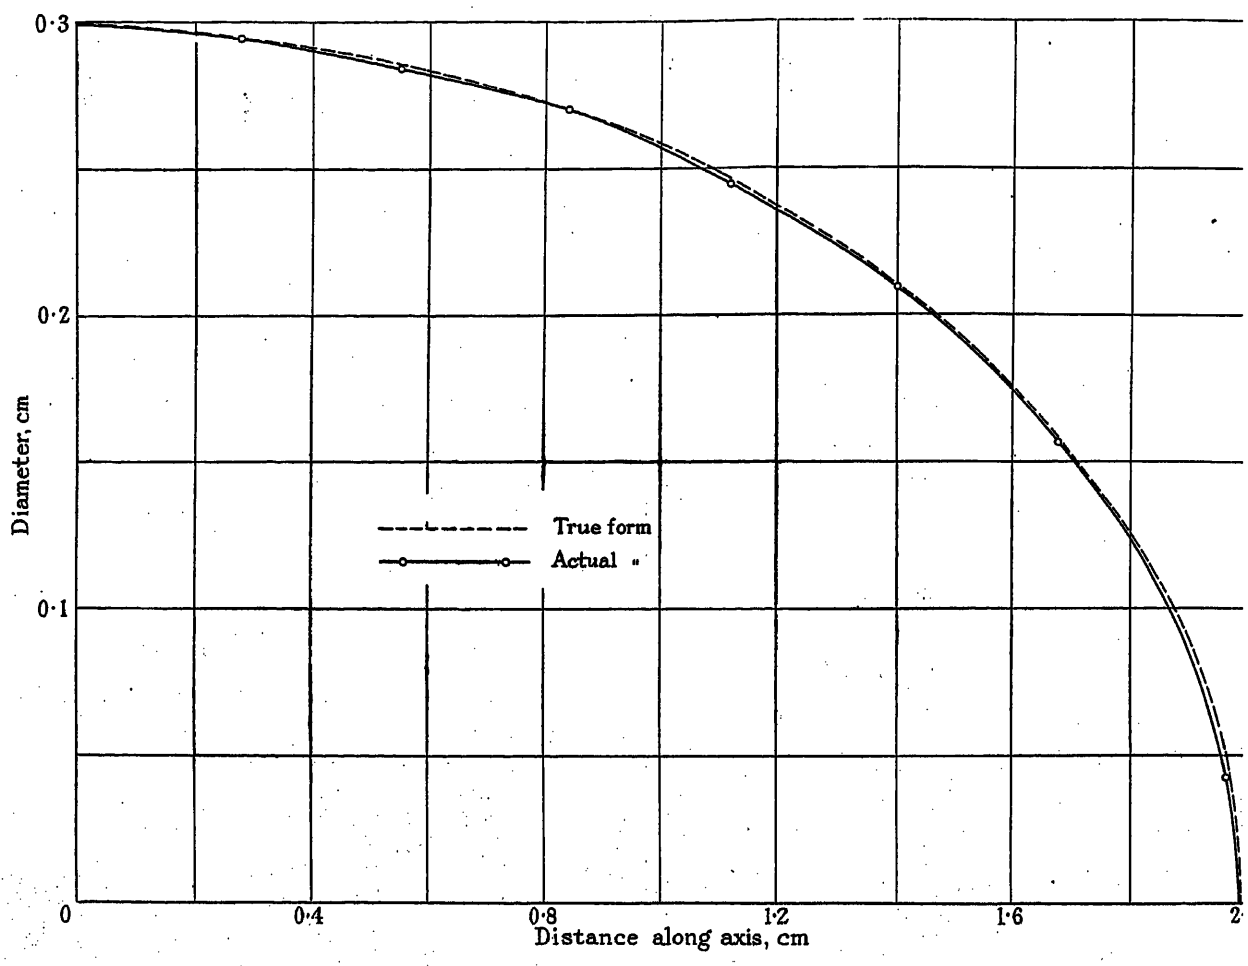

Fig. 2.—Comparison between actual and mathematical forms of the ellipsoid.

The differences between y_1 and y_2 as measured illustrate the difficulty of working from an enlargement, for by the method of shaping the ellipsoid they must be equal.

The average value of $e^2\left(=1-\frac{y^2}{a^2-x^2}\right)$ is $0{\cdot}97761$.

Omitting the last line in Table 2, $e^2 = 0{\cdot}97761$; including it, $e^2 = 0{\cdot}97914$.

The weights to be given to the readings are, however, not equal, for the torque is proportional to the product of charge on any ring element of the surface and its distance from the axis of suspension.

Weighting the values in this way, by taking moments about the axis, $e^2 = 0{\cdot}97872$.

The point of the ellipsoid plays so important a part in the concentration of the field that this may be

From the previous figures,

$$\sqrt{\frac{\mathbf{I}}{V}} = \sqrt{\frac{1{\cdot}6539}{0{\cdot}7388}} = 1{\cdot}4962$$

so that

$$F = 6{\cdot}2832 \times 1{\cdot}4962 \times 0{\cdot}6967(n^2-n_0^2)^{\frac{1}{2}}$$
$$= 6{\cdot}55(n^2-n_0^2)^{\frac{1}{2}} \text{ electrostatic units,}$$

Or, assuming $c = 3 \times 10^{10}$,

$$F = 1\ 965(n^2-n_0^2)^{\frac{1}{2}} \text{ volts per cm} \quad . \quad . \quad (1$$

Knowing from the spacing D of the plates and th tests applied that the field at the centre is uniform, th total applied voltage is FD.

(4) The Arrangement of Plates and Suspension.

The field between two flat parallel plates diverges at the edges in a manner that can be calculated or observed. When high voltages are used these edges are turned back to avoid brush discharge, for where this occurs the potential of the conductor may vary in a remarkable manner.* The spacing of the plates having been determined by trial (see Section 6) to give a negligibly small disturbance of the charge at the surface of the plate by that induced on the ellipsoid, the diameter was chosen to subtend an angle arc tan 70/50 at the centre.

The plates were made 140 cm diameter with $6\frac{1}{4}$ cm diameter rolled edges and spaced by gauge 100 cm

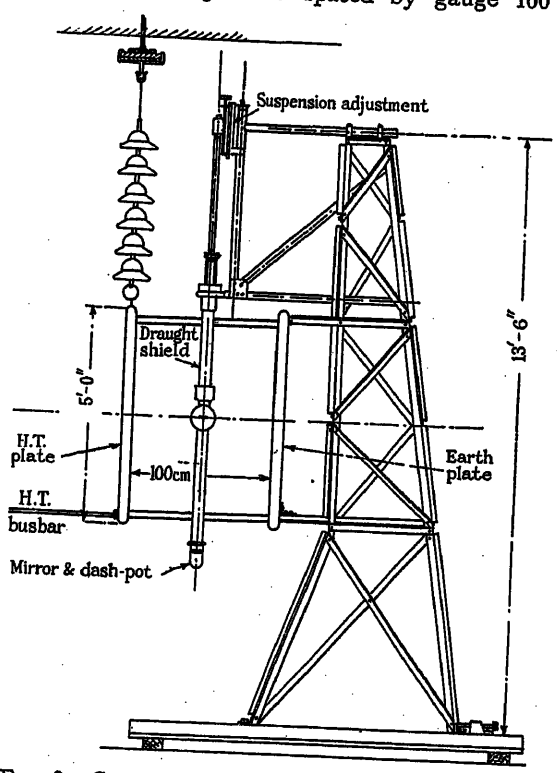

Fig. 3.—General arrangement of first form of ellipsoid voltmeter. Scale 1/53.

apart as a maximum. The distance could be varied by a screw adjustment from the foot supports and rails. Suspension-type insulators were at first used to hang the high-tension plate from an overhead girder, while the earth plate was supported on an iron lattice frame (see Fig. 3). Later the high-tension plate was supported from below and rigidly attached to the earth plate by bakelized paper tubes; the instrument could then be moved about the laboratory.

The most direct method of ascertaining the uniformity of the field between circular parallel plates is by experiment. A typical photograph of its distribution is given in *Wien-Harms Handbuch der Experimental Physik* (vol. 10, G. Hoffman: "Das Elektrostatische Feld," p. 41, Fig. 14). Several other references are quoted by him. Maxwell† gave a diagram of the spreading effect at the edges of two thin infinite parallel plates, but the only complete treatment of two parallel circular discs is that by Dr. J. W. S. Nicholson.* The problem is one of great mathematical complexity. The surface density on the inner side of the plates, of radius a, is there given by the expression for equal potentials

$$\sigma_2 = \frac{a}{4\pi}\sqrt{\left(\frac{\pi}{2}\right)}\int_0^\infty \lambda(1 - e^{-\lambda c})J_0(\lambda\rho)\phi(a\lambda)d\lambda \quad (q.v.)$$

Unfortunately this cannot be applied to discs with rolled edges, and at the present time there is no analytical solution of this most important practical problem. It might be solved by the superposition of the field between two toroids upon that of the parallel discs, but it would not be readily given a practical form.

Table 3.

Distance from centre-line	Time of 20 swings	n^2	$\sqrt{(n^2-n_0^2)}$	Ratio to field at centre
cm	secs.			
10	33·8	0·35	0·537	1·000
15	33·8	0·35	0·537	1·000
25	33·8	0·35	0·537	1·000
35	34·0	0·346	0·532	0·992
45	35·0	0·326	0·513	0·956
55	37·0	0·293	0·480	0·895
70	40·5	0·244	0·426	0·794

In order to examine the uniformity of the field between the plates in the present instrument a narrow metallic ellipsoid 1 cm long was suspended so that its oscillations could be counted when placed in various parts of the field. The results given in Table 3 are measurements taken in a plane midway between the plates, which are 140 cm diameter. The free period was 4·00 seconds per complete oscillation; $n_0^2 = 0{\cdot}0625$.

The field is therefore quite uniform over a diameter of 50 cm.

The details of the suspension of the ellipsoid and shield are given in Fig. 4.

As the ultimate aim was a steady deflection instrument of the mirror type, capable of reading over a wide range of voltage, special consideration was given to the suspension so as to ensure a permanent zero position and consistency of readings. The problem was complicated by the fact that no metal could be brought near the field of the instrument, and yet metal slides and screw feed were essential to the successful operation of the suspension control. Bakelized paper tubes, though flexible in themselves, gave the necessary rigidity when made up into a 5-bar frame (see Fig. 3). At the top of this frame, well out of the field, was mounted the adjusting gear consisting of a saddle sliding smoothly on steel guides, while from the bottom of the frame were suspended the draught tube and shield. For the steady deflection case the ellipsoid was hung by a bifilar suspension from a torsion head, the

sensitivity of the instrument being controlled by a clamp (Fig. 5) mounted on a piston sliding in the tube and actuated by the screw arrangement. When the clamp was lowered or raised the twistable length of

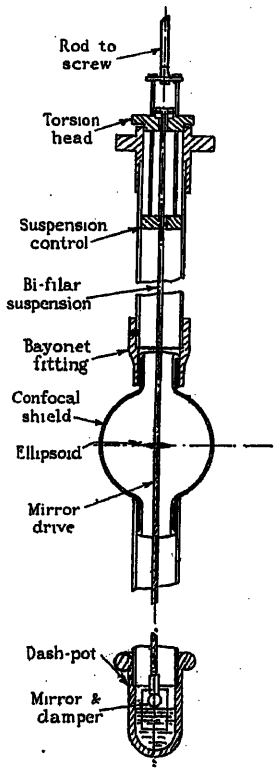

FIG. 4.

the thread was altered accordingly. This method was adopted in preference to moving the plates, for reasons which will be explained later.

When working by the method of steady deflections

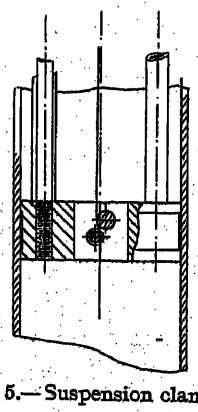

FIG. 5.—Suspension clamp.

the ellipsoid was fitted with a varnished conical paper tube which carried the mirror clear of the plates into a chamber containing a damping pot. This was made metallic to shield the mirror from the field. Attempts were made to use a metal suspension but it was found that a violent lateral oscillation occurred. Glass was also tried but, although mechanically strong enough under ordinary conditions, it was unable to withstand shock. Recourse was finally had to unspun silk, which has proved quite satisfactory.

(5) THE CALIBRATION OF THE TRANSFORMER VOLTAGE BY SPHERE SPARK-GAP.

Much work has been done under the direction of the International Electrotechnical Commission in connection with the standardization of the sphere spark-gap as a means of measuring high voltages. Curves of calibration have been published from time to time which give the distance at which a spark will pass between well-polished spheres of given sizes. Unfortunately these do not yet agree. Paschen's law has been verified over the whole range of gas pressure and temperature likely to be met with in practice, and sphere-gap measurements depend upon this for their consistency.

Measurement by spark discharge is not the most

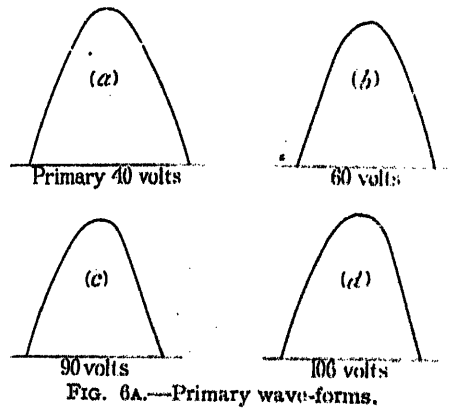

FIG. 6A.—Primary wave-forms.

satisfactory means of observing voltage in routine testing. It gives one point only and the effects of the discharge surge on apparatus connected across the gap may be disastrous. Since, however, the breakdown

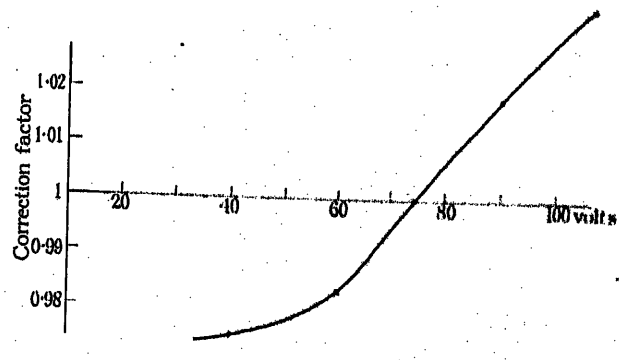

FIG. 6B.—Wave-form correction factor.

voltage does not greatly depend upon the size of the transformer used it is possible when calibrating a voltmeter by the sphere-gap, using a 2-kW transformer, to pass many sparks without the surface of the spheres being destroyed, though individual readings may differ by several per cent.

It is desirable for exact measurement that the applied

voltage should have a sine wave-form, and in the present case oscillograms were taken of the wave-form of the voltage obtained from a small high-speed motor-generator. Although the wave-form was not perfect it was free from ripples and gave consistent readings on the sphere spark-gap.

The spark-over value depends upon the maximum value of the voltage, and in order to compare the readings with those of the ellipsoid voltmeter, which records R.M.S. values, the wave-forms at various voltages were analysed from enlargements and their R.M.S. values calculated. It was then possible to correlate the ellipsoid voltmeter and the sphere-gap readings.

The wave-forms and the correction factors are shown in Figs. 6A and 6B. The change of wave-form is in this case small but not negligible; there is a third harmonic.

The agreement between our determinations of voltage and those of Whitehead and Castellain (*Journal I.E.E.*, 1931, vol. 69, p. 898) proves that the correction of sphere-gap readings for change of wave-form can be made with high accuracy, provided that many readings are taken and the mean values used.

The effect on the transformer of the capacitance load due to the voltmeter was examined, for it was evident that a slight rise of secondary voltage would occur at the closer spacings of the plates. Values of primary current with and without the voltmeter on the secondary are shown in Fig. 7.

The transformer ratio shown in Fig. 14 was found to be constant over the range 10 000–50 000 volts. The secondary voltage was determined by sphere spark-gap, while the primary voltage was measured to 1 part in 1 000 on a standard Weston instrument.

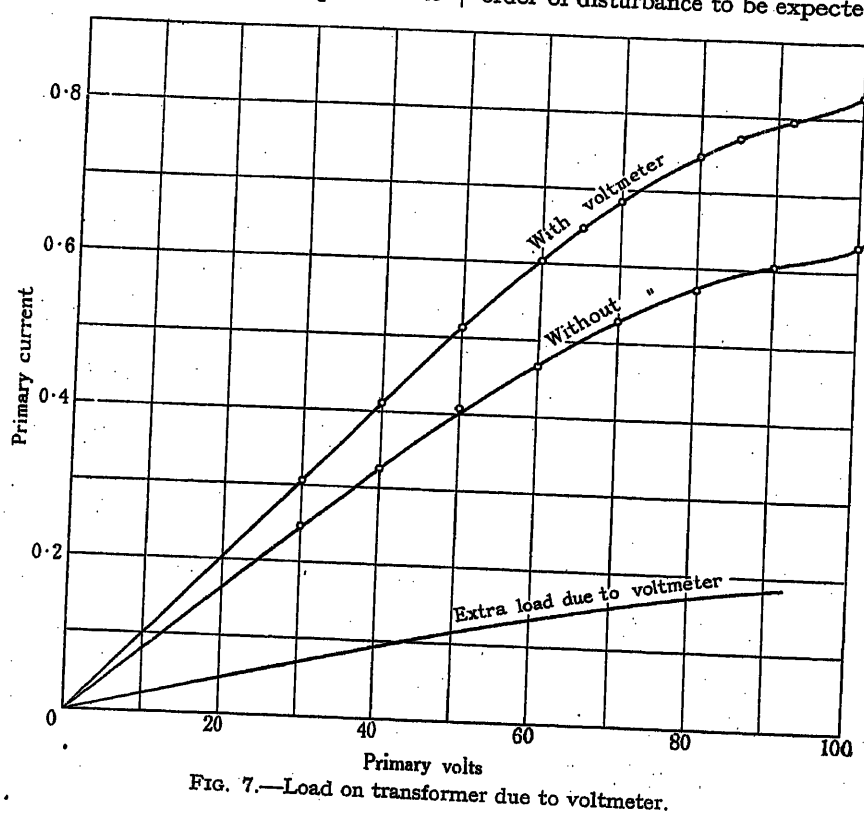

FIG. 7.—Load on transformer due to voltmeter.

(6) THE INFLUENCE OF THE SPACING OF THE PLATES.

It was thought that the charges induced on the ellipsoid might be sufficient to modify the distribution of charge on the pole-plates and have an appreciable influence on the torque.* The theory of this reaction in the case of a conducting ellipsoid making a finite angle with the field has not been worked out, but the following approximation when the two are in line indicates the order of disturbance to be expected.

The field X coinciding with the x axis, the charge on a ring element of radius y is

$$2\pi y\sigma ds = 2\pi y(X/N)\cos\theta\, ds,\dagger$$

where θ is the angle between the normal to the surface of the element and the direction of the field, N the longitudinal reaction coefficient, and ds an element of length of the boundary.

At the point of the ellipsoid $\sigma = X/N$, and $4\pi(X/N)$ is the intensity of field, corresponding to the intensity of uniform magnetization in an iron ellipsoid in a uniform magnetic field.

The charge dq on the element

$$= 2\pi y\frac{X}{N}\frac{dy}{ds}\cdot ds$$

$$q = \pi\frac{X}{N}y^2 = \frac{\pi X}{N}\left(1-\frac{x^2}{a^2}\right)b^2$$

* *Transactions of the University of Durham Philosophical Society*, 1908, vol. 3, p. 85.

† J. J. THOMSON: "Elements of the Mathematical Theory of Electricity and Magnetism," par. 166.

and the charge per unit length of the ellipsoid

$$q_1 = \frac{dq}{dx} = 2\pi\frac{X}{N}\cdot\frac{b^2}{a^2}x$$

The total charge on one half of the ellipsoid is

$$q = \left[\pi\frac{X}{N}y^2\right]_0^b = \frac{\pi b^2 X}{N}$$

Hence $q = 0{\cdot}625X$ electrostatic units of charge, the field being in electrostatic units.

This is the same as the charge on a parallel-plate condenser with the plates having 0·78 cm² area placed 1 mm apart, and is very small compared with that on the pole-plates charged to the same gradient. At 50 cm apart the induced charge on one end of the ellipsoid is 1/28 000 of that on the plates.

Consider the forces on a ring element distant x from the vertical axis and carrying a charge δq (Fig. 8).

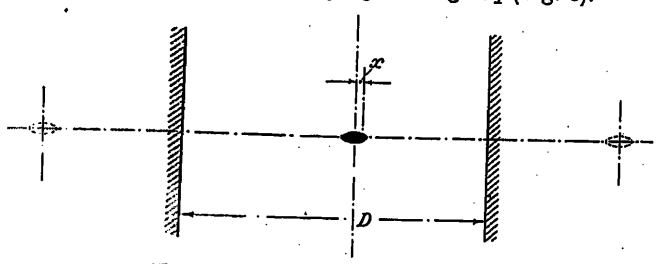

FIG. 8.—Ellipsoid and images.

These forces are:—

(1) An attraction $(\delta q)^2/(4x^2)$ between elements of opposite polarity on the surface of the ellipsoid, and directed towards the centre.

(2) An attraction $(\delta q)^2/(D-2x)^2$ to the opposite image in the nearest plate, and away from the centre.

(3) An attraction towards the centre $(\delta q)^2/(D+2x)^2$ to the image in the far plate.

The total force towards the centre on the element is

$$(\delta q)^2\left\{\frac{1}{4x^2}+\frac{1}{(D+2x)^2}-\frac{1}{(D-2x)^2}\right\}$$

and is less than in an infinite uniform field.

The force separating the charges on the surface is therefore greater than in a perfectly uniform field with no pole-plates present. Writing the equivalent field added by the reaction as X_1 we have

(*a*) If there were no reaction (and X_1 then zero)

$$X_0(\delta q) = \frac{(\delta q)^2}{4x^2}$$

the attraction of the separated charges being in equilibrium with the influence of the initial applied field X_0.

(*b*) The *added* force in the x direction

$$X_1\delta q = (\delta q)^2\left[\frac{1}{(D-2x)^2}-\frac{1}{(D+2x)^2}\right] = \frac{8Dx(\delta q)^2}{(D^2-4x^2)^2}$$

or X_1 (the force on unit charge) $= \int\frac{8Dx}{(D^2-4x^2)^2}dq$

Writing $q_1 = mx$, where $m = 2\pi(X_0/N)(b^2/a^2)$, the resultant field on the ellipsoid due to the summation of forces over the surface superposed on the original field is then

$$X_1 = X_0\left\{1+\int_0^a 2\pi\frac{X}{N}\cdot\frac{b^2}{a^2}\cdot\frac{8Dx^2dx}{(D^2-4x^2)^2}\right\}$$

The ratio a/D was varied during the experiment from 0·25 to 0·04, the latter being the working value. The fourth power of this is negligible for the present purpose and we take

$$X_1 = X_0\left\{1+k\int_0^a\frac{x^2dx}{1-(x^2/p^2)}\right\}$$

where $k = \frac{16\pi b^2}{D^3a^2}\cdot\frac{X_0}{N}$, $p = \frac{D}{\sqrt{8}}$.

Thus $\frac{X_1}{X_0} = 1+k\left(\frac{1}{\sqrt{8}}\log\frac{D+a\sqrt{8}}{D-a\sqrt{8}}-\frac{2a}{D}\right)$

Writing the last two terms as C we have

$$X_1 = X_0(1+C)$$

The influence of the reaction of the charges induced on the ellipsoid by the field upon the distribution of charge on the pole-plates is to increase the initial field X_0 at the ellipsoid by an amount CX_0, making the total field as a first approximation $X_1 = X_0 + CX_0$. The charges on the ellipsoid are therefore increased in this proportion and these added charges give as a second approximation

$$X_2 = X_0 + CX_1' = X_0 + CX_0(1+C) = X_0\{1+C(1+C)\}$$

The next approximation gives $X_3 = X_0 + CX_2$, and by the well-known method of successive images the final field

$$X = X_0\{1+C(1+C(1+C\ldots\}$$
$$X = X_0\{1+C+C^2+C^3+C^4\ldots\}$$

that is $X = X_0/(1-C)$.

This may be written $X = X_0/(1-fX_0)$, where f is a constant depending on the intensity of the field. Since f is very small, $X = X_0 + fX_0^2$ is a close approximation to the resultant field.

The value of a is 1·9845 cm, $\sqrt{8} = 2{\cdot}828$, $a\sqrt{8} = 5{\cdot}613$. The values of X and the resultant increase of field for different spacings D are given in Table 4.

TABLE 4.

Voltage between Plates = 50 kV.

D	X_0 (electrostatic units)	f	fX_0	Percentage increase of field
cm				
25	6·66̇	0·000457	0·003046	0·3046
50	3·33̇	0·000048	0·00016	0·016

100	1·66̇	0·000010	0·0000166	0·00166

The observed results are shown in Fig. 9.

The maximum difference between calculated and observed values is 2½ per cent, much too great to be accounted for by a concentration of charge on the plates induced by that on the ellipsoid.

The values of the field intensity *at the points of the ellipsoid* are greater in the ratio

$$4\pi/N = 12{\cdot}56/0{\cdot}4489 = 28$$

times that of the undisturbed field. Taking the spacing at which the difference in Fig. 9 is a maximum and begins to decrease, as 55 cm, and the applied field as 44 000 volts, or 800 volts per cm, the maximum concentration at the end of the major axis gives a field of 22 400 volts per cm (R.M.S.) or 32 000 crest value. This is very near to the known breakdown strength of air and there can be little doubt that at this spacing and voltage the ellipsoid can no longer hold its induced charge. At the lowest spacings (15 cm) and with this voltage a luminous glow appears at the ends, and at the intermediate spacings and with gradients from 400 to 800 volts per cm, that is with gradients at the point from 11 200 volts per cm and upwards, there are certainly ions formed by collision at atmospheric pressure.

Until the point is reached when the ellipsoid begins to lose its charge its motion is a regular function of the field strength.

The increase in secondary voltage due to the added capacitance of the voltmeter can be determined by calibrating the transformer with and without the voltmeter connected, as shown in Fig. 7.

Assuming as a first approximation that the capacitance current of the voltmeter is inversely proportional to the distance between plates, it is found that the calculated rise in voltage, due to capacitive reactance, above that observed with the 100-cm spacing, agrees substantially with that obtained experimentally (see Table 5).

It is clear that when a small transformer (2 kV) is used the rise of its secondary terminal voltage due to capacitive reactance is a greater cause of possible error than the reaction of the ellipsoids on the pole-plates, but by working at spacings of 100 cm the effects are both extremely small.

As a test of whether any electric wind could be observed from the point of the ellipsoid, smoke from a heap of burning waste was allowed to pass between the plates with the field on, but no trace of streaming near the ellipsoid, such as that observed from a pointed earthed electrode, could be seen.

(7) The Wind Shield.

The previous experiments had all been carried out by the method of swings and with the ellipsoid suspended freely between the plates with no wind shield in use. This, though possible in a room free from air currents, is not suitable for use in test-rooms where there is continuous movement, unless strong fields are used.

In order to protect the ellipsoid and suspension from draughts it was enclosed in a long bakelite tube. The determination of the shielding effect involves a knowledge of the dielectric constant of the shield; this was obtained by converting the tube into a cylindrical condenser.

A long sheet of copper foil was placed in the bakelite tube and rammed tight with cotton waste, while a

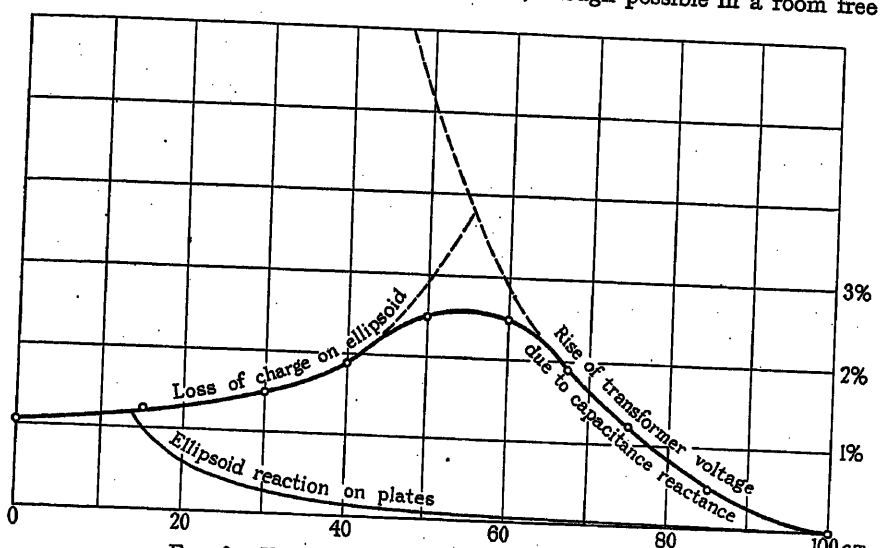

Fig. 9.—Variation of voltmeter reading, with spacing.

the value of the field inside the tube as 75 per cent of the external field, from which it was concluded that the two-dimensional case was not a sufficiently good approximation to use.

The refraction of the vertical component of the three-dimensional field does not lend itself to exact determination. The tube was therefore cut into two parts and cemented to a spherical Pyrex glass vessel set concentric with the ellipsoid.

The radius of this vessel was chosen to be 6·7 cm, for at this value the shell conforms very nearly to an equipotential surface confocal with the ellipsoid.

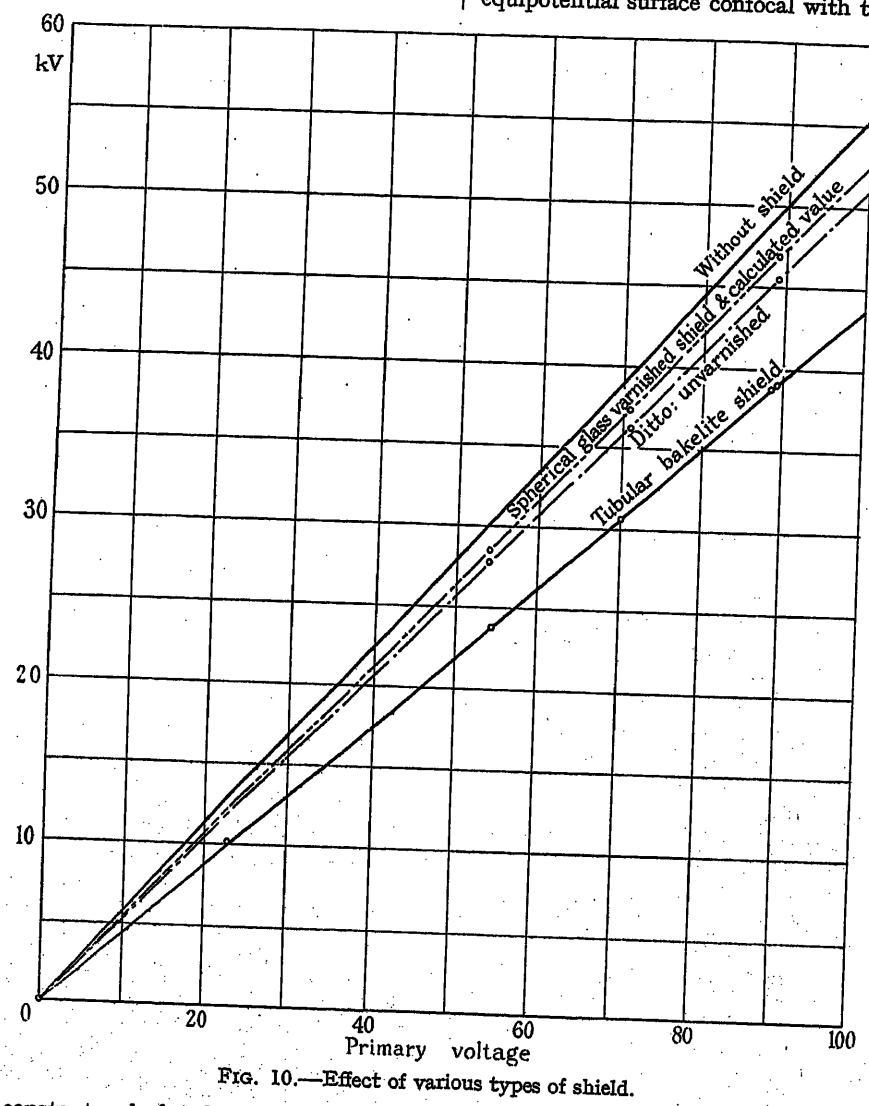

FIG. 10.—Effect of various types of shield.

The dielectric constant calculated from these data is 3·5.

The theory of shielding for the cylindrical case is given by du Bois,* and applying his method the value of the field strength inside the tube was found to be 92 per cent of the original field.

To check this the ellipsoid was suspended inside the tube and its oscillations were observed in a mirror, a beam of light being projected up the tube. This gave

* *Electrician*, 1897–8, vol. 40, p. 816.

The theory of shielding by a spherical magnetic shell as given by du Bois is at once applicable in the present case by substituting for μ in his expressions the known value of the dielectric constant κ for the material of the shell. Taking the ratio of the original field to that when the shell is present as g, du Bois's expression is

$$g = 1 + \frac{2}{9}\frac{(\kappa - 1)^2}{\kappa}(1 - p_1)$$

where $p_1 = (r/r')^3$, r being the inner and r' the outer

radius. In our case $r' = 3{\cdot}2$ in., $r = 3{\cdot}1$ and $\kappa = 4{\cdot}48$ for Pyrex glass.

Thus $$g_1 = 1 + \frac{2}{9} \cdot \frac{3{\cdot}48^2}{4{\cdot}48}\left\{1 - \left(\frac{3{\cdot}1}{3{\cdot}2}\right)^3\right\}$$
$$= 1{\cdot}054$$

so that the field is reduced by shielding, in the calculated ratio $1/g_1 = 0{\cdot}9485$.

The first measurement of the field within the vessel, made by the method of swings, gave $1/g = 0{\cdot}9220$, a difference of 2 per cent. A possible source of this shielding error was moisture on the glass vessel, and to remedy this the shield was coated with non-hygroscopic varnish. An immediate improvement was apparent and on repeating the experiment $1/g = 0{\cdot}9466$, a difference of $0{\cdot}2$ per cent. The means of the results are shown in Table 6 and plotted in Fig. 10.

Thus whenever it is advisable or necessary to enclose the ellipsoid, the field within the spherical enclosure can be readily found to this order of accuracy, a quarter of 1 per cent.

TABLE 6.

Condition	Primary voltage	Period	Apparent field	Real field	Values of $1/g$ after shielding
	volts	secs.			per cent

	54	2·56	28·5	30·2	94·5

(8) THE INFLUENCE OF AIR PRESSURE.

The total enclosure of the suspension made it possible to examine the influence of gas pressure.

This investigation was considered necessary, for, although the change of dielectric constant of air due to variations of atmospheric pressure is negligibly small in its influence, the changes in the conducting state of air in an electric field as the pressure is lowered are well known.

The experiment was carried out by keeping the voltage across the plates constant and measuring the change in the period of oscillation as the air pressure was lowered. From atmospheric pressure down to 30 cm of mercury the period was very nearly constant (see Fig. 11), but at this point the period of the swings began to be longer and it was recognized that the air within the vessel was no longer in the same electrical condition. The torque on the ellipsoid was much less than before; the space around it had become conducting and acted as a shunt or shield to the ellipsoid.

There is no other explanation of the loss of torque except that the ellipsoid could no longer hold its charge steadily, the gradient at its point being 11 000 volts per cm, and the value X/p (volts per cm per mm pressure) being 37.

There would undoubtedly be a discharge from the point of the ellipsoid before this pressure was reached, for the radius of curvature may be taken as about 1 mm. But at the pressure of 30 cm the rate of recombination or absorption of ions as the field is reversed is not in equilibrium with the discharge, and the space becomes ionized, forming a conducting medium after the manner of the Heaviside layer.

The field inside a homogeneous sphere of dielectric constant ϵ placed in a uniform field F is less than the undisturbed field* in the ratio $\frac{3}{\kappa + 2}$. If the observed field is F_1 the apparent dielectric constant $\kappa = \left(3\frac{F}{F_1} - 2\right)$. Since F is inversely proportional to the period of swing, $\kappa = \left(3\frac{T_1}{T} - 2\right)$, T being here the period at atmospheric pressure, T_1 at the lower pressure. This relation between κ and T_1 is linear and is a very sensitive means of measuring change of gas pressure within a closed glass vessel in which a metallic ellipsoid can be suspended and to which an external electric field can be applied.

The apparent dielectric constant of an ionized vapour

50	$1\,040 \times 10^{11}$	0·1561	10	0·0156
40	$1\,635 \times 10^{11}$	0·1955	10	0·0195
30	$2\,340 \times 10^{11}$	0·1557	10	0·0155
20	$3\,960 \times 10^{11}$	0·2285	10	0·0228

The ratio n/N is that of the number of ions present to the molecules of gas per cm³.

Hence, although the number of ions present is exceedingly small compared with the total number of molecules, this small number is sufficient to exercise a marked shielding influence.

The curve of Fig. 11 is logarithmic except at the start and finish, which are rather indeterminate.

Writing $\log (n_2/n_1) = k(p_1 - p_2)$ we get the figures in Table 8.

Thus the rate of increase in the ionic content of the flask as the pressure is lowered, the external electric field being constant throughout, is nearly logarithmic over the greater part of the range, within the limits of experimental error.

(9) THE INFLUENCE OF TEMPERATURE.

The field is proportional to

$$\left[\frac{\mathbf{I}}{V}\left(\frac{LN}{L-N}\right)\{n^2 - n_0^2\}\right]^{\frac{1}{2}}$$

in which the ratio $LN/(L - N)$ is independent of temperature range, so that

$$\frac{\mathbf{I}}{V} = \frac{3m}{20} \cdot \frac{2 - e^2}{1 - e^2} \cdot \frac{1}{a(1 + a\theta)}$$

in which a is the coefficient of linear expansion and θ the change of temperature from normal, m the mass and e the eccentricity,

Thus $\sqrt{(\mathbf{I}/V)}$ is proportional to $1 - \frac{1}{2}a\theta$, neglecting higher powers. $a = 24 \times 10^{-6}$, hence

$$F = F_0\left\{1 - \frac{12}{10^6}(\theta - \theta_0)\right\}$$

which gives a difference of 0·0082 per cent per degree.

For a range of 10 degrees C. in room temperature the difference is 0·012 per cent, which is beyond the limit aimed at in the present work.

Both n^2 and n_0^2 vary inversely as the moment of inertia, and n^2 directly as the volume.

n_0 can be made as small as possible by the choice of suspension, and the change of volume of the ellipsoid with temperature can be regarded as having a negligibly small influence on the measurements.

(10) EXPERIMENTAL RESULTS.

The method of procedure when dealing with the oscillating ellipsoid was to set the primary voltage to give a certain sphere-gap voltage on the secondary and to observe the times of a number of small swings of the ellipsoid. It was found convenient to project a beam from an arc lamp on to the side of the swinging body so that a point of light, due to the convex mirror effect, ran along its polished surface with each swing.

The swings were timed by the method of Gauss with a stop-watch chronometer which was standardized in the building by a seconds pendulum controlled from Greenwich and did not vary more than a few seconds per day.

The duration of each set of swings depended on the field strength and, the damping being small, it was

possible to measure, in successive trials, periods agreeing to 1 part in 1 000.

The observations given in Table 9 are typical of the many made.

The last column is the ratio of the potential difference between the plates, expressed in volts, to that in electrostatic units. The mean value is 299·97.

From the results for the different spacings the derived curves shown in Fig. 9 were obtained.

slows down with the appearance of corona. Raising the voltage still further causes the ellipsoid to sway backwards and forwards between the plates. This effect occurs in a field of 2 400 volts per cm, and indicates the upper limit possible for the given ellipsoid.

It is essential that the earth plate be earthed by a cable properly bonded to it.

In the case of the steady-deflection type of instrument its absolute calibration requires a knowledge of the torsion constant for the suspension. This can be obtained by an oscillation method and a value of the moment of inertia of the moving parts; alternatively a

It will be seen that for accurate results the spacing must be of the order of 100 cm. At a close spacing of 15 cm the ellipsoid has a tendency to instability and

known torque could be applied to the suspension by mechanical or electromagnetic means.

A more direct method of approach is to accept the calibration of the transformer by the oscillation instrument and from a knowledge of the applied field and the resultant deflections to derive the torsion constant, the values of which should be consistent among themselves for the proper working of the instrument.

The equation is

$$A\phi + B \sin\theta \cos\theta = 0$$

$$A = -\frac{B \sin 2\theta}{2\phi} = \frac{bV^2 \sin 2\theta}{2\phi}$$

where θ is the angle which the axis of the ellipsoid makes with the field, ϕ is the torsion angle, and B the polarization constant. By means of the suspension adjustment the voltmeter can be arranged to give any desired range of scale reading for a given voltage variation. The zero of the instrument was found by setting the ellipsoid in such a position that applying a voltage gave no deflection. As a trial an initial angle of 45° was given to the ellipsoid and a series of readings were taken with and without the wind shield. The results are shown in Tables 10 and 11 and plotted in Fig. 12.

The marked advantage of the shield in the steady-deflection method is shown by the fact that the points all lie actually on the curve and by the greater consistency of the values of the torsion constant.

An analysis of the figures in the last column, neglecting the value 10 kV which is really below the range of the instrument, shows a deviation from the mean of 1 part in 300, so that individual results can be relied on to 0·33 per cent. The readings were taken on a circular scale of 5 ft. radius and could be read to 0·01 degree.

From the data already obtained the actual scale form can be determined by extrapolation. Fig. 13 shows the scale to be of a modified square-law type, tending towards saturation at the higher voltages when the ellipsoid pulls into line with the field.

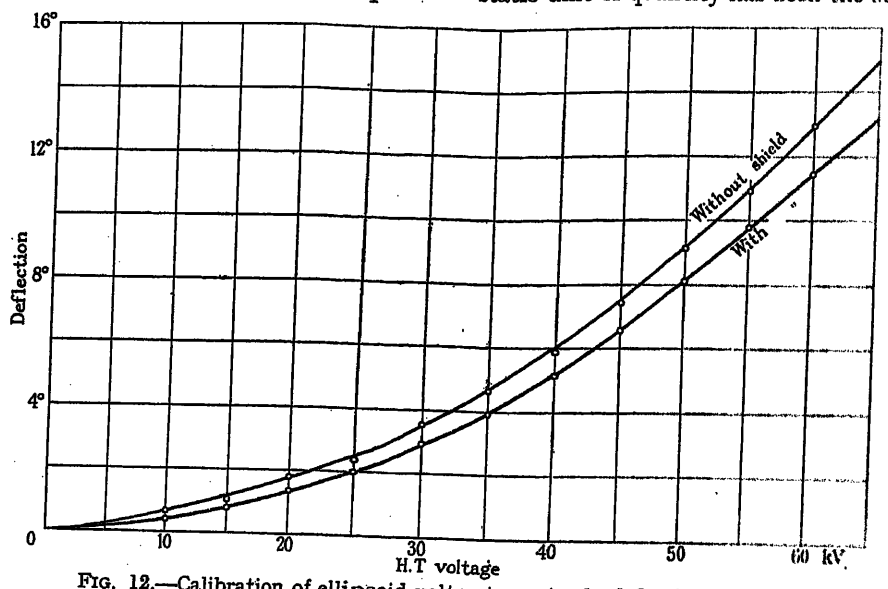

FIG. 12.—Calibration of ellipsoid voltmeter—steady-deflection type.

(11) DETERMINATION OF RATIO OF UNITS.

The ratio c of the electromagnetic unit to the electrostatic unit of quantity has been the subject of a number of careful determinations both optical and electrical. Although the experiments have been carried out by the highest authorities the collected results show a deviation of about 1 per cent on either side of their mean. The ellipsoid voltmeter offers a simple and direct method of determining the ratio of the units at low frequencies.

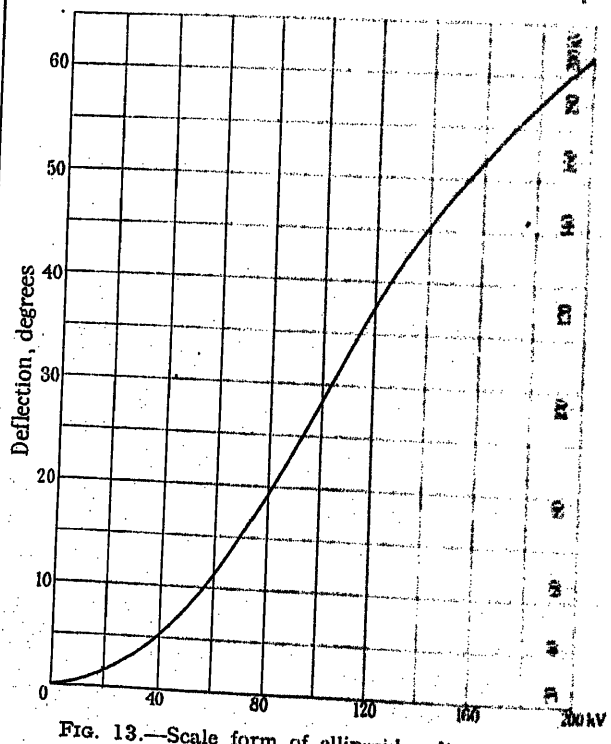

FIG. 13.—Scale form of ellipsoid voltmeter for 0–200 000 volts.

In the determination of the electrostatic quantities no difficulty is experienced in obtaining a reasonable order of accuracy. On the electromagnetic side the problem is not so simple, involving as it does the measurement of the voltage across the plates. This could be done by a capacitance method, but the recent researches carried out by the British Electrical and Allied Industries Research Association on sphere-gaps suggest that, by careful operation under the conditions laid down, results accurate to 0·2 per cent can be obtained.

Thus we have available a method of comparison which, though not absolutely precise in its elements, yet allows a large number of determinations to be easily made, leading to a final average result of a high degree of probability.

As mentioned in Section (5), the transformer was calibrated carefully with a sphere spark-gap, temperature and pressure corrections being rigorously applied, and the new E.R.A. values, which have had striking confirmation in connection with corona work in this laboratory, were used (see Fig. 14).

The mean of the readings in the last column of Table 9, the observations in which were taken without the express intention of determining c, gives the number of volts in 1 electrostatic unit of pressure as determined by this instrument. This corresponds to a value of c of $2{\cdot}995 \times 10^{10}$ cm per sec., which must be divided by the reaction coefficient 1·000016, corresponding to the spacing used, giving $2{\cdot}995 \times 10^{10}$ as a final value.

The voltages given by Whitehead and Castellain for sphere-gap calibration are international units, while those determined by the ellipsoid voltmeter are in C.G.S. units. To express their ratio when both are in C.G.S. units the figures of the last column in Table 9 must be multiplied by $1{\cdot}0004_9$, the ratio of the international to the C.G.S. value. This gives for the ratio c $2{\cdot}996_8 \times 10^{10}$, the subscript figure being retained to indicate the direction of change.

The mean of the best previous measurements is given by Abraham as 3·0001 and by Sir F. E. Smith as 2·998 to 1 part in 3 000.

By isolating the centre portion of the earthed plate another method of measuring c is obtained which is under investigation.

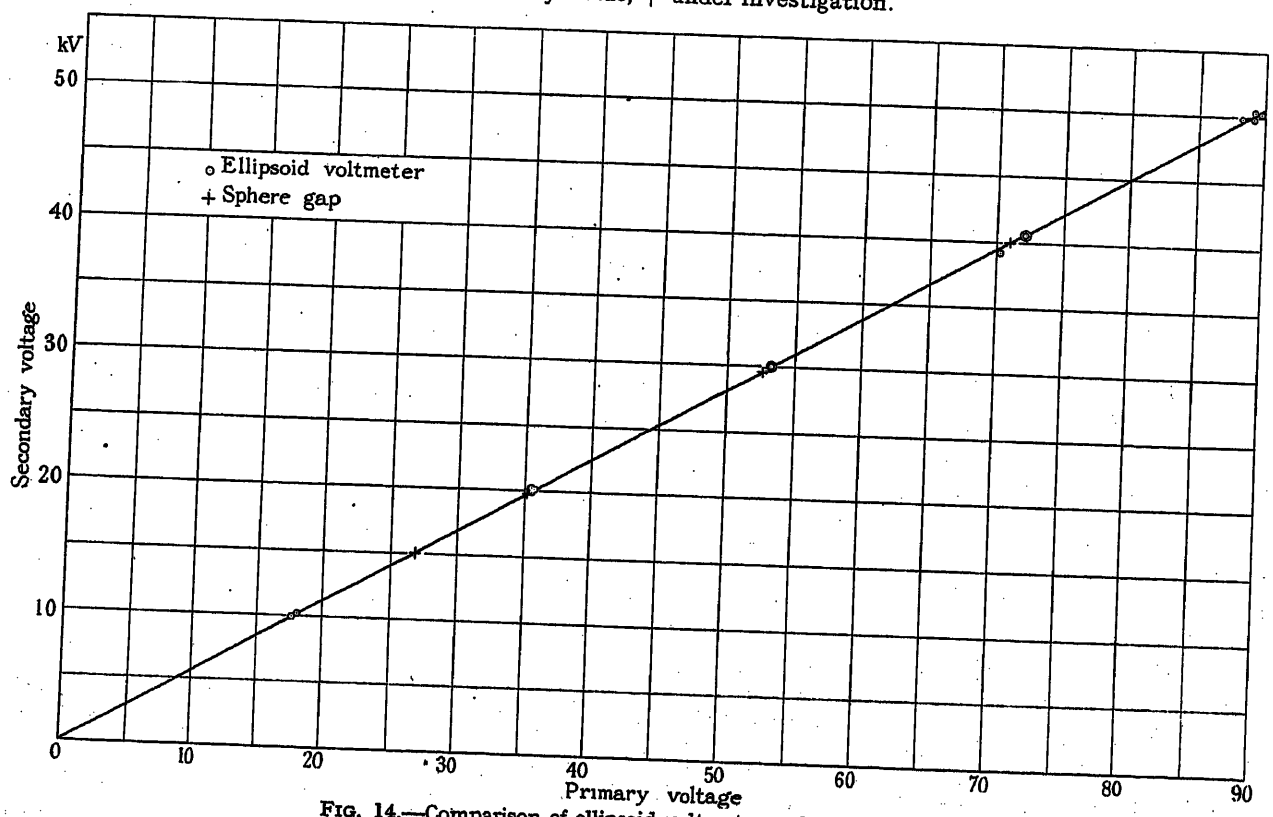

FIG. 14.—Comparison of ellipsoid voltmeter and sphere gap.

Having regard to the above agreement it is considered possible to measure voltages of the order of 100 000 to 200 000 to an accuracy of 1 part in 1 000 by this absolute method. It is, in fact, easier to measure these voltages with high accuracy than those of a lower order, say 1 000 volts, and, unlike the sphere spark-gap method, continuous observations of the voltage can be made by it. The requirements of a standard are fulfilled by the instrument in that it may be readily reproduced from dimensions to any desired order of accuracy and that it is absolute, in electrostatic measure.

ACKNOWLEDGMENT.

The authors wish to take this opportunity of thanking the Department of Scientific and Industrial Research for a grant to one of them which has enabled the work to be carried out.

[The discussion on this paper will be found on page 16.]

DISCUSSION BEFORE THE INSTITUTION, 21ST JANUARY, 1932.

Dr. E. H. Rayner: I do not suppose that a paper on the absolute measurement of voltage has been brought before the Institution in the last 50 years. Possibly the late Lord Kelvin discussed the subject in connection with the attracted-disc electrometer, but I know of no effective work in this country since then. At the Bureau of Standards a few years ago I saw parts of an absolute attracted-disc electrometer for about 200 kV which was being constructed to the designs of Mr. H. B. Brooks. I am not aware what results have been obtained from it. There is also the very beautiful instrument of the attracted-disc type working in compressed nitrogen up to 250 kV (R.M.S.) which was designed by A. Palm.* Under a pressure of 12 atmospheres the clearance can be kept down to 4 cm. The instrument is of an absolute type, the voltage being calculated from the measured force and dimensions. With these exceptions the subject has been left severely alone by workers aiming at some precision, and has only been employed by teachers and examiners as a method of testing the learning or powers of imagination of students. One reason for this is that voltage is a more abstract quantity to deal with than current or resistance. Resistance can be incorporated in a material of suitable character and can be given a wide range of values and forms to suit the particular purpose required. Current can be confined within conductors of desired dimensions and form. Voltage, however, is a more abstruse quantity to deal with, especially from an absolute point of view. Accurate comparisons of voltages are generally easy and simple; but they are usually carried out by means of currents, and thus the problems associated with absolute measurements are avoided. This difficulty is reflected in the recognized methods of dealing with the electromagnetic units—the ohm, ampere, and volt. The ohm and the ampere are regarded as the primary quantities, to be determined on the absolute C.G.S. system, and the volt is derived from them. Without attempting to be dogmatic on the subject I would point out that there may be a philosophical cause underlying the technical choice of the two primary quantities. Resistance has the dimensions of velocity (LT^{-1}), so that it is fundamentally simpler than the other two, which contain the third quantity, mass. To evaluate resistance in absolute measure a dimensional quantity L can be used. Induction is of this type. The other dimensional quantity T^{-1} may be an angular velocity, since an angle is of no dimensions. Resistance may therefore be evaluated as a product of induction and angular velocity. It is obtained in this manner by the Lorenz apparatus, the inductance being calculated from very accurate dimensional measurements of solenoids carrying about 1 ampere. The solenoids are commonly wound in grooves cut in marble cylinders by means of specially accurate lathes. The second quantity, current, has the dimensions $M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-1}$, i.e. the square root of MLT^{-2}, the latter being the dimensions of force. One form of apparatus for evaluating a current in absolute measure is the ampere balance. Solenoids whose linear dimensions are capable of being very accurately measured are wound on marble cylinders for the fixed and for the smaller moving coils, the latter being suspended from the ends of a very sensitive balance. The coils exert an axial force on one another, exactly as in the ordinary Kelvin balance. The force is balanced by the earth's attraction on a mass of a few grammes. The weight of the mass is required, necessitating a knowledge of the local value of "g" to about 5 significant figures. The dimensions of voltage ($M^{\frac{1}{2}}L^{\frac{1}{2}}T^{-2}$) are more complicated, and this quantity is regarded internationally as being derived from the other two. In actual practice an international ampere is not easily "portable" outside the laboratory in which the apparatus for generating it is situated. It is therefore made portable in terms of a portable resistance of known value and a portable source of constant voltage. This source has to be taken as nature provides it; the essential element is constancy, reproducibility also being very desirable. In practice the Weston cadmium cell is chosen, and its e.m.f. in volts as determined from the ohm and ampere naturally contains fractional digits. The value is 1·018+, depending upon temperature and details of manufacture. A paper on absolute measurements affords an opportunity for noting the past, present, and future position of the electrical units on which much research has been and is being devoted. In 1881 an International Conference held in Paris formulated a common system of electrical units for the whole world founded upon the centimetre, gramme, and second, and independent of the properties of particular substances. It was, however, known that a system of units could not be established at once on such foundations. The art of realizing the units to the accuracy required would take much research and development. We have to thank Clerk Maxwell, Kelvin, and Fleeming Jenkin, in particular, who attended that conference, for the scientific method and foresight which restrained the delegates from adopting the easier empirical units then in common use, e.g. those depending upon the resistance of metals having a particular form. The approach to the establishment of the international units on an absolute basis of sufficient trustworthiness has been long. The goal has not yet been attained, but the end of the journey is in sight. In the meantime empirical units in close agreement with them have been in world-wide use. These have from time to time been brought closer in value to the C.G.S. units, as methods and apparatus have been developed, chiefly in recent years in the principal national laboratories of the world. We must remember, however, that fundamental work of high precision was carried out by pioneer workers in earlier years. Not the least important was that done in this country by Maxwell, Rayleigh, Kelvin, Carey Foster, and Glazebrook. This fundamental work is being actively pursued at the present time. Members of the staffs of three of the national laboratories have met in the past year, and

* A. PALM: *Zeitschrift für Technische Physik*, 1920, vol. 1, p. 137.

have worked together for some weeks on the task of carrying out comparisons of the electrical units as maintained at their national laboratories. It is hoped that before long the subject will be on a sufficiently firm basis to enable the empirical units, depending upon the resistivity of mercury and the electrochemistry of silver salts, to be displaced as methods of realizing a common international system of units. The time which has elapsed since 1881 may seem long, the end being still unattained after 50 years. The reason is that the goal has become more difficult of attainment with each decade. Whereas an accuracy of 1 part in 1 000 would have been very welcome at one time, to-day we must have 1 in 100 000. It has been found necessary to aim at this degree of agreement among primary international electrical standards, in order to ensure that the thousands of high-class working standards throughout the world, in all the various branches of the electrical industry, may have the same numerical value assigned to them to the accuracy within which they are capable of being effectively used. The international units are therefore defined to six significant figures in order to ensure adequate agreement, with the knowledge that they are appreciably different from the C.G.S. units. The difference is not large, the greatest discrepancy being perhaps 20 parts in 100 000; when the change to the C.G.S. units is made (and it is hoped to do this by international agreement before long) the result will be practically inappreciable in all ordinary measurements. The measurement of voltage without making use of an electric current resolves itself into the determination of the value of an electric field. This may be done either by observing the effect of the field on an object immersed in it, or by measuring the mechanical force on a conductor forming a boundary of the field. The authors have chosen the former method, involving a 3-electrode type of instrument; while the attracted-disc electrometer, a 2-electrode type, makes use of the latter. The conditions of the problem, particularly as regards the attraction type of instrument, are as follows. In the disc electrometer the force per cm^2 is

$$\frac{1}{4\pi}(\text{Potential gradient})^2 = \frac{1}{4\pi}\cdot\frac{V^2}{d^2}$$

If $V = 1 = 300$ volts, and $d = 1$ cm, then $F = 1/(4\pi)$ dyne, which is less than 0·0001 g. A practical instrument for higher voltages might have a gradient of 25 C.G.S. units per cm, i.e. 7 500 volts per cm. The force on an area of 100 cm^2 would then be about 5 000 dynes (less than 5 g). This at once gives an idea of the difficulty of the absolute measurement of voltage. To obtain a sufficiently intense force for measurement to a high degree of precision (1 in 10 000 or 1 in 100 000) an intense electric field of the order of 5 000 volts per cm has to be used. If the voltage is considerably less than 5 000 volts much smaller working distances than 1 cm may be necessary, and this distance must be known to 1 part in 20 000 if an accuracy of 1 part in 10 000 is aimed at. Further, the 5 g per 100 cm^2 mentioned above would usually have to be an addition to a larger dead weight. The computation of the effective area of an attracted disc, allowing for its edges, is a serious matter. A standard of voltage of the order of 5 000 volts would be inconvenient. If it were to be of practical use it would be necessary to derive the numerical voltage of a standard cell from it, and in order that it might be regarded as a step in generating a unit for international purposes this step-down would have to be determined with an accuracy of 1 in 100 000. The authors by skill and perseverance have arrived at the results given in Table 9, but in my opinion the foundation of some of the many steps on the journey are not as sound as the results seem to indicate. They depend on various quantities: there is the measurement of the voltmeter in Column 1, which is used as a secondary standard for the measurement of high voltage, the primary standard of which is the electric strength of air (Column 2). I confess to a doubt as to the trustworthiness of the breakdown of air as an accurate standard of voltage for precision purposes. The authors suggest on page 1 that differences of 2 per cent may occur, and that by taking sufficient readings a result reliable to 1 in 1 000 is obtainable. This seems to me a doubtful method of obtaining accuracy, and it depends on the real value of someone else's measurements of similar phenomena, made with different apparatus and in different surroundings. The form factor of the machine and equipment has to be known to a high degree of accuracy; for this purpose an oscillograph has been relied upon as an instrument of high precision, accuracies of values to 4 and 5 significant figures depending upon its indications. The authors finally arrive at a value for the number of volts in an electrostatic unit field, approximately 300 (last column). The apparent accuracy of Column 8—5 or 6 significant figures—is arrived at by multiplying the previous column by 100 (the 100-cm distance between the plates). The last two digits of Column 8 are therefore of no significance. I should much have preferred to have seen the arrangement worked backwards, as follows. Measure experimentally the electric field by oscillations, calculate the voltage from the product of field and separation, assume the value of the number of volts (about 300) in 1 electrostatic unit, and deduce the spark-over voltage, knowing the form factor. The four significant figures in the last column of Table 9 imply a knowledge of the spark-gap setting to the same degree of precision. There is no mention of the method adopted of obtaining this accuracy, nor is the size of the spheres stated. There is a serious limitation as regards the use of the swinging-ellipsoid method. The electric field at the ends of the ellipsoid is many times the average value in the space surrounding it. The authors give an instance of 28 times. This means that a large separation of the inducing plates must be used for comparatively low voltages, in order to prevent the production of corona at the ends of the ellipsoid. They use a field up to 1·7 electrostatic units per cm, i.e. 500 volts per cm (see Table 9, Column 7), whereas other methods involving a parallel-plate condenser have enabled fields of the order of 10 000 volts per cm (i.e. 20 times as much) to be satisfactorily used. The authors talk of measuring up to 200 kilovolts. Their actual measurements seem to have been only carried up to about one-third of this figure, and three times the voltage would require apparatus of about three times the

linear dimensions. For many purposes the measurement of the peak value of the voltage is more important than that of R.M.S. voltage. The peak value is the quantity required in determining electric strength, and its use avoids any assumptions as to form factor of the generating plant or ratio of the transformer. The authors' method would seem to be difficult to apply to peak-value measurements, and the measurement of steady high d.c. voltages of the order of 100 to 200 kV would prove difficult, as the ellipsoid and its supports could not be maintained at nearly such a high voltage as under alternating fields. Leakage would become

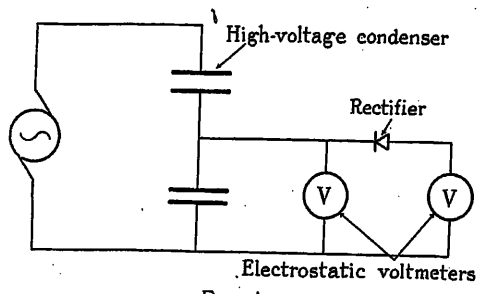

FIG. A.

troublesome. It seems to me that the authors have gone a long and difficult way round when shorter, simpler, and considerably more precise methods of measuring high voltages are available for proving the correctness of their instrument. Measurements of voltage usually entail the use of a potential divider. Up to alternating voltages of 20 or 40 kV, resistor dividers are commonly used. Above 100 kV, capacitance dividers are very valuable. They may take the form of a high-voltage air condenser in series with a fixed or a variable mica condenser, the voltage on the latter being measured by an electrostatic instrument capable of an accuracy of

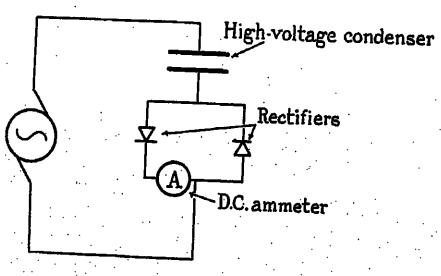

FIG. B.

a few parts in 10 000. An accurate knowledge of the ratio of the capacitances is required, and this can be obtained by an audio-frequency bridge measurement (Fig. A). The method is at once applicable also to peak-value measurements, by rectifying the voltage and using another electrostatic voltmeter. This way of determining the peak value can be compared with the rectified-current method, which does not involve the use of a potential divider but requires an accurate knowledge of the capacitance of the high-voltage condenser (Fig. B). My colleagues at the National Physical Laboratory have compared these methods up to about 1 000 kV, and have found them to give the same value to 1 or 2 parts in 1 000. The results and the details of the methods have been published by the Institution.*

Dr. A. Russell: I had the privilege of sitting in Lord Kelvin's classes some 50 years ago, when he discussed the properties of ellipsoids enthusiastically and at great length. Those, however, were the days before Prof. Thornton's applications of the theory were made. No one would have appreciated this ellipsoidal method more than Kelvin. Fig. 14, showing how the readings of Whitehead and Castellain agree with those obtained by the authors' method, would have given him great satisfaction. Treatises on absolute measurements always give one the impression that the measurements are immensely difficult, as indeed they are if one attempts to obtain the highest accuracy. As regards the value of c, the ratio of the electromagnetic to the electrostatic unit of charge, this was roughly determined 60 or 70 years ago at Glasgow University by one of Kelvin's assistants. Sir F. E. Smith and others have shown that the value of the ratio can be found in a student's laboratory to an accuracy of 1 per cent. I once weighed the attraction between two spheres by means of a chemical balance at voltages between 20 000 and 30 000 volts, and obtained values for c which were less than 1 per cent inaccurate. No special precautions were taken. The balance was made ready for the test in about an hour. Ordinary metal balls, such as are employed in Wimshurst machines, were used, and I was surprised to get such accurate results, seeing that the balls were only approximately spherical. I found out subsequently that Snow Harris, when weighing electrostatic attractions a century ago, had also noticed this effect. I believe Kelvin proved theoretically that the attraction between metal bodies is independent of their exact shape; thus at the same distance two ellipsoids will attract each other with almost the same force as two spheres. Although practically all the experimenters who use metal spheres for absolute measurements take great pains to make them mechanically perfect, judging from some experimental evidence I have examined, much of their labour is unnecessary. I remember once being surprised when I found out mathematically how little the capacitance of an ellipsoid changes when its shape is varied, provided that the volume remains constant.

Dr. C. V. Drysdale: Like Dr. Rayner, I have some difficulty in understanding why the authors consider that the attracted-disc type of absolute voltmeter is unsuitable for high voltages. The electric strength of air at ordinary atmospheric pressure is of the order of 30 000 volts per cm, and therefore with a reasonable factor of safety and allowing for an ordinary form factor, we are fairly safe in working at 6 000 or 7 000 volts per cm. Under such circumstances the force between two parallel discs is of the order of a few grammes for a disc area of 100 cm^2. Such a disc, made of aluminium, need not have a total mass of more than 10 or 12 g, and the measurement of the mass to that degree of accuracy by means of a chemical balance is surely a matter of everyday experience. Furthermore, I cannot see why there should be any difficulty about the use of

* R. DAVIS, G. W. BOWDLER, and W. G. STANDRING: "The Measurement of High Voltages, with Special Reference to the Measurement of Peak Voltages," *Journal I.E.E.*, 1930, vol. 68, p. 1222.

the instrument. In the first place, the high-voltage plate can be above the working plate with the attracted disc in it. The whole of the working parts of the instrument could be at earth potential, and I think it is clear that the dimensions would be less than the authors indicate. Assuming (as I think is justifiable) that we can work with a higher electrostatic stress and that the distribution of the electrostatic field at the surface of the plates is no less uniform than in the intervening space, it would seem that even for voltages of 200 kV the plates need be only 35 to 40 cm apart, and, using the same ratio of dimensions as has been adopted by the authors, plates of about 60 or 65-cm diameter with well-curved edges should be sufficient. Moreover, I think that such an instrument could easily be made. The disc electrometer is more simple for use at very high voltages. It involves no greater stresses, as the high-voltage plate is merely put at such a height that the voltage gradient in the air is kept below the safe limit. If the distance apart of the plates is as large as 35 or 40 cm, it is not so essential that the planes of the plate and of its guard ring should be so absolutely identical as they are in the low-voltage instrument. It is a small matter to support the attracted disc on springs, and by using a little optical lever we could get a deflectional instrument. With a separation of 35 to 40 cm, a 0·1 mm movement of the disc above or below the plane of the plate cannot be a serious factor, and this displacement would be more than sufficient for a large deflection. On the other hand, the condenser-potentiometer method of working lends itself to a very high degree of accuracy, provided that the electrostatic voltmeter is of constant capacitance. If the lower-voltage condenser is of sufficiently high capacitance small variations of the instrument capacitance do not matter. I do not see why a very high order of accuracy should not be obtained by means of this arrangement. Had I been confronted with the problem of producing an absolute voltmeter for high voltages, I should have designed an instrument on the lines of the old guard-ring electrometer, but I fully appreciate the theoretical and experimental skill of the authors in producing the first absolute instrument for such high voltages.

Mr. W. J. John: The authors' results would be more satisfactory if their apparatus had been checked against some more reliable standard than the one they have adopted; the condenser arrangement described by Dr. Rayner would be excellent for checking purposes. There are several points of detail in the paper to which I should like to refer. On page 4 the three possible values given for e^2 are 0·97761, 0·97914, and 0·97872, showing a maximum variation of about 1·5 parts in 1 000. Such a difference is rather disturbing, because the all-important dimensions L and N depend on e. Again, tests were made to establish the uniformity of the field parallel to the plates. Should not other measurements have been made to establish the uniformity of the field in a direction at right angles to the plates? If the instrument is to be used commercially, in place of sphere-gaps, say, it must be fitted with a wind shield, and it seems to me that the Pyrex glass wind-shield and the bayonet joint illustrated in Fig. 4 must prevent uniformity of the field in a direction at right angles to the plates. It is interesting to note the authors' statements that a difference of 2 per cent is possible between individual sphere-gap readings and that it is necessary to take the mean of many readings to obtain results reliable to 1 part in 1 000. The belief is apparently held in many test-rooms that the sphere-gap is accurate to much narrower limits and that only a single reading is necessary. I should like to ask whether the authors can see any objection to the use of their instrument at voltages of the order of 1 000 kV. The problem of accurately measuring voltages of this order is a very difficult one, and I am interested to note from Dr. Rayner's remarks that the condenser method enables one to measure 1 000 kV with accuracy. How many readings of the authors' instrument are necessary to obtain accurate results in any given case? Is it better than the sphere-gap in this respect?

Mr. F. L. Best: The instrument described by the authors gives indications proportional to the R.M.S. voltage, so that if two equal voltages are applied, the first being direct and the second alternating, the instrument will give the same deflection in each case, irrespective of the wave-form of the a.c. voltage. There is some similarity between the measurement of magnetic fields by a small magnetic needle and the measurement of electrostatic fields by an ellipsoid, in that the observation of the periodic time is the only one taken. The authors explain that the ellipsoid is used because it is practically the only body of suitable shape for which the full theory has been developed. The ellipsoid would appear to be the ideal body from another point of view, namely that because of its rounded surfaces it will not so readily give rise to brush discharge and corona when placed in very strong electrostatic fields. There is little doubt that an absolute method of measuring high voltages, particularly alternating high voltages, is necessary. It is remarkable that the "grid" scheme has been evolved and put into operation without such a standard being developed, much less employed. In view of the enormous quantities of power to be transmitted over the grid system at high voltages, it becomes of increasing importance that the exact voltage should be known, for the power delivered to a circuit is proportional to the square of the voltage, and a small percentage inaccuracy in the high-tension voltage may lead to a considerable loss of power. With regard to Prof. Thornton's statement that the instrument is suitable for use on direct current, it is well known that one cannot employ the condenser multiplier for the measurement of high-tension direct current. If one attempts to do so, the reading of the indicating instrument (assumed to be itself an electrostatic voltmeter) will either creep up and beyond its full scale limit, or else down until it reads zero. The explanation is simple. It is not possible to get two condensers whose leakances are in the ratio of their capacitances. Thus over a period of time one condenser is charged up more than the other. I should like to ask, therefore, what happens in the case of the ellipsoid voltmeter on direct current, regarding it as two condensers in series. Also, what is the effect of impressing a static charge on the ellipsoid? The theory of the instrument (page 2) involves the moment of inertia of the ellipsoid, and I

should be interested to know how it is possible to determine this quantity accurately Presumably it would be the subject of a secondary experiment, comparison being made with an accurately turned cylinder. Whether this or another absolute standard comes into use, it will be interesting to see which of the present-day industrial methods of measuring high voltages will survive in the future. The most popular method in use at the moment, of course, is that of the potential transformer. In conclusion, I should like to associate myself with Dr. Rayner and express regret that the authors' results have been compared with those obtained by means of a sphere-gap. In spite of the difficulties of determining the constants of the ellipsoid, and the considerable amount of mathematical work which lies behind the simple observations made, the ellipsoid voltmeter can be rendered more reliable and accurate than the sphere-gap.

Mr. S. Whitehead: The most salient feature of the authors' method is that it avoids the actual measurement of a force by transforming it into the observation of a time of oscillation. The measurement of small forces is usually rather difficult, and in dealing with gravitational forces, for example, it is much easier to make measurements with a pendulum than with a torsion balance. In view of what has been said as to the advantages of the attracted-disc electrometer at high voltages, it is significant that at the present time there are available three types of attracted-disc instruments, but that none of these is both precise and absolute. First, there is the Abraham voltmeter or Kelvin volt-balance, which does not aim at precision, and in most forms of which the movement of the attracted disc is sufficient to prevent high accuracy. Secondly, there is the type in which the moving plate is very much reduced in size and is allowed to rotate rather than to move, its slight motion being amplified optically. Thirdly, there is the type in which the moving plate is replaced by a fibre, the motion of which can be observed through a microscope. The last two have been devised comparatively recently, and their object is to reduce the size of the moving or attracted plate, but neither is absolute. I should like to ask the authors whether they have determined the constants of the voltmeter by both the oscillation and the direct deflection methods, and whether they have deduced from these measurements the linear dimensions upon which the constants depend. It would be of interest to compare the constants of the instrument used (*a*) as an oscillator and (*b*) with direct deflections. If k is the constant under the first condition and k_1 is the constant under the second, i.e. in the notation of Section (10) k_1 is $\sqrt{(A/D)}$, then it may be shown that if k and k_1 are taken under the same conditions, $k_1^2 = k^2 n_0^2 D^2$. The quantity n_0 can be found if desired from the moment of inertia and torsion constant, while D is the spacing if k is the "field" constant given in the paper. If k is the "voltage" constant, $k_1^2 = k^2 n_0^2$. As regards the use of the sphere-gap for high-voltage measurement, the results given in the paper confirm those which Mr. Castellain and I obtained when making calibrations of the 62·5-mm sphere-gap. In our paper* we stated that we did not regard the sphere-gap as comparable with a precision voltmeter; nevertheless, my experience in the course of those and other experiments shows that under suitable conditions the sphere-gap will give consistent values for a week—or possibly weeks—at a time. It will not, however, give consistent results for months at a time. The greatest difficulty in connection with the use of the sphere-gap is to know when it will go wrong. I agree with Dr. Rayner in advising the use of a condenser potential-divider, which in the Electrical Research Association is employed for the routine measurement of higher voltages. The potential divider is inexpensive and easy to make, and its ratio can be obtained to a fair order of accuracy by calibration. If a suitable design is adopted one can be sure that the ratio will remain constant, so that if there is an error it will be a consistent error throughout the measurements. The potential divider can be adapted for use as an absolute null method; by means of an electrometer one can balance the given alternating potential against a continuous potential from a d.c. potentiometer which is standardized in the normal manner. Although I have actually used this method,* I am not prepared to recommend it, because the difficulties of the electrometer are such that a high degree of precision can be attained but not maintained. With regard to Prof. Thornton's question as to the value for the velocity of light which was inherent in the measurements made by Mr. Castellain and myself, our measurements were in international volts and therefore the normal value for the velocity of light will be modified by the difference between international volts and true C.G.S. units. I should like to ask whether the authors have examined the effect of extraneous objects upon the field between the plates. What are the screening conditions which must be insisted upon? It seems to me that a considerable clear space will be necessary in order to obtain the highest accuracy, in view of the fact that the electric field used for the purpose of measurement is small. The problem of ionization in the air is a possible serious difficulty in the present instrument. Have the authors made any experiments with irradiation by ultra-violet light to determine the effect of artificially-introduced ions? By using an enclosure with a suitable window it is possible to remove the initial ionization of the chamber, and then to reintroduce ionization in a fairly well-controlled manner by means of radiation.

Prof. W. M. Thornton and **Dr. W. G. Thompson** (*in reply*):—Dr. Rayner has given an excellent review of the whole question of absolute units and of the peculiar position of the volt as in theory one of the two fundamental units but in practice, and by the ruling of the International Electrotechnical Commission, derived from the units of current and resistance. In the present investigation we were concerned in the first instance with finding an accurate voltmeter by which sphere spark-gaps and the ionic wind voltmeter could be calibrated or compared, and after considering the Bureau of Standards attracted-disc electrometer—as exemplifying the latest developments in the theory and design of that type of instrument—we came to the conclusion that the

* *Journal I.E.E.*, 1931, vol. 69, p. 898.

* S. Whitehead and D. Barham: *Journal of Scientific Instruments*, 1930, vol. 7, p. 337.

ellipsoid voltmeter had advantages as a standard which the other had not. Our experience has confirmed this. The ellipsoid voltmeter is simple to make, robust, easily read, and gives true R.M.S. values. There was no intention of using the instrument to measure c except as a check on the order of accuracy of the results, and the values obtained (see Table 9) are an example of how the check was applied. That the values of the significant figures of c are as good as they are gave us the assurance we desired, and we now use the instrument frequently when comparing R.M.S. and crest values of our 250-kV transformer supplied by different machines and on different loads, the crest values being measured by means of the sphere spark-gap. In reply to Dr. Rayner's question as to range, this particular instrument with the 100-cm spacing has had a peak voltage of 500 kV across it without flashing over. In the work described in the paper it was only used up to 60 kV, for at that time we had only one transformer available from which a sine-wave secondary voltage could be obtained. For peak values we now use the ionic wind voltmeter calibrated by the sphere-gap. For use in test rooms this instrument is very convenient as it avoids all spark-discharge measurements. Its use for this purpose will be described in a subsequent paper. One purpose of our work was simplification of accurate measurement of test-room voltages, where each kind of apparatus under test distorts the wave-form to a different extent and gives different peak values.

Dr. Russell's remarks on the accuracy possible in electrostatic measurements are very interesting. In the case of attracted spheres, or indeed in any case in which the force is a simple pull or push, the precise form of the surfaces may not be essential to accuracy; but where the induced charge on a surface varies with its movement in the field the form of the surface is more important. For this reason, and as a result of our experience with the earlier ellipsoids, we had ours accurately shaped by Messrs. Hilger.

We agree with Dr. Drysdale that the attracted-plate voltmeter is at first sight simpler and has the advantage that higher fields may be used, but the corrections to be applied are much more difficult to determine and are very complex, as was shown by Chester Snow.* It is possible to make the present instrument read both as an attracted-disc voltmeter and as an ellipsoid instrument, and further—by measuring the current from the disc—to determine c directly by this instrument alone. We have not gone into the question of the accuracy of condenser potentiometers on bad voltage wave-forms, but I should have thought that the influence of harmonics, which are always difficult to avoid in test-room practice, would have had a serious effect on the tapped readings compared with the line voltage.

In reply to Mr. John, we were fully aware of the need for careful determinations of the eccentricity, and the value of c finally obtained is a justification for the value chosen. We estimate that the mean value of e^2 chosen is correct to 1 part in 1 000, but $(1 - e^2)$, which is the determining factor in the calculation of L and N, has a mean departure of 0·5 per cent. The final values are probably correct to 1 part in 1 000. The gradient between the plates was undoubtedly uniform. It is only when there is a conduction current between electrodes that the voltage gradient between them is affected, and in our case—with alternating fields and air at atmospheric pressure—the amplitudes of any ionic movements are too small to affect the field shape. In test-room practice measurements of high voltages are made by means of the sphere spark-gap, the condenser-current method, the potential divider, and the ratio of transformation—and the derived values rarely coincide. In the present case the ellipsoid voltmeter gives readings close to the ratio of transformation values. With regard to the measurement of voltages of the order of 1 000 kV, we can say definitely that if R.M.S. readings are desired the ellipsoid voltmeter will give them, but for peak values the null-reading ionic wind instrument is the best known to us.

Mr. Best raises the important question of why the "grid" has been put into commission without a standard high voltage being specified or required. The answer, we think, is that if there had then been such a standard it would have been used to specify voltage limits. As yet the demand for a high-voltage standard does not appear to have been felt. A great deal of work was done on the standard chemical cell for use with the d.c. potentiometer, and perhaps the time is approaching when it will be recognized that it is as easy to construct a high-voltage standard as it is to make a standard cell. The use of the ellipsoid voltmeter on direct current is made possible by the fact that there is no conduction current to the ellipsoid, and it therefore does not acquire charge; on the other hand, if the ellipsoid were charged it would not affect the readings in an alternating field, for there is no resultant torque. If the ellipsoid were to be charged it would have to be by a proof-plane, since the suspension is non-conducting. We are glad to have Mr. Best's opinion that the ellipsoid voltmeter can be made more reliable and accurate than the sphere-gap, but it is possible that an improved form of the latter may shortly be available.

Mr. Whitehead makes the interesting comment that the instrument transforms the measurement of a feeble force into that of a time. This is an important point which may account for the consistency of the readings. It is a new thing in voltage measurement to obtain the readings by timing swings. This mode of working is comparable perhaps with the measurement of speed in the Lorenz method of standardizing resistance, and it makes for high accuracy. The instrument, like all air condensers, must not be placed too near other sources of high voltage, though in most test rooms it is not usual to have more than one source of high potential or other metallic parts at high potential close together in one place. Ionization does not appear to have any effect; illumination by an arc lamp has none. There is no form of electrical discharge to be observed at working pressures on either the ellipsoid or the plates. In this respect the design is satisfactory. The conversion of the value obtained for c at the end of Table 9, so as to give both sphere-gap voltages and those observed by the ellipsoid voltmeter in C.G.S. units, is obtained by multiplying the figure $2{\cdot}995 \times 10^{10}$ by 1·00049, the ratio of the international to the C.G.S. volt. This gives $2{\cdot}996 \times 10^{10}$ as the corrected value.

* *Bureau of Standards Journal of Research*, 1928, vol. 1, p. 513.

Mr. J. A. Harle: The paper describes an attempt to reduce extra-high-voltage measurements to an absolute basis, so that electrical quantities may be measured in terms of non-electrical dimensions. The two forms of the authors' instrument—the oscillating and the static-deflection ellipsoid voltmeters—each have their own particular applications. The former would be particularly suitable for metering on high-voltage systems, where it would form the absolute standard for the voltage-measuring device. The deflection type of instrument would appear to be useful in research work and for standardizing other classes of measuring instruments used for routine testing purposes, but it would be subject to the drawback that it is difficult to obtain pure sine waves on large-power high-voltage test equipments at an economical cost. In consequence of the wave-form distortion on generating plant and the effect of the magnetizing currents of the testing transformer and the capacitance of the transformer windings and load, peak-voltage readings appear to be essential at present with most high-power voltage testing equipments. With regard to the deflection-type instrument, I should be glad if the authors could state the maximum voltage response in kV per sec. at which the device would follow the applied voltage, and, in addition, the maximum rate at which the mirror would follow the ellipsoid. These two factors would appear to constitute a possible source of trouble in connection with the use of the instrument for testing purposes, as rates of rise of from 5 to 10 kV per sec. are in use. As regards Fig. 7, is the extra load due to the voltmeter taken as the arithmetical or the vectorial difference between the currents? The latter would more truly represent the load effect. Have the authors considered placing their instrument in a high-pressure enclosure on similar lines to that of the Hartmann and Braun precision voltmeter? While this arrangement would give high field strengths without corona for a given space occupied, it is possible that the effect of the ellipsoid on the field would be appreciably greater and would result in a more distorted scale. The authors' view on the possibilities of applying this suggestion to the design of a voltmeter for higher voltages than those mentioned in the paper, in order to reduce the space occupied by the instrument, would be interesting. Have any difficulties been encountered due to interference set up by adjacent bodies?

Mr. E. Fawssett: The theory of the authors' absolute standard voltmeter involves the assumption that the insertion of the ellipsoid in the field does not alter its distribution: if this assumption were false the instrument would break one of the first rules of measurement—that the apparatus employed must not of itself alter the quantity to be determined. I am not altogether convinced that the extremely high absolute accuracy claimed by the authors for such a difficult measurement is entirely justified on this score. As regards Section (5), dealing with the calibration by means of a sphere spark-gap, in my opinion it is a case of good fortune rather than a proof of high accuracy that the calibrations agree so well with those of Whitehead and Castellain, as I am not yet convinced that the mean values of spark-gap determinations are necessarily correct to a high order of accuracy, and the wave-form correction factor is, relatively speaking, large and erratic. The relation between R.M.S. and spark-gap reading on such a wave as (*d*), Fig. 6A, would surely be appreciably affected by the difference in steepness of the two sides of the wave, according to which represents rising voltage, for the same R.M.S. value. These detail criticisms are, however, only prompted by a slight doubt as to whether absolute accuracy can be guaranteed to so close a limit as 1 in 1 000.

Mr. T. R. Warren: The results obtained by the authors show that a new and much improved method of determining the value of high potentials in absolute measure will shortly be available. There are, however, one or two points in the paper which call for criticism. In my opinion the value of e should be chosen smaller, in order to prevent any small discrepancies due to imperfect workmanship giving rise to relatively large errors when determining the values of L and N. Although it will be conceded that any appreciable departure from a value nearly equal to unity will give rise to a reduction in torque for given values of F and V, I gather that there is already more than sufficient torque available to enable the required degree of accuracy to be obtained. I do not agree with the statement (page 4) that the torque on the ellipsoid is proportional to the product of the charge on any ring element of the surface and its distance from the axis of suspension, since the expression for the torque arrived at in this way, using the formula for the distribution of charge given on page 7, does not coincide with the expression given on page 2. It is important to determine the extent of field distortion due to the reaction on the plates when the ellipsoid is placed in position, since the spacing of the plates for a given degree of accuracy is largely dependent upon this factor. The theory given in Section (6), however, contains several inaccuracies, and I would suggest to the authors that they should proceed as follows. Consider an image of the ellipsoid in each plate. The field at the ellipsoid due to corresponding ring charges on each image is given by

$$\partial X_1 = \frac{4\pi X b^2 x \partial x}{Na^2(D-x)^2}$$

Therefore
$$X_1 = \frac{4\pi X b^2}{Na^2}\int_{-a}^{+a}\frac{x dx}{(D-x)^2}$$
$$= \frac{4\pi X b^2}{Na^2}\left(\frac{2aD}{D^2-a^2} - \log_e\frac{D+a}{D-a}\right)$$

Hence
$$\frac{X_1}{X} = \frac{8\pi a b^2(2D^2+a^2)}{3ND^3(D^2-a^2)}$$ (neglecting terms containing the fifth and higher powers of a)
$$= \frac{16\pi a b^2}{3ND^3}$$ (since a^2 is small as compared with D^2)

By taking successive images, the above expression becomes

$$\frac{X_1}{X} = \frac{16\pi ab^2}{3ND^3}\left(1 - \frac{1}{2^3} + \frac{1}{3^3} - \frac{1}{4^3} + \ldots\right)$$

The percentage increases in the field for the various spacings shown in Table 4 are now found to be as given in the following table.

D	Percentage increase of field
cm	
25	0·04215
50	0·005269
75	0·001561
100	0·000659

These values are much less than those given by the authors, and they indicate that a closer spacing of the plates is permissible without fear of introducing any appreciable error due to reaction.

Prof. W. M. Thornton and **Dr. W. G. Thompson** (*in reply*): In reply to Mr. Harle, the instrument should be regarded rather as a standard than as suitable for routine testing. Peak-voltage readings are much more easily obtained by the ionic wind voltmeter, using a null method. The response to change of voltage is slow, and the ellipsoid instrument is not suitable for observation of rapid changes. The voltages in Fig. 7 were added vectorially. With regard to enclosure, this would be difficult if the instrument had to be used for absolute measurements, but it might be made about half the size and without the metal-frame support. This is the final form it will probably take.

Mr. Fawssett's suggestion that the field distribution may be so greatly changed by the presence of the ellipsoid that the charges on the pole plates are modified, is considered in Section (6) of the paper. The field in the immediate neighbourhood of the ellipsoid must necessarily converge on it in order to give the condition that a field only enters or leaves a metallic surface at right angles to it. A good deal of time and care was spent in determining the influence of wave distortion such as that shown in Fig. 6A: the result is Fig 6B. It would have unduly increased the length of the paper to have given details of the analysis of the wave-forms. If the oscillograph is in perfect condition and the records are taken with a revolving-film camera these wave-forms are as accurate representations of voltage waves as it is possible to obtain. The records agree very closely. They were much enlarged, and then analysed laboriously by the method of ordinates. Fig. 6B gives the ratios by which the peak values calculated by multiplying the observed R.M.S. values by $\sqrt{2}$, were multiplied to give true peak values of the wave-forms. They could then be compared with sphere-gap measurements of peak voltages.

Mr. Warren is right in thinking that the difficulties involved in making an elongated ellipsoid to an exact profile are greater than when it is less pointed, but the eccentricity chosen (0·989) is that which gives $LN/(L - N)$ a maximum value. The expression on page 2 for the torque is calculated from that on a ring element in the manner stated. The distance between such an element and its image should surely be $(D - 2x)$, and there are several images to consider in the same manner; but it is satisfactory to see that his method gives still smaller values than ours for the reaction at the pole plates. With conducting ellipsoids 2·5 cm long having the same proportions it is possible to bring the spacing down to 20 cm, provided that the field is kept low. We hope that this instrument may commend itself to "grid" engineers and others as a simple standard of reference for high voltages; but the paper should be regarded as a preliminary study of a new and absolute method of measuring high voltages rather than as the description of a finished instrument. The work is being repeated and comparisons are being made between this and all other available methods.

REPORT OF THE COUNCIL FOR THE YEAR 1931–1932, PRESENTED AT THE ANNUAL GENERAL MEETING OF 5TH MAY, 1932.

REPORT.

The Council, at the Sixtieth Annual General Meeting of The Institution of Electrical Engineers, present to the members their Report for the year 1931–32, covering approximately the period from the 1st April, 1931, to the 31st March, 1932.

The Council desire once more to thank most cordially the many members, too numerous to be mentioned by name, who, by placing their services at the disposal of the Institution, serving on its committees, etc., contribute so materially to the fulfilment of its objects.

(1) MEMBERSHIP OF THE INSTITUTION.

The changes in the membership since the 1st April, 1931, are shown in a table included in Appendix A.

The following table shows the net growth of membership for the last 10 years:—

Year	Membership	Increase
1923	10 911	+ 636
1924	11 415	+ 504
1925	11 743	+ 328
1926	12 142	+ 399
1927	12 647	+ 505
1928	13 043	+ 396
1929	13 561	+ 518
1930	14 200	+ 639
1931	14 670	+ 470
1932	14 884	+ 214

(2) EXAMINATIONS.

Graduateship Examinations were held in May and November, 1931, in London, Belfast, Birmingham, Cardiff, Dublin, Glasgow, Manchester, Newcastle-on-Tyne, Norwich, and Southampton, and, in November only, in Australia, Brazil, Ceylon, F.M.S., Hong Kong, India, New Zealand, and South Africa.

During the year a number of candidates were permitted to fulfil the educational requirements for Associate Membership by the submission of satisfactory written papers or theses in lieu of an Examination.

Mr. J. R. Shewan was awarded the Page Prize (value £5) for the best Thesis submitted, his subject being "The Theoretical and Practical Training of the Apprentice Electrician."

(3) NATIONAL CERTIFICATES AND DIPLOMAS IN ELECTRICAL ENGINEERING.

England and Wales.—In 1931 the Joint Standing Committee, representing the Board of Education and

the Institution, was associated with the final examinations of 150 courses at colleges and schools in England and Wales approved in connection with the above certificates and diplomas.

The final examinations were held during the summer of 1931 and the number of awards was as follows:—

592 Ordinary Certificates.
279 Higher Certificates (including 8 Post-Higher Certificates).
8 Ordinary Diplomas.
3 Higher Diplomas.

Scotland.—In conjunction with the Scottish Education Department, the Institution was associated with 5 courses in Scotland during the year under review.

The final examinations were held during the summer and the number of awards was as follows:—

5 Ordinary Certificates.
3 Higher Certificates.
11 Higher Diplomas.

(4) Honorary Member.

The Council have pleasure in recording that, as announced at the Ordinary Meeting on the 21st January, 1932, they have elected Mr. William Morris Mordey, Past-President, to be an Honorary Member of the Institution.

(5) Faraday Medal.

The eleventh award of the Faraday Medal was made by the Council to Sir Oliver Lodge, D.Sc., F.R.S., Honorary Member.

(6) Minister of Transport.

The Council are especially gratified at the appointment of Mr. Percy John Pybus, Member, to the office of Minister of Transport and offer him the Institution's hearty congratulations.

(7) Honours and Distinctions Conferred on Members.

O.M.

Bragg, Sir William Henry, K.B.E., M.A., D.Sc., F.R.S. (Honorary Member).

Knighthood.

Goodman, William George T. (Member).

O.B.E.

Cohen, Bertram Sydney (Member).
Withycombe, Robert (Associate Member).

The Council are also pleased to place on record the Election of the Secretary of the Institution as an Honorary Member of the Société Française des Électriciens.

(8) Deaths.

The Council regret to have to record the death of the following 85 members of the Institution during the year:—

Honorary Member.

Edison, T. A.

Members.

Aldridge T. H. U.
Allan, P. F.
Bailey, F.
Baron, J. T.
Black, A. S.
Bulkley, J. N.
Clinker, R. C.
Dando, H. A.
Denham, J.
Drake, B.
Esskildsen, M. K.
Fuller, G.
Gregory, J. P.
Griffith, W. G., B.Sc.(Eng.).
Gwyther, C. W.
Hancock, W. J., D.Sc.
Harrison, Gen. Sir R., G.C.B., C.M.G.
Julius, C. H.
Leaf, H. M., D.S.O.
Moffett, F. J., B.A.
Nalder, F. H.
Packham, W. B.
Prentice, H. N.
Shaw, James H.
Smith, H. B.
Soldan, C. P.
Taylor, H. M.
Teasdel, J. E.
Walker, S. F.
Walton, A. H.
Wilkinson, H. D.
Wilson, Prof. E.
Wilson, S. N.
Winning, W. L.
Wright, Arthur

Associate Members.

Austin, E. P.
Belfield, S. St. G. C.
Brownell, J.
Burke, R. T.
Cooper, W. James
Cuthbert, M.
Darker, A. H.
Davies, F. H.
Ellis, W.
Foggo, J. J.
Gilbert, H. W.
Giles, F. C.
Grut, C. A.
Haley, W. E.
Harrison, T. C.
Haydon, G. S.
Hunter, K. H. W., B.Sc
Johnston, J. S.
Lakey, E. A.
Lambourn, W. C.
Law, G. C.
Lines, S. L. B.
Lund, A.
Maybury, Major P. T., B.Sc.Tech.
Miles, J. W.
Parkhurst, F. C.
Robertson, T. E., O.B.E.
Tate, T. F.
Tetley, T. R. H.
Thompson, F. W.
Wray, W. J. Roberts.

Companion.

Renwick, Sir H. B., Bart., K.B.E.

Associates.

Barnes, S. E.
Brash, J.
Chisholm, A. H.
Darlington, W. E.
Goold, R. L.
McGuigan, W.
Whitehouse, A. E.

Graduates.

Kershaw, R.
Kruger, N. D., B.Sc.
Lapraik, D. R., B.Sc.
Williams, H. L.

Students.

Calver, R. F. J.
Chapman, K. G.
Chapple, J.
Maidwell, C. L.
Shuttleworth, J. H.
Sleight, L.

(9) Institution Building.

The Institution continues to grant facilities for the free use of its premises to kindred societies in connection with their meetings, and 200 such meetings were held during the past year.

Arising out of the scheme for floodlighting public buildings in September, 1931, on the occasion of the

International Illumination Congress and the Faraday Centenary Celebrations, the Council, who gave wholehearted support to the scheme, decided that the Institution Building should be floodlighted not only for the period concerned, but at other times, and a permanent equipment has accordingly been installed. At present the Building is lighted until 8.30 p.m. every day (excluding Sundays) during the winter months.

The Institution's largest tenant, the British Broadcasting Corporation, will be vacating at an early date the premises which it has occupied in the Institution building since 1923. Some of the space so released is being let to the British Electrical Development Association and the Electric Lamp Manufacturers' Association who are extending their offices, and steps are being taken to obtain suitable tenants for the remainder of the available space, the rentals for which are lower than those prevailing in the Strand district.

(10) Oil Paintings.

During the past year the painting of the late Dr. de Ferranti, referred to in the last Annual Report, has been hung in the Lecture Theatre. The portrait, which is the work of Mr. David Jagger, was presented by Mr. H. Marryat.

Reproductions of all the portraits in the Lecture Theatre have been issued with recent numbers of the *Journal*.

(11) Unauthorized Use of Membership Initials.

During the past year there have been several cases of the use, by unauthorized persons, of initials or descriptions implying that they were members of the Institution, and, with one exception, it has been possible to ensure the discontinuance of the practice by the persons concerned without the necessity of taking legal action.

Legal action became necessary, however, as the result of the renewed use of the initials "A.M.I.E.E." by an ex-Student, against whom a perpetual injunction had been obtained in 1928. A report of this case has already been published in the *Journal* (April, 1932, No. 424, p. 473).

(12) Meetings.

During the past twelve months, 467 meetings have been held in London and the Local Centres by the members, the Council, and the various Committees. A detailed statement is given in Appendix B.

(13) Premiums.

The Premiums awarded by the Council for papers read at meetings or accepted for the *Journal* will be announced at the Annual General Meeting.*

(14) Coopers Hill War Memorial Prize.

The award of the Coopers Hill War Memorial Prize, which consists of a Bronze Medal, a parchment Certificate, and a Money Prize of £29, fell this year to the Institution, and the Council selected for the award Mr. M. G. Say, Ph.D., M.Sc., for his paper on "High Voltage Underground Cables." Five papers were submitted for consideration. Only Corporate Members of the Institution under 35 years of age are eligible to compete.

* See page 148.

The Prize consists of two awards, one of which is made annually by the Institution of Civil Engineers, and the other triennially in turn by the Institution of Electrical Engineers, the School of Military Engineering, Chatham, and the School of Forestry, Oxford.

(15) Local Centres and Sub-Centres.

Reports from the Committees of the Centres and Sub-Centres indicate that the attendances at the meetings and the interest in the discussions, etc., have been well sustained.

The President attended functions and meetings at the Centres at Birmingham, Cardiff, Dublin, Glasgow, Leeds, Liverpool, Manchester, and Newcastle-on-Tyne, as well as at the Hampshire, Sheffield, and Tees-Side Sub-Centres.

On each occasion the President addressed the members and was gratified at the activities of these branches of the Institution and impressed by their great value in extending its influence and prestige.

Full details of the meetings and other activities of the Local Centres and Sub-Centres are contained in the Annual Reports presented each year to the local members.

Members are reminded that local technical libraries have been established by the Institution at Birmingham, Dublin, Leeds, Loughborough, Manchester, Middlesbrough, and Newcastle.

Full particulars of the arrangements for borrowing or referring to the books at these libraries can be obtained on application to the Local Honorary Secretaries.

(16) Local Honorary Secretaries Abroad.

During the Session, the Council received the resignations of Mr. A. Gibbs (Local Honorary Secretary for New Zealand) and of Mr. A. C. Kelly (Argentine), and wish to tender the Institution's cordial thanks to these members for their zealous work on behalf of the Institution during their tenure of office. In their places, the Council have appointed Mr. A. C. Owen and Mr. R. G. Parrott respectively.

The Council also appointed Professor P. H. Fraenkel as Local Honorary Secretary for Western Australia in place of the late Dr. W. J. Hancock.

(17) Activities of Overseas Members.

In addition to the Local Committees, which, as stated in the last Annual Report, have already been set up in New South Wales, Victoria and Tasmania, South Australia, Western Australia, New Zealand, and the Transvaal, a Local Committee has now been set up in Queensland and Committees are also in process of formation in the following towns in India—Bombay, Calcutta, Lahore, and Madras.

Social gatherings, and in some cases meetings for the reading and discussion of papers, have been held with success in New South Wales, Queensland, and Victoria, and Faraday Centenary Celebration meetings have been held jointly with other scientific bodies in New South Wales, Queensland, and New Zealand.

The question of increasing further the overseas activities of the Institution is being carefully considered by the Overseas Activities Committee set up by the Council.

(18) Wireless Section.

The interest and activities of the Wireless Section continue to be well maintained. Nine meetings have been held, at which eight papers were read and two discussions took place, one on technical problems in connection with "Television" and the other on "Selectivity." In addition, five papers have been published or accepted for publication in the *Journal*. The average attendance at the meetings was 129, as compared with 107 for last Session.

The Council approved the issue of a list of members of the Section, and copies were posted with the March number of the *Wireless Proceedings*. The number of members is 590.

(19) Meter and Instrument Section.

Eight meetings of the Meter and Instrument Section have been held during the past year, the average attendance being 80, which compares with 79 for the preceding 12 months. The meetings have been uniformly successful and the discussions have been well sustained and interesting. The programme included an Informal Debate to which there were no fewer than 58 contributors.

A most successful Summer Visit to Cambridge took place on the 2nd May, 1931. The party, which numbered over 150 members and ladies, enjoyed the hospitality of the directors of the Cambridge Instrument Co., Ltd., whose works were inspected and who provided lunch for the visitors, and of Prof. C. E. Inglis, O.B.E., M.A., LL.D., F.R.S., who threw open the Engineering Laboratory for inspection and provided tea. Some of the Colleges were also visited. The success of this visit, as well as of the Section Dinner which was held on the 11th December, 1931, was most gratifying.

The Rules have been revised so as to provide for the immediate Past-Chairman to serve on the Committee. There are now 556 members in the Section, and a list of names is about to be published.

(20) Informal Meetings.

Ten meetings have been held during the Session, the average attendance being 62, as against 55 last year.

The Informal Meetings Committee again cordially invite members to write to the Secretary indicating subjects which they wish to suggest for discussion. Offers from members to open discussions will also be welcomed and carefully considered by the Committee.

(21) Students' Sections.

The eight Students' Sections, viz. at London, Birmingham, Glasgow, Leeds, Liverpool, Manchester, Newcastle-on-Tyne, and Sheffield, have carried out during the Session a very full programme of meetings, visits to works, and social functions. Full details and accounts have been given from time to time in the *Students' Quarterly Journal*.

The actual membership of the eight Students' Sections is in the aggregate 3 300, which includes some 1 200 Graduates under the age of 28, who are now entitled under the Bye-laws to the same privileges as Students.

The "Students' Lectures" were delivered this Session by Dr. C. C. Garrard and Mr. R. E. G. Horley, at the places indicated:—

Lecturer	*Subject*	*Place*
Dr. C. C. Garrard	"Switchgear"	Leeds
		Newcastle-on-Tyne
		Sheffield
		Glasgow } Scottish
		Edinburgh } Section
Mr. R. E. G. Horley	"Oil-filled Cables"	London
		Birmingham
		Liverpool
		Manchester

The total attendances at the nine Lectures, which were greatly appreciated, were approximately 700, compared with 530 for the nine Lectures given last Session by other lecturers. Although this increase is gratifying, it is hoped that the Lectures will receive even greater support next Session, as it is felt that the attendances should be still higher, taking into account the total membership of the Sections.

Eight papers were submitted by Students, and by Graduates under the age of 28, in the competition for the second Students' Prize of £10 offered for the best paper on the subject of "The Relations between Economics and Engineering." After due consideration it was decided that a Prize, value £5, be awarded on this occasion to Mr. C. M. Johnston (Graduate) for the paper submitted by him, and that a further Prize of £5 be offered this Session for the best paper received on the same subject. The award of this Prize will be announced as soon as possible.

In order to afford an opportunity for the personal interchange of views on matters of common interest to the various Sections, arrangements have been made for an Annual Meeting of the Honorary Secretaries of the Sections to be held in London, and the first of these meetings took place on the 5th February, when a very useful and interesting discussion took place on points of organization and routine.

The Students' Section Summer Tour was held in Northern Italy and Switzerland from 25th July until 4th August, 61 Students and Graduates taking part.

The party travelled from London to Milan, where they remained for five days. During that time visits were made to Messrs. Pirelli Ltd., Messrs. Brown Boveri, Milan University, and the Engineering School, the trunk telephone exchange, and a number of hydro-electric power stations belonging to the Cisalpino Electricity Supply Co.

From Milan the party proceeded to Glion (above Montreux) for the remainder of the tour. From here visits were made to the Barbarine Dam, hydro-electric power stations at Château Naye, Sembrancher, and Orsières, and a large preserving factory at Martigny.

Both in Milan and Montreux, time was devoted to seeing local scenery and visiting places of general interest.

The Council desire to express the thanks of the Institution for the hospitable welcome extended by those who entertained the party and gave facilities for visits to works, etc. The meeting was highly successful and thanks are due to Mr. T. H. Lockett, the then Honorary Assistant Secretary of the London Students'

Section, for his very capable handling of the organization of the tour on behalf of the Committee of the Section.

(22) "Students' Quarterly Journal."

The *Students' Quarterly Journal* has continued to make excellent progress. The support received in the shape of articles and suggestions has been so great, and the standard so high, that it has not been necessary to go outside the Students' Section for any of the material, and there is every indication that this desirable state of affairs will be maintained.

The influence of the publication in stimulating attendances at meetings and improving the corporate spirit of the individual members has been evidenced in several directions, while a very happy co-operation is growing up between the various Sections in different parts of the country. The publication is also greatly appreciated by overseas readers who find it an invaluable link with their old associations.

(23) Summer Meeting.

In anticipation that many members would be attracted to London in September, 1931, by the Faraday Centenary Celebrations, the International Illumination Congress, and the Annual Conversazione, it was considered opportune to hold the Summer Meeting in London during that month, and an extensive programme of visits and other functions took place from Tuesday the 22nd to Friday the 25th September. The Council were glad to be able to welcome on the occasion of this Meeting a party of members of the Société Française des Électriciens and their ladies.

The Meeting commenced on Tuesday morning with a Conference at Kingsway Hall, an account of which has already been given in the *Journal*, and ended with a Ball at Grosvenor House on Friday evening. The 23rd September was set aside for a Private View and the Official Opening of the Faraday Exhibition, and the remaining time was spent in visits to works and other places of interest, including Hampton Court, Windsor Castle, and some of the Colleges at Oxford. The thanks of the Council have been sent to the following firms and bodies whose hospitality was cordially appreciated by all the members and ladies, some 420, who took part:—

British Broadcasting Corporation (Brookman's Park transmitting station).
Messrs. Callender's Cable and Construction Co., Ltd. (Erith works).
Messrs. Carreras Limited.
Central Electricity Board (132-kV transforming station at Swanscombe).
County of London Electric Supply Co., Ltd. (Barking generating station).
Messrs. Fraser and Chalmers, Ltd.
General Electric Co., Ltd. [Osram G.E.C. lamp works and M.O. valve works at Hammersmith; Osram G.E.C. glass works and lamp works (No. 7 Factory), and the research laboratories at Wembley].
Gramophone Co., Ltd.
Messrs. W. T. Henley's Telegraph Works Co., Ltd. (Gravesend works).
Messrs. Huntley and Palmers, Ltd.
London General Omnibus Co., Ltd. (Chiswick overhaul and repair works).
London Power Co., Ltd. (Deptford power station).
Messrs. J. Lyons and Co., Ltd. (Greenford chocolate factory).
Messrs. Morris Motors, Ltd. (Cowley works).
National Physical Laboratory.
North Metropolitan Electric Power Supply Co. (Brimsdown generating station.)
Port of London Authority (King George V Dock, etc.).
Post Office [Post Office (London) Railway and Baldock radio station].
Royal Zoological Society (Electrical installation at the Reptile House, Zoological Gardens).
Messrs. Standard Telephones and Cables, Ltd. (Hendon works).
Underground Railway Co. (Carriage overhaul works, Acton).

(24) Faraday Lecture.

The Faraday Lecture this Session was delivered by Prof. J. K. Catterson-Smith, M.Eng., who chose as his subject "Everyday Uses of Electricity." The Lecture was given at Dublin, Leeds, Liverpool, Manchester, Newcastle-on-Tyne, and Swansea. Prof. Catterson-Smith will also give the Lecture at Aberdeen before the Session closes.

The six Lectures so far delivered this Session have been attended by a total audience of approximately 3 230, of whom over 2 570 were non-members.

(25) Reviews of Progress.

Continuing the series of reviews of progress in electrical engineering published in the *Journal* since 1926, reviews on the following subjects have been published during 1932:—

Power Stations and Their Equipment.
Radio-Telegraphy and Radio-Telephony.
Telegraphy and Telephony.

The reviews to be published in 1933 will be on the following subjects:—

Electric Traction.
Electrical Equipment of Automobiles.
Electrical Plant and Machinery.
Electricity Applied to Ships.
Electro-Physics.
Industrial, Agricultural, and Domestic Applications, including Illumination and Tariffs.

(26) Scholarships.

The following Scholarships have been awarded by the Council during the Session:—

Ferranti Scholarship.

(Annual Value £250; tenable for two years.)

W. G. Thompson, Ph.D. (Armstrong College, Newcastle-on-Tyne).

Duddell Scholarship.

(Annual Value £150; tenable for three years.)

C. H. W. Clark (Sevenoaks Grammar School).

Silvanus Thompson Scholarship.

(Annual Value £100, plus tuition fees; tenable for two years.)

C. H. Lackey (Messrs. A. Reyrolle and Co. Ltd.).

David Hughes Scholarship.

(Value £100; tenable for one year.)

G. L. d'Ombrain [City and Guilds (Engineering) College].

Salomons Scholarship.

(Value £100; tenable for one year.)

S. H. Padel (Manchester College of Technology).

Paul Scholarship.

(Annual Value £50; tenable for two years.)

W. T. Darwin (London County Council School of Engineering and Navigation).

Thorrowgood Scholarship.

(Annual Value £25; tenable for two years.)

P. W. Ottley (The Underground Electric Railway Co. of London, Ltd.).

War Thanksgiving Education and Research Fund (No. 1).

The Council have made grants from the above Fund for research purposes as follows:—

£50 each to:—F. J. Clark (East London College).
J. H. Wagstaff (University College, London).

£25 to:—Miss W. Hackett (Birmingham University).

With the exception of the Paul Scholarship, which is awarded in alternate years only, all the above scholarships and grants are awarded annually.

(27) Faraday Centenary Celebrations.

The Faraday Centenary Celebrations which took place in September, 1931, were an unqualified success. A full account will be found in the November, 1931, issue (No. 419) of the *Journal*. The report of the Organizing Committee of the Exhibition was published in the January, 1932, issue (No. 421, p. 164).

(28) Hughes Centenary.

The centenary of the birth of David Edward Hughes, who was born on the 16th May, 1831, was commemorated by the Institution on the 14th May, 1931, when a discourse on the life and work of Hughes was given by Mr. Sydney Evershed. The discourse was printed in the *Journal* in October, 1931 (No. 418, p. 1245).

(29) Varley Centenary.

The centenary of the births of Cromwell Fleetwood Varley (6th April, 1828) and Samuel Alfred Varley (22nd March, 1832) will be commemorated by the Institution on the 5th May, when a discourse on their lives and work will be delivered by Lieut.-Col. A. G. Lee, O.B.E., M.C., B.Sc.

(30) Swan Memorial Fund.

It was stated in the last Annual Report that an appeal had been published in January, 1931, with the support of the Institution and the Royal Photographic Society of Great Britain, for funds for the establishment of a memorial to Sir Joseph Swan, the inventor, *inter alia*, of the incandescent electric lamp, in the form of scholarships in electrical engineering science to be administered by the Institution. The final result has been that a sum of approximately £3 000 has been received which, it is regretted, is considerably short of the desired total of £5 000. It will therefore only be possible to establish one scholarship, instead of two as originally proposed. The Conditions of Award for this scholarship are at present being drawn up and the first award will probably be made in 1932.

(31) International Relations.

Paris International Electrical Congress, 1932.

The object of this Congress is the celebration of the 50th anniversary of the first International Electricity Congress which took place in Paris in 1881, when fundamental and far-reaching decisions regarding electrical units were arrived at.

The Council have set up a British Organizing Committee to collaborate with the French authorities in arranging for the presentation of papers by British authors for this Congress, which will be held in Paris in July, 1932. Ten papers by British authors have been sent through the British Committee to Paris for this purpose.

International Union of Suppliers and Distributors of Electrical Energy.

The Council have considered the question of becoming formally associated with this Union and have recommended that the electricity supply organizations in this country should join it as Adherent Members.

(32) Anniversary Celebrations and Conferences.

During the year under review, the Institution has been represented at Anniversary Celebrations and Conferences, etc., arranged by other bodies as shown in the following table:—

Name of Body	*Nature and Date of Function*	*Name of I.E.E. Representative*
Association of Teachers in Technical Institutions	Annual Conference, Manchester (23–26 May, 1931)	Prof. Miles Walker, D.Sc.
British Association for the Advancement of Science	Centenary Celebrations (23–30 Sept., 1931)	Mr. Clifford C. Paterson, O.B.E. (then President).
Cambridge University	Clerk Maxwell Centenary Celebrations (1 & 2 Oct., 1931)	Mr. Clifford C. Paterson, O.B.E. (Past President).
Carnegie Institute of Technology	Third International Conference on Bituminous Coal, Pittsburg (16–21 Nov., 1931)	Mr. Gano Dunn (Local Hon. Secretary for the U.S.A.).
International Commission on Illumination	International Illumination Congress (1–19 Sept., 1931)	Lt.-Col. K. Edgcumbe, T.D., R.E.T. (Ret.) (Past President). Mr. P. Good. Mr. H. T. Harrison. Prof. J. T. MacGregor-Morris. Dr. J. W. T. Walsh.

Name of Body	*Nature and Date of Function*	*Name of I.E.E. Representative*
Royal Dublin Society	Bi-Centenary Celebrations (22–26 June, 1931)	Mr. F. H. Whysall (Chairman, Irish Centre).
Royal Institution	Faraday Centenary Celebrations (19–25 Sept., 1931)	Mr. Clifford C. Paterson, O.B.E. (then President).
Royal Sanitary Institute	Annual Congress, Glasgow (4–11 July, 1931)	Mr. E. Seddon (Chairman, Scottish Centre).
Société Française des Électriciens	Faraday Centenary Celebrations, Paris (26 Nov., 1931)	Mr. J. M. Donaldson, M.C. (President).
		Mr. Clifford C. Paterson, O.B.E. (Past President).
		Lt.-Col. K. Edgcumbe, T.D., R.E.T. (Ret.) (Past President).
		Mr. P. F. Rowell (Secretary).

(33) Local Wireless Sections in Canada.

The scheme for the formation of Local Wireless Sections in Canada, in co-operation with the Engineering Institute of Canada, is almost complete and it is hoped that it will be possible shortly to inform members in Canada of the details of the scheme.

(34) Annual Conversazione.

The Faraday Exhibition at the Royal Albert Hall afforded an opportunity for the Annual Conversazione to be held there on the 22nd September, 1931, and it was made the occasion of a Private View of the Exhibition which was opened to the public on the following day. The guests included, among others, many delegates to the Faraday Centenary Celebrations, and the total attendance of members and guests was 2 400.

(35) Annual Dinner.

The Annual Dinner was held at the Connaught Rooms, London, on the 4th February, 1932, when nearly 700 members and guests were present.

An account has been published in the *Journal* (No. 424, p. 470, April, 1932).

(36) Electrical Appointments Board.

The Board keeps a classified register of members seeking positions, and the Secretary of the Board will gladly put employers in touch with highly qualified electrical engineers.

The Council earnestly hope that members who are in a position to assist will not fail to make use of the register.

(37) Library.

During the year, 189 books and pamphlets were presented to the Reference Library by members and others, and 137 volumes were purchased. The total number of readers for the year was 6 762, of whom 560 were non-members, as against 4 359 and 336 respectively in 1930–31.

Sixty-eight new volumes were added to the Lending Library and 2 522 books were issued to 1 007 borrowers, the corresponding numbers for the previous year being 2 444 and 938 respectively.

(38) Gifts to the Institution.

The Council express their cordial thanks to the donors of the following gifts to the Institution:—

Donor	*Gift*
Elektrotechnischer Verein of Berlin	A replica of the original Gauss-Weber electromagnetic telegraph made in 1833.
Mr. A. Evelyn Barnard ..	A small plaster bust of Michael Faraday by M. Noble, 1854.
	An engraved reproduction of A. Blaikley's painting of Faraday lecturing at the Royal Institution.
Mr. F. A. Downs	An early milliamperemeter.
Mr. J. Forrester	A voltaic pile made by the late F. V. Andersen.
	An early amperemeter.
Sir Robert Hadfield, D.Sc., F.R.S.	A plaque of Faraday.

(39) "Science Abstracts."

The Physics volume of *Science Abstracts* for 1931 contains 4 365 abstracts, as compared with 4 165 in 1930. The Electrical Engineering volume contains 2 607 abstracts, as compared with 2 537.

The very slight interest taken in *Science Abstracts* by the general body of members is still a matter of considerable disappointment to the Council. The publication, which appears monthly in two sections, namely, Section "A" (Physics) and Section "B" (Electrical Engineering), consists of full abstracts from the leading scientific and technical journals and the proceedings of learned societies of the whole world, and presents in a form convenient for immediate reference a complete and concise record of the progress of physical science and electrical engineering. It is therefore surprising that, out of a membership of some 14 900, fewer than 1 400 subscribe to *Science Abstracts*, only 805 members subscribing to both Sections and 579 to Section "B."

The Council regret to record that this represents a decrease of 100 in the total number of subscribers during the last twelve months, and they earnestly hope that greater support will be given to the publication in the future. *Science Abstracts* may be obtained, if ordered in advance, by Students of the Institution, as well as by Graduates under the age of 28, at the special rate of 7s. 6d. per annum for both Sections, or 5s. for either the Physics or the Electrical Engineering Section, and by all other members of the Institution at 20s. for both Sections, or 12s. 6d. for either Section alone, the rates charged to the general public being £1 15s. per Section, or £3 for both Sections.

(40) Model General Conditions for Contracts.

The proposed set of Model Conditions "E" for the supply, laying, and erection of cables at home is still under consideration. The Committee set up by the Council to deal with the matter has been increased to include representatives of additional interested Associations.

(41) London Building Act, 1930.

The Institution was given an opportunity to suggest amendments to the above, and the following representations were made:—

(*a*) Electricity generating stations, except in regard to architectural appearance, should be fully exempted from the Act;

(*b*) Electricity substations should be similarly exempted, except those which abut on other buildings; and

(*c*) The right of appeal to the Tribunal provided for in the Act should be allowed to electricity authorities.

(42) Regulations for the Electrical Equipment of Buildings.

The Wiring Regulations Committee are proceeding with the revision of the present (Ninth) Edition of the Regulations and, in order to expedite the work, have appointed a small Executive Committee to complete the revision and to deal with the numerous matters which arise from time to time in connection with the Regulations. The Wiring Regulations Committee collaborate not only with the British Standards Institution in this country, but also with the organizations in Australia and New Zealand which deal with regulations for electrical installations.

An Advisory Sub-Committee assists in matters relating to the application of the Regulations, and answers inquiries as to interpretation in particular cases. Several new sub-committees have been set up to consider special Sections of the Regulations, particularly from the point of view of recent developments such as luminous tube signs, electric clocks, etc. In order to provide for such switchgear as "splitter units," a new clause (69 M) relating to distribution boards was issued in May, 1931, in the form of a Supplement to the Ninth Edition.

There is a steadily increasing demand for copies of the Regulations (the Ninth Edition is now in its 21st thousand), a sure indication of the growing appreciation of the Regulations and of the extent to which they are being adopted.

(43) Electricity Regulations.

On the 19th June, 1931, the Electricity Commissioners published three Supplementary Regulations for Securing the Safety of the Public, under the Electricity (Supply) Acts, 1882 to 1928. These relate to "Insulation or Protection," "Underground Shafts, etc." and "Service Lines into Consumers' Premises." It is understood that the remainder of the Safety and Supply Regulations will be published within the next few months.

(44) Radiological and Electro-Medical Technical Committee.

The above Committee has been set up by the Council to obtain papers on radiological and electro-medical subjects, and to deal with such other matters as may be referred to it by the Council, the aim being to stimulate interest in the electrical engineering aspect of radiology. The Committee is representative of electrical engineers, medical men, and radiographers.

(45) Benevolent Fund.

The Committee of Management of the Benevolent Fund of the Institution report that on the 31st December, 1931, the total assets of the Fund amounted to £20 461 11s. 9d., of which £17 811 17s. 2d. was on Capital Account, and £2 649 14s. 7d. in respect of unexpended Income. The donations and subscriptions to the Fund in 1931 amounted to £3 069 0s. 8d., in which amount are included the proceeds of Golf Competitions organized by the Mersey and North Wales (Liverpool) and Scottish Centres. A legacy of £100 was also received from the executors of the late Mr. E. Garcke.

In the course of 1931, grants were made to 38 persons, amounting to a total of £1 870 7s. 6d. During the last few years, the annual totals of the grants made have shown a distinct increase from year to year.

The Council most earnestly desire to bring the Fund to the notice of all members of the Institution. Donations and promises of annual subscriptions of any amount will be gratefully received.

(46) Summary of Annual Accounts.

Income and Expenditure.—After making provision for contingencies, there is a deficit on the Revenue Account for the year ended 31st December, 1931, of £427 13s. 7d. This deficit, which has been carried to the debit of the General Fund, and compares with a balance to the good of £3 616 2s. 2d. in 1930, is entirely accounted for by items of non-recurring expenditure (Faraday Centenary Exhibition, etc.) specially indicated in the Revenue Account.

Assets.—Taking the investments at cost and the Institution Building and lease, the library and furniture, etc., at the values standing in the books after writing off depreciation—

	£	s.	d.
the Assets amount to	201 998	0	10
against Liabilities	19 597	18	2
leaving a surplus of	182 400	2	8
which, in comparison with that of the year 1930, viz.	182 760	2	3
shows a reduction of	£359	19	7

The surplus of £182 400 2s. 8d. referred to above is made up as follows:—

	£ s. d.	£	s.	d.
Assets.				
Institution building and lease		73 028	6	10
Investments, cash, etc. ..		120 797	12	7
Stock of paper, libraries, and furniture		8 172	1	5
		£201 998	0	10
Less *Liabilities.*				
Trust Fund Accounts ..	346 1 6			
Sundry creditors ..	6 270 15 9			
Overdraft at Bank ..	8 644 4 1			
Repairs Suspense Account	4 035 13 10			
Subscriptions received in advance	301 3 0			
		19 597	18	2
		£182 400	2	8

Investments.—The investments made during the year were as follows:—

	£	s.	d.
£2 400 Ayr County Council 5 per cent "A" Stock (1947–57)	2 484	4	0
£2 400 Union of South Africa 5 per cent Stock (1950–70)	2 436	4	0
	£4 920	8	0

(47) THE INSTITUTION AND BODIES ON WHICH IT IS REPRESENTED.

Appendix C shows in diagrammatic form the organization of the Institution and the bodies on which it is represented.

APPENDIX A.

MEMBERSHIP OF THE INSTITUTION.

The changes in the membership since April 1, 1931, are shown in the following table:—

	Hon. Mem.	Mem.	Assoc. Mem.	Com.	Assoc.	Grad.	Stud.	TOTAL.
Totals at 1 April, 1931	13	1 973	5 660	115	1 612	2 175	3 122	14 670

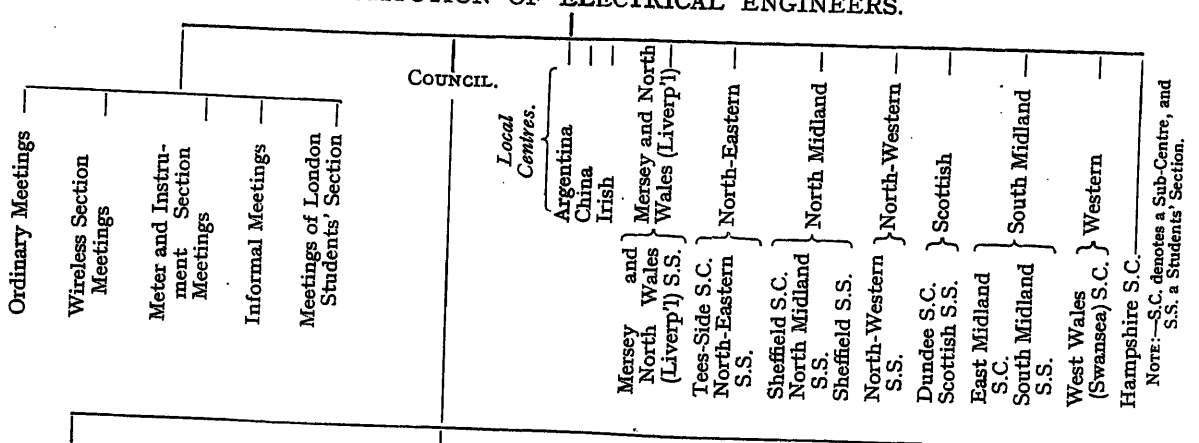
APPENDIX B.



MEETINGS.

The following is a list of the meetings held during the past 12 months:—

Ordinary Meetings ..	18
Annual General Meeting	1
Annual General Meeting (Benevolent Fund)	1
Wireless Section ..	9
Meter and Instrument Section	8
Informal Meetings ..	10
Council Meetings ..	14
Local Centres:—	
Irish	7
Mersey and North Wales (Liverpool)	10
North-Eastern ..	12
North Midland ..	13
North-Western ..	12
Scottish	13
South Midland ..	10
Western	9
Local Sub-Centres:—	
Dundee	7
East Midland ..	9
Hampshire ..	10
Sheffield	7
Tees-Side	8
West Wales (Swansea)	5
Students' Sections:—	
Liverpool	11
London	17
North-Eastern ..	11
North Midland ..	8
North-Western ..	9
Scottish	13
Sheffield	7
South Midland ..	10
Committees:—	
Benevolent Fund ..	5
Examinations ..	6
Faraday Celebrations (and Sub-Committees) ..	5
Finance	13
General Purposes (and Sub-Committee)	8
Informal Meetings	5
International Relations (and Sub-Committee) ..	2
Local Centres ..	2
Membership ..	7
Meter and Instrument Section (and Sub-Committees)	18
National Certificates (England)	4
National Certificates (Scotland)	2
Overseas Activities	6
Papers (and Sub-Committee) ..	10
Scholarships ..	3
"Science Abstracts" (and "Physics" Panel)	4
Wireless Section (and Sub-Committees)	17
Wiring Regulations (and Sub-Committees)	38
Other Committees	33
Total ..	467

APPENDIX C.

THE INSTITUTION OF ELECTRICAL ENGINEERS.

Committees of Council.

- Examinations
- Finance
- General Purposes
- Library and Museum
- Membership
- Papers

Special Committees.

- Benevolent Fund
- E.H.T. Conference, Paris, British National Committee
- Electricity (Supply) Regulations
- Faraday Medal and Honorary Membership Advisory
- Informal Meetings
- International Relations
- Local Centres
- Meter and Instrument Section
- Model General Conditions
- Overseas Activities
- Patent Law
- Scholarships
- "Science Abstracts"
- Ship Electrical Equipment Regulations
- Wireless Section
- Wiring Regulations

Technical Committees.

- Electrical Plant and Machinery, including Marine Applications
- Electricity in Mines
- Electro-Chemistry and Electro-Metallurgy
- Industrial, Agricultural and Domestic Applications, including Illumination and Tariffs
- Power Stations and their Equipment
- Radiological and Electro-Medical
- Telegraphs and Telephones
- Traction
- Transmission and Distribution

Overseas Advisory Committees.

- India
- New South Wales
- Queensland
- South Australia
- Victoria and Tasmania
- Western Australia
- New Zealand
- Transvaal

Bodies on which the Institution is Represented.

- Alloys of Iron Research Committee (Royal Society)
- Bristol University
- British Cast Iron Research Association
- British Electrical and Allied Industries Research Association
- British Electrical Development Association
- British National Committee of the International Electrotechnical Commission
- British National Committee, World Power Conference
- British National Illumination Committee of the International Illumination Commission
- British Standards Institution
- City and Guilds of London Institute
- Council for the Preservation of Rural England
- Electrical Association for Women
- Engineering Joint Council
- Imperial College of Science and Technology, Governing Body
- Imperial Minerals Resources Conference, Copper Committee
- Institute of Metals, Corrosion Research Committee
- Institution of Civil Engineers, Engine and Boiler Testing Committee
- International Association for Testing Materials
- International Electrotechnical Commission
- Leeds Municipal Technical Library Committee
- Loughborough Technical College Advisory Committee
- Metalliferous Mining (Cornwall) School, Governing Body
- Middlesbrough Technical College, Governing Body
- National Certificates and Diplomas in Electrical Engineering, Joint Committees for
- National Committee on Physics (Royal Society)
- National Committee on Radio-Telegraphy (Royal Society)
- National Physical Laboratory, General Board
- National Register of Electrical Installation Contractors
- Professional Classes Aid Council
- Radio Manufacturers' Association, Committee on Battery Eliminators
- Royal Engineer Board
- Science Museum, S. Kensington, Advisory Council
- Smoke Abatement League of Great Britain
- Technical and Economic Advisory Council for the Building Industry
- Union of Lancashire and Cheshire Institutes, Panel for Engineering
- War Office Mechanical Warfare Board
- Women's Engineering Society

ERNEST LEETE,
Honorary Treasurer.

P. F. ROWELL,
Secretary.

We beg to report that we have audited the Balance Sheet of The Institution of Electrical Engineers, dated 31st December, 1931, and above set forth, together with the annexed Statements of Account. We have obtained all the information and explanations we have required. In our opinion the Statements are correct and the Balance Sheet is properly drawn up so as to exhibit a true and correct view of the state of the Institution's affairs according to the best of our information and the explanations given to us and as shown by the books of the Institution.

19th April, 1932.

RECENT DEVELOPMENTS IN CATHODE-RAY OSCILLOGRAPHS.

By A. B. Wood, D.Sc.

(*Paper first received* 18*th September, and in final form* 1*st December*, 1931; *read before the* Meter and Instrument Section *5th February*, 1932.)

Summary.

The paper deals briefly with some of the more important developments in design and use of cathode-ray oscillographs. Methods of increasing the photographic or recording sensitivity are first considered, particular attention being given to (*a*) focusing the cathode-ray stream, (*b*) increasing the sensitivity of the photographic film, (*c*) the use of phosphorescent materials as a means of increasing photographic sensitivity and of facilitating "external" photography, and (*d*) increasing the exciting voltage and consequently the kinetic energy and penetrating power of the cathode rays. With regard to (*d*), particular attention is paid to Lenard's observations on the penetrating power of high-velocity cathode rays and the application of his results to the design of high-voltage oscillographs fitted with a "window" for direct external photography.

Referring to the technique of recording by cathode rays, consideration is given to the various methods of generating a "time" axis and to methods of voltage subdivision. The paper concludes with a section dealing with the recording of isolated electrical impulses.

(1) Introduction.

In a paper* communicated to the Institution in 1924, attention was drawn to the growing importance of cathode-ray oscillographs. Three typical forms were described and consideration was given to the questions of electrostatic, electromagnetic and photographic sensitivity. Since that time these three forms of oscillograph have been used extensively, both in routine commercial work and in research.

This increased use of the cathode-ray oscillograph has naturally led to improvements in design and technique. It is the purpose of this paper to draw attention to a number of these improvements and to indicate as far as possible some of the more promising lines of future development.

In view of the fact that the medium-voltage oscillograph mentioned in the previous paper can now be used for direct photography with exciting potentials as low as 500 or 600 volts and for visual observation at even lower potentials, no useful purpose would be served by drawing the distinction between low-, medium-, and high-voltage oscillographs. A more natural classification is simply high- and low-voltage oscillographs, the former working over a range of 10 kV upwards and the latter over a range 10 kV downwards. The former type usually, but not necessarily, employ a cold cathode, whilst the latter invariably use a hot cathode.

The line of progress has been concerned mainly with methods of improving the photographic conditions in the cathode-ray oscillograph. This improvement has been achieved in various ways, direct and indirect. The first part of the paper will deal more particularly with some of these methods. The extended use of the cathode-ray oscillograph in the study of impulsive and very high-frequency phenomena such as those encountered in lightning discharges, in wireless transmission, and in surges in high-power lines, has necessarily evoked much ingenuity on the part of engineers and physicists to devise suitable timing circuits for recording. When it is considered that non-periodic electrical impulses of duration not exceeding 10^{-6} sec. are recorded as a matter of routine, it will be realized to what degree of perfection this timing is carried out. The latter part of the paper will deal with some of the more important methods of generating a time scale and in timing unexpected impulses (for example, lightning flashes) of short duration. Some consideration will also be given to various forms of potential dividers, more particularly those required in recording high-voltage phenomena exceeding the voltage-deflection limits of the oscillograph.

* See References (1) and (2).

(2) Methods of Increasing Recording Sensitivity. "Internal" and "External" Photography.

The electrostatic and electromagnetic sensitivity of a cathode-ray oscillograph are defined simply by the linear dimensions of the apparatus and the voltage used to accelerate the cathode rays. The photographic sensitivity is, however, much more difficult to control. The efficiency of an oscillograph from the standpoint of its practical utility is dependent largely on its photographic sensitivity. It is consequently a matter of importance to consider the various possible methods of increasing this sensitivity. In the papers already referred to the following methods were discussed:—

(*a*) Focusing of the cathode stream and, in the case of the hot-cathode oscillograph, increasing the emission of the cathode.
(*b*) Improvement of the photographic film.
(*c*) Use of phosphorescent materials to increase, or otherwise facilitate, the photographic effect.
(*d*) Increasing the accelerating voltage.

It is convenient to deal with them in this order again.

(*a*) *Focusing the Cathode Stream.*

In the paper* read before the Physical Society of London in 1923, various methods, mechanical, electrostatic, and electromagnetic, of focusing a beam of cathode rays were described. Of these the electrostatic method, using a Wehnelt cylinder surrounding the cathode, was considered to give the best results. When a very small, intense recording spot was required, however, it seemed doubtful whether focusing was an advantage as a means of increasing intensity. The

* See Reference (2).

beam of rays appeared to consist of a heterogeneous bundle of fine pencils varying in intensity within wide limits. When one of these fine, intense pencils was deflected through the pinhole tube a brilliant recording spot was obtained which usually proved sufficient for high-speed recording. An ideal focusing device would of course converge all such fine pencils of rays into a single small spot, but that is somewhat difficult to carry out in practice. Using a modified form of Western Electric cathode-ray tube, M. von Ardenne* has recently employed the Wehnelt cathode with considerable success. Instead of connecting the Wehnelt cylinder to one end of the filament, or leaving it in a " floating " condition, he finds that a negative voltage applied to it produces a good initial concentration of the cathode beam which passes through a 2 mm dia. aperture in the anode without loss due to screening. Divergence of the beam after passing the anode is prevented by nullifying the space charge in the tube. M. von Ardenne states that this latter condition is effected by the presence of a trace of a rare gas in the vacuum " by the ionization of which a considerable number of positive ions is produced, causing the electrostatic repulsion due to the space charge to be outweighed by the electrodynamic attraction of the convection currents moving approximately parallel to one another in the ray." Whether or not this is the true explanation of the focusing action, the spot obtained is small and brilliant. A number of other observers have used the Wehnelt cathode with success, for example S. Watanabe† and R. H. George.‡ This method is, of course, particularly applicable to low-voltage, hot-cathode oscillographs.

The electromagnetic method of focusing has been used by W. Rogowski§ in a cold-cathode oscillograph operated at 60 kV. Max Knoll considered, however, that focusing is unnecessary at these high voltages, when the cathode rays have a very high velocity (e.g. at 64 kV $1{\cdot}5 \times 10^{10}$ cm per sec., i.e. half that of light).

In connection with the question of focusing cathode rays emitted from an electrically heated filament a difficulty may arise on account of the strong magnetic field at the surface of emission. In the case of a thin wire this field may reach a high value sufficient to produce a large bending of the track of a cathode ray as it leaves the filament, for example with a filament 0·005 cm radius carrying 1 ampere the field strength at the surface is 40 gauss, which is sufficient to give a large initial deflection to an electron at the instant of emission. The path of a cathode ray is therefore dependent not only on the type of focusing device employed but also on the state of the magnetic field (due to filament current) at each element of the surface of the filament. A close examination of the cathode stream leaving an oxide-coated filament surrounded by a Wehnelt cylinder reveals this effect very clearly. Inside the conical beam isolated " rays " having curved paths may be seen, the curvature and direction of these paths varying considerably. Reversal of filament current produces a marked change in the appearance of the beam. One method of overcoming this difficulty may be to use an indirectly heated emitting surface. For example, the use of a filament with an oxide coated sheath, as in a.c. valves, might prove a satisfactory solution. Perhaps the same result could be achieved by coating a filament with a *thick* layer of calcium or barium oxide. For example, if we assume the filament to have a diameter of 0·004 in. and the coating (or sheath) 0·020 in. dia., this would reduce the strength of the magnetic field at the emitting surface to 20 per cent of its value at the surface of the bare filament. This assumes, of course, that the current flowing through the heated oxide layer is negligible.

Another alternative is to use a filament wound non-inductively with the turns as close together as possible. This method has given good results in practice.

Apart from such methods of focusing, further increase of intensity of the beam in hot-cathode tubes may be obtained by increasing the temperature of the filament. The thermionic emission of a filament increases extremely rapidly with filament current,* small increases of current producing large increases of filament temperature and thermionic emission.

Until recently the upper limit appeared to be fixed by the fusing temperature of the filament (coated with oxides of alkaline earths, Ca, Ba, and Sr), but W. Rogowski† has produced a tube with an extremely high cathode emission by the use of a *molten* cathode. The tube will operate for several hundred hours without appreciable variation in the cathode-ray emission, owing to the fact that the surface of the molten cathode is continuously changing, thus providing a fresh, clean surface for emission of electrons. The brilliance of the phosphorescent screen in Rogowski's experiments was so great that it was actually considered as a means of producing light! The oscillograph was consequently adopted for both " internal " (or direct) photography, or for " external " photography, the luminous image being focused by a camera lens.

With a view to increasing the electron emission at lower temperatures, a large amount of work has been done recently in connection with the development of oxide-coated filaments, in particular with barium-oxide coating, for use in valves. The electron emission from a barium-oxide-coated filament is very much greater than that of a bare filament at the same temperature, and Hodgson‡ states that he has not been able to detect any change in the amount of barium present in a filament after 1 000 hours' running. Such a filament should therefore prove very suitable for a cathode-ray oscillograph.

(b) *Photographic Film.*

The sensitivity of photographic films to cathode rays bears practically no relation whatever to their sensitivity to light. The point of importance is to provide a sensitive layer which contains a large proportion of sensitive silver granules *which can be reached by the cathode rays.* The difficulty of selecting a suitable sensitive photographic plate only arises in the case of low-voltage cathode rays. At voltages of the order of 10 000 upwards the rays are sufficiently penetrating to affect the lower layers of silver bromide in an ordinary photo-

* See Reference (8).
‡ *Ibid.*, (5).
† *Ibid.*, (4).
§ *Ibid.*, (6).

* See Reference (7).
† *Ibid.*, (8).
‡ *Ibid.*, (7).

graphic film. With lower-velocity rays, however, generated at voltages below 5 000, the absorption in the gelatine is very rapid and only surface layers of silver bromide are affected. The thickness of film on an ordinary plate is approximately 10^{-3} cm, which is just penetrated by cathode rays at 30 000 volts, whilst rays at 3 000 volts can only reach a depth of 1 per cent of the thickness.

Half-tone plates (manufactured for engraving work) are an improvement on ordinary plates. The film is much thinner and the proportion of silver to gelatine is increased. They have a very fine grain and can be developed, fixed, washed, and dried more quickly than ordinary plates. The blackness of the developed image is, however, disappointing but may, of course, be intensified. For recording at low and moderate speeds these plates are fairly satisfactory.

A very sensitive plate of the Schumann type is made by Hilgers. This plate, the Hilger-Schumann plate, contains approximately 100 times the silver-gelatine ratio that an ordinary plate does. With these plates good single-traverse records have been made with a cathode-ray voltage as low as 500 volts. The plates are, however, rather expensive and require care in handling during development and drying.

Even greater sensitivity is obtained by eliminating the gelatine almost completely. Plates of this kind have been prepared for the author by Mr. Jackson, of the Admiralty Research Laboratory, by depositing silver iodide on glass. These plates show a remarkably high sensitivity to low-voltage cathode rays, a single traverse at 100 000 cycles per sec. giving a good trace with a cathode-ray exciting voltage as low as 600 volts. The difficulty of handling these plates is not appreciably greater than that experienced with Schumann plates.

An alternative to the Schumann plate is known as the "Schumannized" plate. These are ordinary plates converted by a somewhat delicate operation into Schumann plates by dissolving out the gelatine.* The ordinary plates are immersed for 4 hours in a bath of sulphuric acid (100 cm^3 acid at 66° F. to 1 litre water),† carefully withdrawn, washed in gently running water for 30 minutes, and dried. Such plates contain only a very thin layer of emulsion, uniformly distributed, and are poor in gelatine. Aston‡ found that some of these plates, made from half-tone plates, were even more sensitive than Schumann plates, and gave also a cleaner background and sharper definition. The plates are developed in ordinary hydroquinine developer diluted to half strength, sufficient bromide being added to bring the time of development to about 1 minute. Schumannized plates deteriorate more rapidly than ordinary plates and should be used fresh to get the best results.

High-velocity cathode rays will, as already stated, record well on ordinary plates. It should be quite possible, however, to obtain a further increase of photographic sensitivity, if at any time it is required, by thickening the sensitive layer and increasing the silver-gelatine ratio to absorb and utilize efficiently the whole of the cathode-ray stream.

* See References (9) and (10).

† Aston used battery acid of density 1·225 diluted with an equal volume of water.

‡ See Reference (10).

(c) Use of Phosphorescent Materials to Increase or Facilitate Photography.

The possibility of recording by means of the secondary effect of luminosity produced by the cathode rays falling on a phosphorescent material has always appeared attractive, and a number of observers have used this method. The chief advantage to be gained is, of course, that of external photography. In the earliest days of the Braun tube it was possible to photograph a pattern such as a Lissajous figure in which the cathode beam retraces the same track a large number of times. The cumulative effect of the successive traverses of the luminous spot ultimately produced sufficient effect on a photographic layer (bromide paper or film) placed in close contact with the external glass surface of the phosphorescent screen.

An attempt to make use of this luminous effect *in addition* to the direct photographic effect was made by the author* in 1920. A Schumann plate was prepared with a small proportion of calcium tungstate mixed in the sensitive silver-bromide layer. Calcium tungstate phosphoresces with a light rich in ultra-violet, and Schumann plates are extremely sensitive to ultra-violet light as well as to the direct action of cathode rays. A definite improvement was noticed when very small proportions of calcium tungstate were used. Excess of this phosphorescent material, however, produced a marked *decrease* in sensitiveness. This is explained by the fact that calcium tungstate is a heavy material which easily stops the cathode rays and consequently reduces the direct photographic action.

R. Terroux† has suggested that the indirect luminous effect might be comparable with the direct photographic effect of the rays, thence inferring that an oscillograph with external photographic arrangements would have equal photographic sensitivity to one fitted for internal "direct" photography. Terroux employed in his experiments a simple cold-cathode tube excited from a spark coil. The cathode rays were directed on a quartz window coated on the vacuum side with willemite (zinc ortho-silicate), quartz being used to transmit any ultra-violet light in the phosphorescence. Exposures ranging between 1 sec. and 0·01 sec. were made. The blackening was such that Terroux estimated that an average exposure of 10^{-4} sec. would still have an effect. No comparison was made, however, between the "direct" effect and the "indirect luminous effect" of the cathode rays.

In order to test this important point the author made the experiment, some years ago, of traversing a beam of 4 000-volt cathode rays across a Schumann plate one-half of which was covered with a quartz plate (0·5 mm thick) coated with a thin layer of calcium tungstate, a material which phosphoresces with a light rich in ultra-violet rays and photographically very active. One-half of the plate was therefore exposed to the direct action of the cathode rays and the other half to the luminosity of the phosphorescent screen. The records showed conclusively that the direct effect was many times greater than the luminous effect, the former giving intensely black records whilst the record made by the latter was hardly visible. In comparing this result with Terroux's

* See Reference (1).

† *Ibid.*, (11).

observations it must be remembered, of course, that he used a cold-cathode tube with high-voltage rays, whereas in the above experiment the exciting voltage was relatively low. W. Rogowski,* however, has also compared "direct" and "luminous" effects with a high-voltage oscillograph, his results confirming the author's.

The advantages of external photography by the phosphorescent-screen method in certain circumstances outweigh other considerations. Where the speed of recording is not too great, and the cathode stream is sufficiently intense, good records may be obtained in a single traverse. M. von Ardenne† has recently proved very successful in the design of a tube of this kind. Using a Wehnelt cathode and the focusing arrangements already described, he has succeeded in obtaining small recording "spots" which give good records of audio-frequency phenomena. He uses a camera lens of aperture F/2·5, or F/1·5 if required, to form an image of the phosphorescent transient on a super-sensitive photographic plate. He uses calcium tungstate or willemite as the phosphorescent material for the screen, and anode potentials of 1 000 to 2 000 volts. This tube is a distinct advance on previous forms of cathode-ray tube of similar type. It has many applications in the faithful recording of audio-frequency phenomena and in the recording of transients, provided the frequency is not too high. As a matter of interest, it may be mentioned that the tube worked equally well with either d.c. or a.c. heating of the filament. This is achieved by the simple expedient of looping the filament leads to neutralize the magnetic field due to the filament.

W. Rogowski and E. Ruhlemann‡ have measured the luminous output of the screen of a high-voltage tube. At 55 kV the value found was 35 lumens per watt, using a Buchler zinc-sulphide screen. They consider that other phosphorescent materials are not likely to be better than this.

(*d*) *High-Voltage Oscillographs. "Internal" and "External" Photography.*

(i) *Internal Photography.*—The kinetic energy, and consequently the square of the velocity v of the cathode rays, is directly proportional to the accelerating potential V

i.e. $$\text{Kinetic energy} \propto v^2 \propto V$$

The depth of penetration d of the rays into a photographic layer§ is proportional to v^4,

i.e. $$d \propto v^4 \propto V^2$$

On these grounds it is obvious that one of the most powerful and direct methods of increasing photographic sensitivity is the use of large accelerating voltages. This was appreciated by A. Dufour,‖ who constructed the first effective high-voltage oscillograph. His lead has been followed by numerous Continental and American workers, who have realized its great value in the study of transient phenomena encountered in high-voltage power circuits.

Of course the electrostatic voltage-sensitivity δ of an oscillograph is inversely proportional to the cathode potential, i.e.

$$\delta = \frac{k}{V} \text{ cm per volt}$$

where k is a constant depending on the linear dimensions of the oscillograph,* which implies a small electrostatic sensitivity when V is large.

When high-voltage phenomena are to be recorded, however, this question of voltage sensitivity is of negligible importance. The gain in photographic sensitivity obtained by increasing V outweighs all other considerations. Two high-voltage oscillographs are represented diagrammatically in Figs. 1(*a*) and 1(*b*). Fig. 1(*a*) is a representation of Dufour's oscillograph, using a cold cathode, whilst Fig. 1(*b*) is one due to Rogowski† in which a hot cathode is employed. In both these oscillographs the applied potential is in the neighbourhood of 60 000 volts. A photograph of a 500-volt (and upwards) oscillograph designed by the author is shown in Fig. 1(*c*) for comparison. Modified forms of the high-voltage oscillographs have been used by R. H. George‡ in America and H. Mathias and M. Knoll§ and others on the Continent. All these workers agree that the photographic effect at high generating voltages is so great that almost any speed of recording is possible. Thus W. Rogowski and E. Flegler‖ have obtained

oscillograph records which indicate an average recording speed of 63 000 km per sec., nearly one-quarter the velocity of light. At this enormous recording speed oscillations of frequency 10^8 per second and transients having a duration of the order of 10^{-9} second have been recorded. It will be seen, therefore, that the upper frequency-limit of recording is not likely to be set by the photographic effect, but rather by the finite velocity of the cathode rays. This latter point has been considered in some detail by J. T. MacGregor-Morris and R. Mines,* who have dealt with the theoretical aspect of the problem of high-frequency deflection of cathode rays of known velocity passing between electrostatic deflecting plates of known dimensions. At very high frequencies also it becomes a matter of considerable importance to allow for the inductance and capacitance of the leads

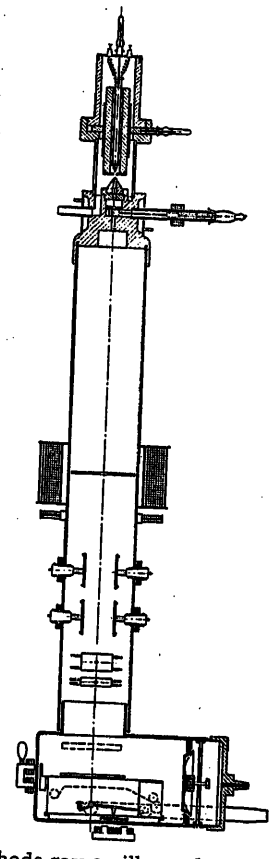

FIG. 1(*b*).—Cathode-ray oscillograph due to W. Rogowski (hot cathode, 60 kV).

and deflecting plates of the oscillograph itself. Great care is required at the highest frequencies to avoid trouble due to resonance in the oscillograph circuit. It is not unlikely that the upper frequency of recording will be set by such considerations.

(ii) *External Photography. Use of Lenard Window.*—In a paper read before the Physical Society of London in 1923† reference was made to an attempt "which is being made to develop a sealed form of cathode-ray oscillograph with external photographic arrangements. For this purpose experiments are in progress with various focusing devices, so as to obtain an intense beam of cathode rays which will give an appreciable photographic effect after passage through a window." It was intended to employ cathode rays of voltage 4 000 to 5 000 and "windows" of aluminium foil (or leaf) or thin mica slips covering a slit. The cathode rays would oscillate along this slit, under the impressed deflecting voltage, and after passage through the window would fall on a photographic film revolving at the desired speed. Subsequent calculation soon showed, however, that such experiments

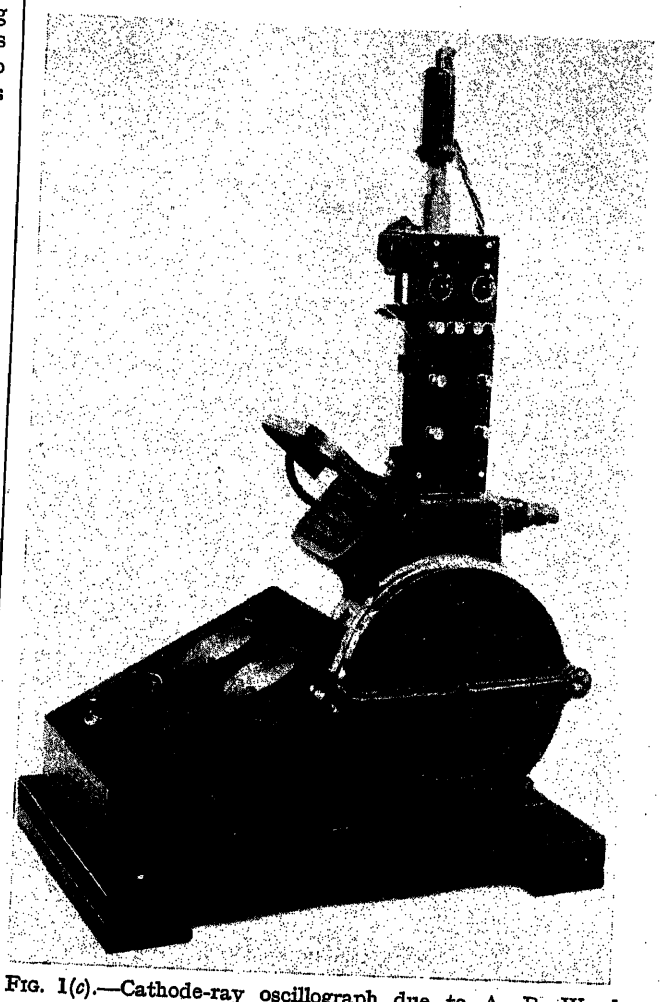

FIG. 1(*c*).—Cathode-ray oscillograph due to A. B. Wood (hot cathode, 1 000 volts).

were likely to fail, for the minimum thickness of a window which would withstand atmospheric pressure applied to the slit would completely stop such low-voltage cathode rays. Of course there still remains the possibility of using extremely thin foil (aluminium leaf $0{\cdot}8 \times 10^{-4}$ cm thick) if the camera side of the foil were evacuated (to 1 or 2 mm pressure) simultaneously with the cathode-ray tube. No opportunity has hitherto been afforded for such an experiment.

If cathode rays of much higher velocity are used, corresponding to 60 kV, for example, the "window" at once becomes a practical possibility. It is profitable at

† *Ibid.*,

this stage to deal with Lenard's observations on the absorption and loss of velocity of cathode rays on passing through varying thicknesses of aluminium.

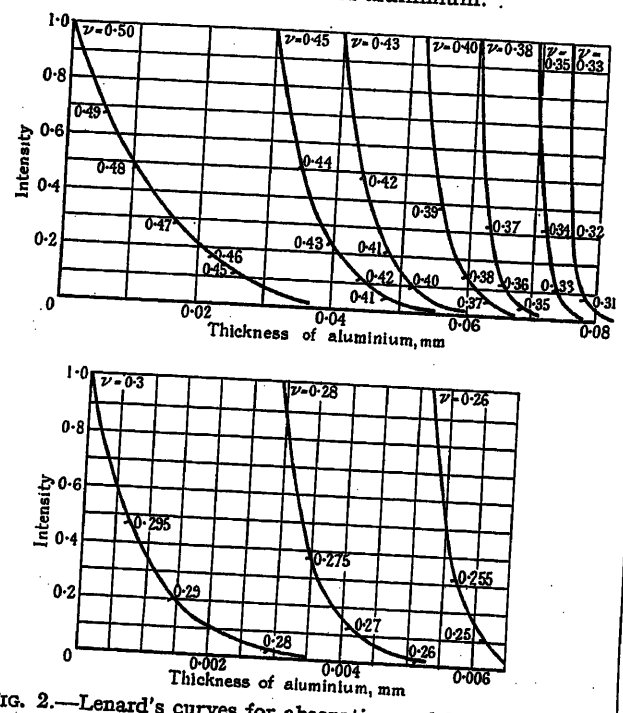

FIG. 2.—Lenard's curves for absorption and loss of velocity of cathode rays in aluminium.

Lenard's absorption curves are represented graphically* in Fig. 2. Each curve commences at the top of the diagram with an arbitrary value of unit intensity. The velocity v is indicated at various points along the curve. When the values of intensity become inconveniently small a fresh curve is started from unit intensity. The range of cathode-ray velocities covered by the curves is 0·25 to 0·50 times the velocity of light

* See Reference (18).

(3 × 10^{10} cm per sec.), corresponding to accelerating potentials in the range 15 to 63 kV approximately. For the sake of convenience in studying Lenard's absorption curves, Fig. 3, showing the relation between cathode-ray velocity and applied voltage, is reproduced.* The

TABLE.

Voltage	Initial velocity × c (c = 3 × 10^{10} cm/sec.)	Thickness of aluminium required to halve intensity	Emergent velocity × c

velocity v, expressed as a ratio in terms of c the velocity of light, is calculated from the relation

$$v = 6\sqrt{V} \times 10^7 \text{ cm per sec.}$$

or

$$\frac{v}{c} = 2\sqrt{V} \times 10^{-3},$$

where $c = 3 \times 10^{10}$ cm per sec.

This relation, of course, only holds over a limited

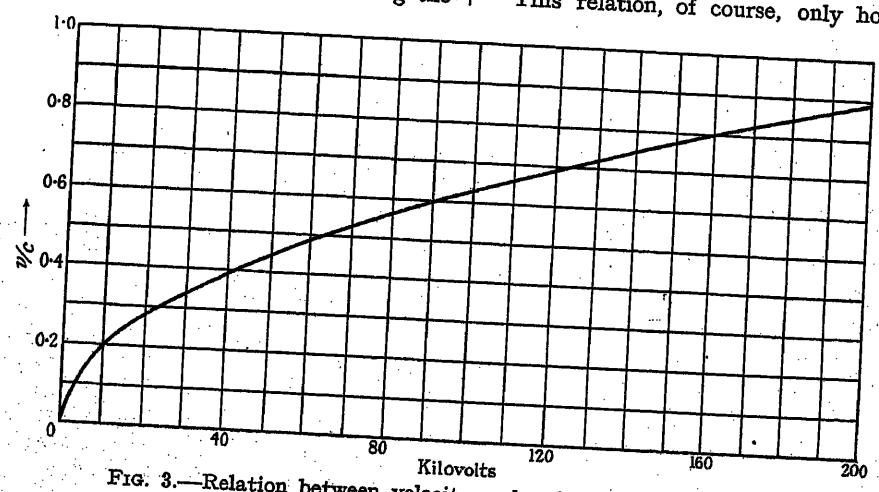

FIG. 3.—Relation between velocity and voltage of cathode rays.

$v = 6\sqrt{V} \times 10^7$ cm/sec.
$= 2\sqrt{V} \times 10{-}3 \times$ velocity of light (c).
i.e. $v/c = 2\sqrt{V} \times 10{-}3$ (approx.).

velocity range, but may be regarded as approximately correct over the range 0 to 0·9c shown in the diagram.

The above table, derived from curves such as those shown in Fig. 2, gives the thickness of aluminium required

* See Reference (19).

to reduce the intensity of the cathode-ray stream to half its initial value. A column is added to indicate the emergent velocity of the cathode rays.

From this table and Lenard's absorption curves it is a relatively simple matter to determine the maximum permissible thickness of aluminium to use for a cathode-ray window when the voltage of the rays is known, or alternatively to calculate the voltage of the rays for a given thickness. Thus, for aluminium leaf of thickness $0{\cdot}5\mu$ ($0{\cdot}5 \times 10^{-3}$ mm) the voltage necessary, if a loss of intensity of 50 per cent is not to be exceeded, is approximately 20 000 volts. It is evident then that low-voltage cathode rays (of the order 5 000 volts) are out of the question as regards external photography through a window* (but see page 48). A glance at the curves and the table reveals, however, that the penetrating power of the rays rapidly increases with voltage. For example, at a voltage of 63 kV the rays can penetrate 10μ (0·01 mm) aluminium with only 50 per cent loss of intensity. It will be noted that the diminution of velocity is quite small in all the cases shown in the table; the energy of the cathode rays which emerge therefore remains practically unchanged. Now aluminium foil of thickness 10μ mounted on a supporting grid of reasonably small mesh is capable of withstanding atmospheric pressure without collapsing and, as we have seen, will transmit 50 per cent of 63-kV cathode rays with almost undiminished velocity. Under such conditions, therefore, " external " should be almost as good as " internal " photography.

The first successful oscillograph to employ external photography through a Lenard window appears to be due to Max Knoll† and his collaborators at the high-voltage laboratories of the Technische-Hochschule, Berlin. A window of aluminium 7 to 10μ thick ($1\mu = 10^{-3}$ mm) or of cellon 16μ thick and 4×6 cm^2 in area was supported on a grid of steel ribbon with a close-knit mesh of phosphor-bronze gauze stretched over it. The meshes of the wire gauze were small compared with the breadth of the lines of the oscillograph record, the area of each mesh being 0·003 mm^2. The mesh of the steel-ribbon grid was about 1 cm^2, the ribbon of course being arranged edgewise so as to cast the minimum amount of shadow on the photographic plate. The exciting voltage used was 75 kV, the current being limited to 1 mA. Such high-voltage rays can, as we have seen from Lenard's curves, penetrate 10μ aluminium foil without appreciable loss of intensity or velocity. Consequently the blackness of the photographic trace is practically as good as that obtainable inside the vacuum. Knoll's oscillograph records obtained through this window show practically the same sharpness of line as high-vacuum photographs. On account of the scattering of the cathode rays the fine-wire gauze does not cast a definite shadow and is consequently imperceptible in the oscillograph record. The steel-ribbon grid, 1 cm square, can be seen as a faint shadow which serves admirably as a co-ordinate system.

Using this method, Knoll has recorded oscillations of frequency 10^8 per sec., the maximum recording speed in this case being 5 000 km per sec. The maximum sensitivity of the oscillograph reached 0·1 mm per volt at an exciting potential of 75 kV. Knoll's work demonstrates the great advantages of using high-voltage cathode rays when voltage sensitivity is unimportant. The use of a Lenard window and external photographic arrangements simplifies and increases the speed of working and eliminates many of the difficulties inherent in high-vacuum photography. It should be mentioned, however, that the " window " method still requires a high-vacuum pump in constant operation, for thin metal and cellon foils are porous to air. Small air-leaks through pores and small holes may, however, be easily kept " in hand " by a good quick-acting vacuum pump. This type of oscillograph possesses obvious advantages also when continuous records are required over long periods. Thus Knoll refers to such an oscillograph working for many hours a day in a lightning observatory on Monte Generoso in Switzerland, during the whole summer of 1929, without a single disturbance of the vacuum. During a long thunderstorm it was possible to record automatically more than 1 000 oscillograms on one single film. In this connection also an interesting reference is made to a cathode-ray oscillograph fitted with a mercury barometer device by means of which films of any length could be drawn continuously from free air through the high vacuum. As Knoll remarks, external photography through a Lenard window is of great importance, for in this way the size, weight, and manufacturing costs of the oscillograph can be considerably decreased and the whole photographic process considerably simplified.

About the same time that Knoll was developing the metal-foil Lenard window oscillograph, C. M. Slack,* in America, used a Lenard tube with a thin glass window 0·005 to 0·01 mm thick and pointed out the possibility of using it as a " Lenard-ray " oscillograph. No supporting grid was used, the glass window being hemispherical to withstand atmospheric pressure. Such a shape of window of course necessitates the use of film or bromide paper fitting closely to the curved surface, otherwise the cathode-ray stream would be scattered by the intervening air.

In view of the fact that aluminium and glass have approximately the same density (aluminium 2·65, crown glass 2·4 to 2·6) they will absorb cathode rays about equally and we may consequently regard Lenard's curves reproduced in Fig. 2 as being approximately applicable to glass also. Hence if the exciting voltage of the cathode ray were raised still further, say to 160 kV instead of 75 kV used by Knoll, the thickness permissible to give 50 per cent transmission would be increased to 0·17 mm. A glass sheet of this thickness and of moderate area would support a considerable pressure. The advantage of glass over aluminium is, of course, its relatively small porosity. With such a window, a completely sealed high-voltage oscillograph should be possible and the continuous use of the vacuum pump eliminated.

The low-voltage hot-cathode oscillograph still remains

* As a matter of interest, however, it is worth noting that extremely thin metal films capable of withstanding considerable pressures are obtainable. Thus, Carl Müller (*Sitzungberichte der Preussischen Akademie der Wissenschaften zu Berlin*, 1925, vol. 25, p. 464; also *Engineering*, 1926, vol. 121, p. 199) has prepared films of metal (gold, silver, platinum, nickel, and iron) of thickness $0{\cdot}04\mu$ (4×10^{-6} cm) of diameter 6 cm, and $0{\cdot}01\mu$ of smaller diameter. Such nickel films have been mounted (over wire gauze) as windows in discharge tubes and have resisted gas pressures equivalent to 25 cm of mercury. For comparison it may be stated that ordinary gold leaf has a thickness of $0{\cdot}08\mu$, and aluminium leaf $0{\cdot}5\mu$ approximately.

† See Reference (20).

* See Reference (21).

pre-eminent, however, where voltage-sensitivity is important. The problem of the Lenard window for this oscillograph is a difficult one, but it seems not impossible that some means will be found of dealing with it successfully. A number of avenues require exploration. For example, it may be possible to accelerate the cathode rays *after electrostatic deflection*, by the use of a high potential applied in the region between the deflecting plates and the photographic plate. It should be possible also to use windows of very thin leaf by employing a forevacuum on the camera side of the Lenard window. With such an arrangement (aluminium leaf $0{\cdot}8\mu$ thick) the pressure difference acting on the window need never exceed a few millimetres of mercury, and the percentage transmission of the cathode rays would not be excessively low (see also pages 46 and 47).

(3) The Technique of Recording by Cathode Rays.

When a cathode-ray oscillograph is employed to record rapid fluctuations in the voltage or current in a circuit, certain operations are necessary to ensure a satisfactory result. It is first of all necessary to provide a suitable time scale and means for deflecting the cathode stream in a known manner. If the electrical phenomenon to be recorded is of an impulsive or non-periodic character it may be necessary to provide an accurate timing device to ensure that the electrical impulse occurs when the cathode-ray spot is at a suitable point of its travel on the photographic plate. Another difficulty which may arise is that of recording a high-speed high-voltage effect, which renders it necessary to utilize a suitable potential-divider in the recording circuit without distorting the wave-form. During the past five or six years various ingenious methods have been introduced to deal with such operations. The impossibility of providing a universal treatment to meet all cases will be appreciated, but the large majority of oscillograms may be obtained by methods which are now fairly generally recognized. It is the purpose of this section of the paper to refer briefly to some of the more important of these methods.

(*A*) *Generation of a Time Axis.*

The time scale of an oscillogram may be derived either by the use of an auxiliary time-marking device, by driving the film, or by traversing the cathode "spot" over the photographic plate or film in a known manner. As the last two methods are in general use and appear to be the most important we shall deal with these cases only. Mechanical, electrostatic, and electromagnetic methods or combinations of these are available.

(*a*) *Mechanical Methods.*

These methods are in daily use with all forms of oscillograph and are sufficiently well known without further description here. Various authorities differ as to the limit of film speed attainable, but a linear speed of 50 or 100 metres per second may be provisionally assumed to be a safe working maximum for general purposes.

(*b*) *Electromagnetic and Electrostatic Methods.*

(i) *Sinusoidal Time-base.*—One of the simplest methods, and perhaps the earliest, is to deflect the cathode stream by means of alternating current of known frequency and good wave-form applied either to an electromagnet or to a pair of electrostatic deflecting plates, thus producing a sinusoidal oscillation of the cathode rays. This method, whilst possessing the advantage of simplicity in recording isolated electrical impulses, is obviously unsuitable for recording wave-forms of alternating currents. Even in the case of impulse recording, the resultant record requires careful analysis to transpose the sinusoidal time-deflection into a linear one. It was used by A. Dufour* to record damped oscillations in spark circuits, later by D. A. Keys† to record piezo-electric impulses, and by R. A. Watson Watt‡ to record outlines of atmospherics. Dufour generally combined this method with the mechanical method [(*a*) above]. The effect to be recorded was arranged to deflect the rays along the direction of the mechanical drive and at right angles to the axis of sinusoidal deflection.

(ii) *Linear Time-base.*—The advantages to be obtained by using a linear instead of a sinusoidal time base are self-evident. A number of very reliable methods have been devised to give a time base approximately linear. In some of these methods the cathode-ray spot is arranged to flash across the plate or screen once only at a uniform rate, whilst in others this linear deflection is repeated at regular intervals. The former method is applicable more particularly to oscillographs which are capable of recording a single traverse. The latter method is applicable to any form of oscillograph and is particularly valuable when (*a*) an electrical impulse is to be recorded and the exact instant of arrival is not known, and (*b*) a repetition phenomenon is to be observed.

(ii)$_1$ *Single Traverse.*

We shall consider first a number of methods of obtaining a single traverse of the spot at a uniform speed.

Inductance method.—If a voltage E is suddenly applied to a circuit of inductance L and resistance R [see Fig. 4(*a*)] the current i at any instant t is given by

$$i = \frac{E}{R}\left(1-e^{-\frac{R}{L}t}\right)$$

$$= \frac{E}{R}\left\{\frac{R}{L}t - \frac{R^2}{2L^2}t^2 + \text{terms containing higher powers of } t\right\}$$

Provided t is always small compared with L/R we may write

$$i = \frac{E}{L}t$$

that is, in the early stages of rise of current in the circuit the current i is a linear function of the time t. In the actual application of this method it is advantageous to use an auxiliary winding to the deflecting electromagnet (which may be an iron-core or an air-core solenoid), this winding carrying a steady current to deflect the spot off the left-hand edge of the plate. On

* See Reference (12). † *Ibid.*, (22). ‡ *Ibid.*, (23).

closing the circuit of the main deflecting magnet the spot is swept across the plate at a uniform speed to the opposite side. The maximum speed will of course be limited ultimately by the inductance of the deflecting magnet itself. At very high speeds an air-core magnet must therefore be used.

An alternative arrangement [see Fig. 4(*b*)] connects the electrostatic deflecting plates across the inductance L which in this case has a resistance negligible compared

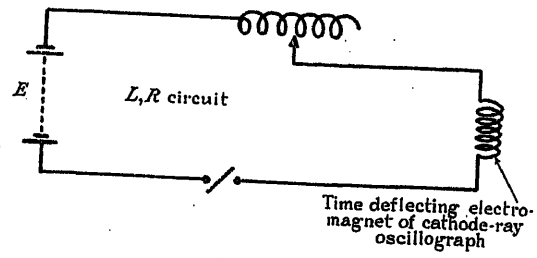

FIG. 4(*a*).

with that of the remainder of the circuit. The instantaneous voltage across the inductance L is now given by

$$v_L = Ee^{-(R/L)t} = E\left(1 - \frac{R}{L}t + \frac{R^2}{2L^2}t^2 - \text{etc.}\right)$$

or, in the case when t is small compared with L/R,

$$v_L = E\left(1 - \frac{R}{L}t\right)$$

which represents a linear fall of voltage with time across the inductance, and consequently across the deflecting plates of the oscillograph.

A transformer may in some cases provide a convenient means of continuously varying the inductance in the

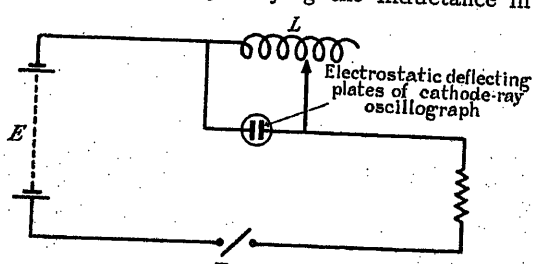

FIG. 4(*b*).

" time " circuit [see, for example, Fig. 4(*c*)]. The transformer primary P in series with the deflecting electromagnet has an effective inductance L' depending on the load on the secondary circuit

$$L' = L_0 - M\frac{i_2}{i_1}$$

(assuming perfect coupling). If, therefore, a variable resistance be connected across the secondary circuit S of small inductance, the load and hence the effective inductance of the primary may be varied over a wide range. With a short-circuited secondary the primary self-inductance is almost neutralized and the primary current rises rapidly, whilst with an open secondary the primary current is choked down by the large effective primary self-inductance.

Condenser Method.—A convenient method of producing a linear deflection with time employs a condenser of capacitance C which may be charged or discharged through a resistance R [see Fig. 4(*d*)]. In the case of a charging current, the voltage v_c across the condenser at any instant t after closing the circuit is given by

$$v_c = E(1 - e^{-t/CR})$$

which, in the case of small values of t compared with CR, reduces to

$$v_c = \frac{E}{CR}t$$

In this case also we see that the voltage across the electrostatic deflecting plates of the oscillograph increases

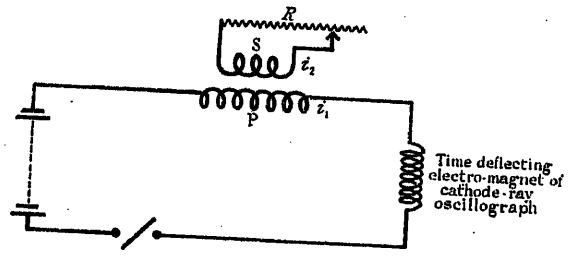

FIG. 4(*c*).

linearly with time, provided the assumed conditions are fulfilled.

At very high speeds of traverse the inductance method is not so good as the capacitance method. If iron-cored magnets are used the rate of current-rise is limited by lag in the iron, and if open air-solenoids are used there is risk of distortion due to stray fields. The condenser method is free from these disadvantages and is consequently generally used in high-speed recording.

The single-traverse method, using either inductance or capacitance, is very convenient in recording alternating-current wave-forms or single impulses. In the

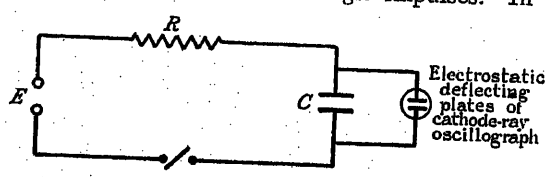

FIG. 4(*d*).

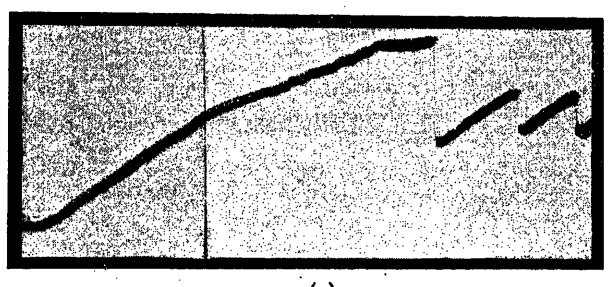
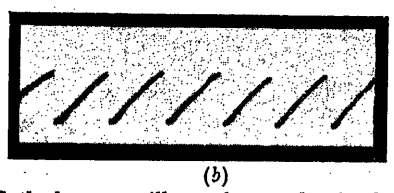


former case recording is relatively simple, a hand-operated switch being sufficient to traverse the oscillating spot across the plate. Methods of recording single impulses are considered later (see page 54).

$(ii)_2$ *Repeated Traverse.*



In many cases it is advantageous to repeat the linear time-traverse indefinitely. This can be achieved in a number of ways, of which the following are now best known.

Rotating Potentiometer.—This device can be used, like the inductance in $(ii)_1$ above, as a means of producing a linear current variation in the deflecting electromagnet or a linear voltage variation across the electrostatic deflecting plates. In its simplest form the rotating potentiometer consists of a motor-driven rheostat (a single turn of

high-resistance wire mounted on the edge of a disc) which gives a linear variation of resistance with time between the limits R and zero. A discontinuity occurs when the brushes on the rheostat reach the end of the wire, the resistance rising from zero to R linearly and suddenly dropping from R to zero. The cathode-ray spot consequently crosses the plate or screen at a uniform speed from left to right, when it suddenly jumps back to its zero position and the cycle of operations is repeated. The frequency of repetition is of course determined by the speed of revolution of the disc. When the potentiometer is used as a current-varying device in the electromagnet deflecting circuit it is important that the brush resistance should always be small, otherwise the current will vary erratically and the time deflection of the spot will be non-linear. Such a trouble is not likely to arise in the case of electrostatic deflection. In this case, however, there is a limited range of practicable voltage

(*a*)

(*b*)

FIG. 5.—Cathode-ray oscillograph records of voltage fluctuations in neon-lamp flashing circuit.

(*a*) Commencement of flashing.
(*b*) Steady oscillation.

variation consistent with sufficient mechanical strength and electrical resistance in the potentiometer wire.

The rotating-potentiometer method is limited to low speeds of traverse since it becomes impracticable, or at any rate very difficult, to obtain satisfactory working at high speeds. For recording low-frequency phenomena, however, it serves a very useful purpose.

The inductance and capacitance deflecting circuits shown in Fig. 4 may of course be used to give repeated linear traverses if the key shown in the diagram is replaced by a revolving commutator and brushes. The duration of make and break on the commutator will depend, of course, on the particular circumstances in which it is to be used.

Neon-Lamp Method.—The peculiar property of a neon lamp by virtue of which it requires a higher voltage to initiate than to maintain its luminosity has been utilized by a number of workers to produce an intermittent action of controllable frequency. This effect was first observed by H. St. G. Anson and S. O. Pearson,* using a condenser of capacitance C in series with a resistance R and a voltage E, the lamp being connected in parallel with the condenser. On making the circuit, the condenser begins to acquire a charge and the voltage v_c across its terminals will rise according to the law

$$v_c = E(1 - e^{-t/CR})$$

The lamp will flash as soon as the voltage across the condenser reaches the upper critical striking voltage. When this occurs the condenser becomes shunted by a fairly low resistance, the lamp, and consequently loses its charge. The lamp continues to glow until the condenser voltage v_c falls to the lower critical voltage at which current through the lamp ceases. The process is then repeated indefinitely. The time of a complete cycle is directly proportional to the capacitance in parallel and the resistance in series with the lamp. The periodic time is also affected by the applied voltage E. This device provides a very simple means of producing intermittent currents over a wide range of frequency. Cathode-ray oscillograph records of the voltage fluctuations across the condenser in such a circuit are shown in Fig. 5. The records show clearly the exponential rise

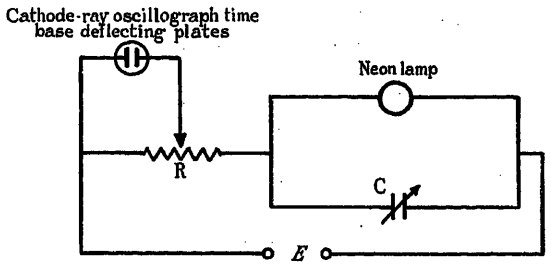


FIG. 6.—Neon-tube circuit for repeated linear time base.

of voltage as the condenser charges and the sudden fall as the lamp flashes. It will be seen that the voltage variation with time over the range lying between the two critical voltages of the lamp is approximately linear (actually, of course, the line forms a small part of an exponential curve).

N. V. Kipping* has made use of this property of the neon-lamp flashing circuit to give a repeated linear (or almost linear) deflection of the cathode rays in a low-voltage oscillograph. The circuit is shown in Fig. 6. The "time base" deflecting plates are connected as shown across a part of the series resistance R which limits the rate of charging of the condenser C. The frequency of repetition is controlled by varying R and C. With this arrangement Kipping was able to demonstrate the formation of a stationary pattern when the flashing frequency was synchronized with the wave-form under investigation. The method is advantageous when using an oscillograph in which it is not possible to photograph a single traverse of the cathode-ray "spot." It is useful also for the visual examination of single impulses or phenomena which occur at irregular intervals.

G. I. Finch, R. W. Sutton, and A. E. Tooke† have recently devised a modification of the neon-lamp time circuit by means of which cathode-ray oscillograph traces due to recurring electrical and magnetic phenomena

* See Reference (24).

* See Reference (25). † *Ibid.*, (26).

can be accurately superposed, even though the train-frequency be subject to wide and irregular fluctuations. The underlying principle of this time base lies in the use of a glowing neon lamp which is extinguished by energy furnished either directly or indirectly by the phenomenon under investigation. The circuit was developed primarily with a view to the study of ignition-coil phenomena, consisting of trains of damped oscillations recurring at somewhat irregular intervals. In spite of the irregularities in the contact breaker, the non-uniform cam surfaces and the variable speed of the cam drive, the oscillograms, each consisting of several thousand superposed traces, indicate that a remarkably good synchronization has been obtained.

The "Ticking-grid" Method.—A novel form of repeating the linear time-axis for cathode-ray oscillographs has been described by E. V. Appleton, R. A. Watson Watt, and J. F. Herd.* This involves a special triode oscillator the potential changes of which, applied to the deflecting plates, cause the cathode-ray spot to move uniformly from left to right over a suitable range in a definite and

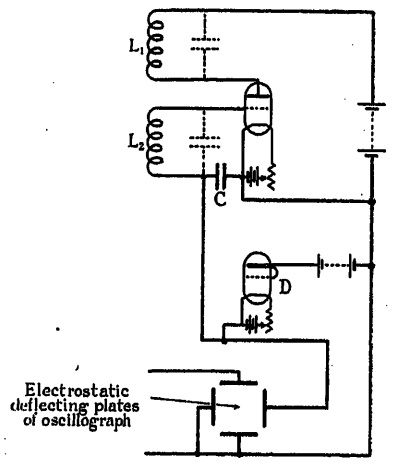

FIG. 7.—Linear time-base oscillator.

controllable time, returning to zero almost instantaneously. The circuit for supplying these voltages and applying them to the cathode-ray oscillograph is shown in Fig. 7. Oscillations of about 1 million per second are generated in the triode circuit which contains the coupled inductances L_1 and L_2 (flat spiral coils having sufficient self-capacitance to complete the oscillatory circuit). In the grid circuit of this oscillator a condenser C is connected in parallel with a diode D. With suitable adjustments, such an oscillator will generate very brief trains of oscillations with uniform periods of quiescence. During the short oscillatory period the grid side of the condenser C is rapidly charged negatively, so that the cathode-ray spot is caused to travel practically instantaneously from right to left, the negative grid potential reducing the anode current to a value at which oscillations can no longer be maintained. At this stage the condenser commences to discharge at a uniform rate through the saturated diode in a time determined by the constants of the diode and the capacitance of the condenser C. This causes the cathode-ray spot to travel uniformly from left to right during the quiescent period of the oscillator. The rise of grid potential then raises the anode current to a critical value sufficient to restart oscillation, when the whole process is repeated. To make the right-to-left journey of the spot very rapid, the natural frequency of the oscillator is kept high and the capacitance of the condenser C as low as possible (e.g. less than $0{\cdot}01\mu F$). The control of the rate of discharge of the condenser is most conveniently effected by means of the filament current of the diode. It is advisable, however, to run the valve filaments as brightly as possible to obtain the best conditions for linearity of the left-to-right deflection. Calibration of the time base may be effected by application of a sinusoidal oscillation of known frequency to the "vertical" deflecting plates of the oscillograph. If this a.c. frequency is 5 to 10 times the frequency of the time base, a check on the linearity of the deflection may be readily obtained.

This type of repeating linear time-base has been used by R. A. Watson Watt and his collaborators as a powerful means of studying the wave-form of atmospherics.

$(ii)_3$ *Circular or Elliptical Time Axis. Harmonic Comparison of Frequencies.*

The cathode-ray oscillograph provides a very convenient means of frequency comparison for high-frequency electrical oscillations. N. V. Kipping* and D. W. Dye† have both described such methods, and the latter has also applied them to the production of an approximately linear time-base for recording periodic phenomena.

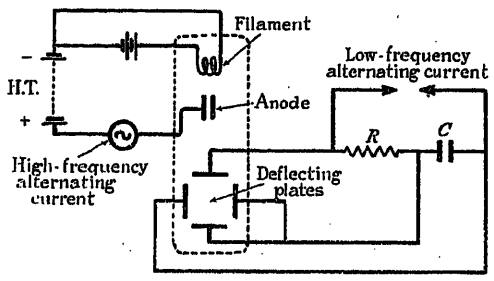

FIG. 8.—Low-frequency circular time trace with high frequency superposed on anode potential to give radial oscillation.

The simplest method of frequency comparison consists in forming a Lissajous figure by applying an alternating e.m.f. of known variable frequency to one pair of deflecting plates and the e.m.f. of unknown frequency to the other pair at right angles. When the ratio of these frequencies is a whole number the spot describes a Lissajous figure. If the ratio is an exact integer the figure is stationary, but if the ratio departs slightly from a whole number the figure appears to change slowly, repeating its original form at a frequency corresponding to the number of cycles per second departure from the exact whole-number ratio. The method can be applied conveniently up to a ratio of 10 : 1 in frequency; but much beyond this ratio the exact setting is somewhat troublesome. The method may be applied, however, to determine a high frequency (e.g. 10^6 cycles per sec.) in

* See Reference (27).

* See Reference (25).

† *Ibid.*, (28).

terms of an accurately known low frequency (10^3 cycles per sec.—a tuning-fork) in steps of, say, 10 : 1.

The alternative method, devised independently by Kipping and Dye, allows the direct comparison of greater frequency ratios than are possible by the Lissajous-figure method. The method consists in producing a circular or elliptical time-trace, of known frequency, on which the oscillations to be investigated are superposed. Kipping obtains the circular trace by the phase-splitting method indicated in Fig. 8, in which the resistance R is made equal to $1/(\omega C)$. In this way two equal deflections in quadrature produce the circular trace. The high-frequency oscillation is now superposed on the anode potential. This results in a small oscillation in the

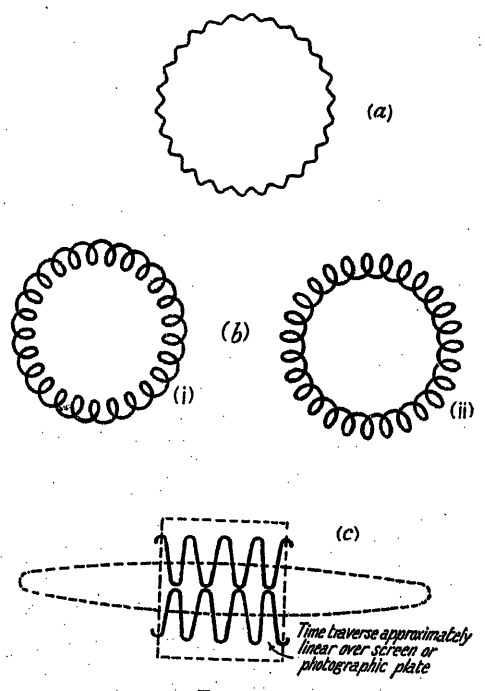

FIG. 9.

(*c*) Linear oscillations superposed on long elliptical time-base.

velocity of the cathode rays and a consequent oscillation in the sensitivity of the oscillograph. The diameter of the circular trace therefore varies with the total instantaneous anode potential, the alternating voltage thus producing a radial displacement. If the frequency of the alternations applied to the anode circuit is any whole multiple N of the circle frequency, then the circle will have N waves on its circumference [see Fig. 9(*a*)]. A disadvantage of this method of superposition is that a rather high voltage at the upper frequency is required to produce a sufficient radial deflection.

Dye has used this method also, employing a tuning-fork of standard frequency (1 000 cycles per sec.) provided with an amplifier and "smoother" as a source of alternating current for the circular time-base. He describes also two other methods in which the high-frequency oscillation is superposed on the circular (or elliptical) time-base (*a*) as a small circular movement and (*b*) as a vibratory movement in a fixed direction. With regard to (*a*), the appearance is that of a circular looped pattern, the number of loops being $(N \pm 1)$, where N is the ratio (a whole number) of the superposed frequency to that of the circle. The plus and minus signs arise on account of the simultaneous rotation of the circular time-base and the high-frequency oscillation in the opposite or the same direction [see Fig. 9(*b*)].

This method is, however, unsuitable for the examination of wave-forms. For this purpose method (*b*) is preferable. The high-frequency motion now takes place along a straight line of fixed direction, whilst the low-frequency time-base remains as before. Instead of using a circular time-base, however, the spot is now arranged to follow an elliptical path of large eccentricity. This is achieved by reducing the potential applied to one pair of plates and increasing the potential of the component in quadrature. The time base is now a long, narrow ellipse with the high-frequency displacement at right angles to the major axis [see Fig. 9(*c*)]. By this means a considerable portion of the "time-ellipse" is now described with almost uniform velocity, thus providing an almost linear time-base. The wave-form of a superposed high-frequency oscillation is delineated in this region without appreciable distortion. These three methods developed by Dye are very convenient for the study of the frequency and wave-form of high-frequency oscillations by means of a simple visual-type oscillograph (e.g. the Western Electric 300-volt oscillograph). When the stationary figure has been obtained it is possible to obtain a record directly on bromide paper by placing it in close contact with the phosphorescent screen for a few seconds.

(*B*) *Potential Dividers.*

When the voltage applied to the electrostatic deflecting plates of the oscillograph becomes so high that the maximum possible deflection is attained, it is necessary either (*a*) to reduce the sensitivity of the oscillograph by increasing the distance apart of the plates and/or reducing their length, or (*b*) to provide some means of reducing in a known ratio the potential applied to the deflecting plates of the oscillograph.

With regard to the second method, it is important to ensure that this potential-division is not accompanied by distortion of wave-form. This implies that the distribution of current and voltage is not appreciably disturbed by the introduction of the potential divider, as might occur by the introduction of appreciable resistances or capacitances in a resonant circuit. At very high frequencies or in the case of impulses of very short duration, such a condition is not always easy to fulfil. It is clearly impossible to deal even briefly with all the cases which may arise, but it may be of some value to refer to one or two specific cases of general interest. The question of potential-dividers for cathode-ray oscillographs has been dealt with in some detail by W. Rogowski, O. Wolff, and H. Klemperer.* They refer to cases where potentials of the order of 10 to 30 kV have been applied *directly* to the deflecting plates of a high-voltage oscillograph (the exciting potential

* See Reference (29).

being of the order of 60 or 70 kV). In general, however, they regard 5 kV as an average upper safe limit of voltage to apply to the deflecting plates of such an oscillograph. High voltages require exceptionally good vacuum conditions and large clearances between the leads to the deflecting plates and the body of the oscillograph, otherwise a discharge is likely to occur across the internal insulation.

Potential division is most conveniently carried out by means of resistances or condensers or combinations of both.

(*a*) *Capacitance Potential Dividers.*

A simple arrangement which is often used is indicated in Fig. 10(*a*). Two condensers, C_1 and C_2, are connected

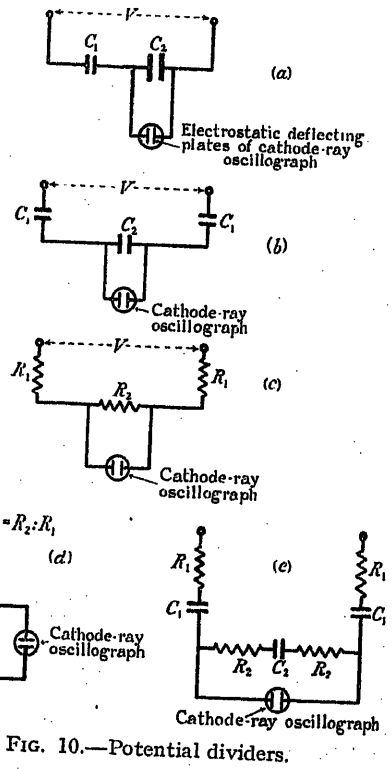

FIG. 10.—Potential dividers.

in series across the points in the main circuit where the potential fluctuation is to be recorded. As mentioned above, these condensers must be chosen so as to interfere as little as possible with the distribution of voltage and current in the main circuit. If V is the instantaneous potential applied to the divider and v that across the condenser of capacitance C_2, and consequently across the oscillograph deflecting plates, then

$$\frac{v}{V} = \frac{C_1}{C_1 + C_2}$$

or, in the case where C_2 is large compared with C_1,

$$v/V = C_1/C_2.$$

It is preferable in all cases that the total capacitances C_1 and C_2 should be kept as small as possible. The capacitance C of the oscillograph deflecting plates and leads can often be neglected, but in cases where C_1 and C_2 are very small, e.g. when recording very high-frequency oscillations or impulses of short duration, due allowance must be made for the small capacitance C (usually of the order of a few centimetres only) in parallel with C_2. Although the circuit shown in Fig. 10(*a*) serves the purpose at relatively low frequencies it is preferable to divide the condenser C_1 into two equal parts so as to render the arrangement symmetrical as shown in Fig. 10(*b*). The relations connecting the voltage-ratio and the capacitances then become (neglecting the capacitance of the oscillograph)

$$\frac{v}{V} = \frac{C_1}{C_1 + 2C_2}.$$

or, when C_2 is large compared with C_1,

$$v/V = C_1/(2C_2)$$

At very high frequencies it is, of course, equally important to make allowance for capacitance to earth—particularly in the case of oscillographs in which the deflecting plates are surrounded by an earthed metal enclosure.

It should be noted, however, that the above considerations would require modification in the case of "gas-filled" oscillographs of the Western Electric and von Ardenne types. A correction is then required for the effective internal resistance of the oscillograph. The simple potentiometer formulæ are only applicable to high-vacuum oscillographs.

With the arrangement shown in Fig. 10(*b*), in which C_1 and C_2 are both 50 cm, W. Rogowski has obtained with a high-voltage oscillograph correct potential-division and exact reproduction of wave-form for complex impulses (including square-topped waves) of duration 10^{-6} sec.

The oscillograph may, of course, be used equally well for recording the *current* fluctuations in a circuit if the deflecting plates are connected directly or via the potential divider across a known non-reactive resistance in series with the main circuit. The permissible values of this resistance will of course depend on the particular conditions obtaining in the main circuit.

(*b*) *Resistance and Combined Resistance-Capacitance Potential Dividers.*

The condenser type of potential divider is particularly suitable when the phenomena to be recorded are of very short duration. For slowly-varying effects the method is not so useful, the leakage of the condensers beginning to be noticeable. An alternative is that of the simple high-resistance potential divider shown in Fig. 10(*c*), in which

$$\frac{v}{V} = \frac{R_2}{2R_1 + R_2}$$

the resistances being, of course, non-reactive. The resistance potentiometer must be used with caution, otherwise it is liable to produce serious distortion of wave-form. For example, the resistance method would be quite unsuited to the case of recording variations in a small electrostatic charge such as that produced by pressure in a piezo-electric crystal of small capacitance.

Rogowski has also experimented with various combinations of resistance and capacitance potential divider such as those shown in Figs. 10(*d*) and 10(*e*) as a means of subdividing voltage conditions intermediate between those of (*a*) and (*b*). He shows that potential dividers of the resistance and resistance-capacitance types are not suitable for dealing with phenomena of very short duration, in consequence of the capacitance of the deflecting plates of the oscillograph. For such purposes only the capacitance type of potential divider can be used with safety.

(*C*) *Timing of Single Impulses.*

The recording of an alternating voltage by means of a cathode-ray oscillograph is a relatively simple matter. The spot is set in oscillation, under the action of one pair of deflecting plates, before the traverse occurs, and it continues to oscillate both during and after the traverse of the spot across the plate. In the case of a single impulse, however, it is necessary (*a*) to traverse the spot at such a speed that the resultant record shows sufficient detail, and (*b*) to arrange that the complete electrical impulse occurs whilst the spot is on the photographic plate. The simultaneous achievement of these two conditions often requires considerable ingenuity and technical skill.

Take, for example, a relatively simple case of an impulse lasting 0·001 sec., a recording speed of 20 or 30 metres per sec., and a plate length of about 5 cm. Using the single-traverse inductance method described on page 8, we require to arrange that the impulse deflection commences about 1 cm from the left-hand edge of the plate, the spot being deflected initially to a point off the left-hand edge of the plate by means of an auxiliary winding on the electromagnet. A time-delay mechanism is necessary and for this purpose a double-switch is convenient. This switch, which may be operated electrically or mechanically, is arranged to close first the deflecting circuit (through the electromagnet or the condenser) and at a definite instant later to initiate the electrical impulse. In the particular case we are considering the time interval will be of the order of 0·001 sec. A simple arrangement* consists of a pivoted gravity-arm carrying a pair of contact rods of adjustable length, which fall into mercury cups. The arm is prevented from rebounding after the contacts enter the mercury by means of a spring clip. Assuming the velocity of entry of the contact rods into the mercury to be about 2 metres per sec., then 2 mm difference of setting in the contacts corresponds to a time interval of 0·001 sec. This simple arrangement has given good results in recording impulses of total duration of the order of 0·0001 sec., e.g. the damped oscillation of a condenser discharging through an inductive resistance at a frequency of 20 000.

The same principle is, of course, applicable to much higher speeds of recording. The gravity control of the contacts must in such cases be replaced by a strong spring, and the weight of the arm carrying the contacts must be reduced as much as possible. The contact arm in this case may be operated electromagnetically. The delay between the commencement of the traverse of the spot and the instant of application of the impulse to be recorded is in this case conveniently adjusted either by varying the contact-gaps by a fine screw or by varying the tension in the control spring.

An alternative to this arrangement employs a revolving commutator with two pairs of adjustable brushes to give the required time-interval. This device can be used at very high speeds, but it is then liable to give trouble due to uncertain contact between brush and commutator.

Since the advent of the Dufour high-voltage oscillograph, a considerable amount of attention has been paid by high-voltage electrical engineers to the study of the effects of lightning and of surges due to switching in high-voltage lines. In the latter case the "timing" of the record can be brought under control by a suitable arrangement of automatic switches. For example, K. B. McEachron* describes a study of the time-lags in spark-gaps by means of the Dufour oscillograph. The time-base of the record was that used by Dufour† in

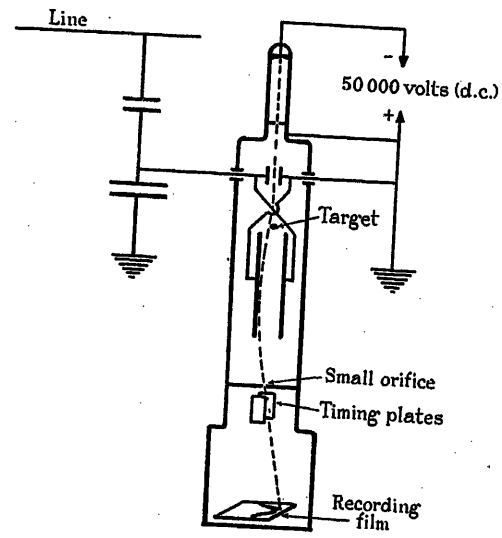

FIG. 11.—Norinder relay-oscillograph.

which a relatively low-frequency oscillation is impressed on the cathode rays in a direction at right angles to the direction of rotation of the recording drum (supporting the film). The high-voltage impulse was then arranged to deflect the rays at right angles to the low-frequency deflection, the timing of the impulse being carried out by means of an automatic switch in a manner somewhat similar to that described above. K. Berger‡ has studied by such methods the surges arising from short-circuits, earth faults, and switching operations in high-voltage lines. By means of the oscillograph he followed the progress of a surge through a transformer winding. As a result of such observations he was able to point out the dangers of using certain forms of choking coils for protection against surges.

The recording of lightning effects is a much more difficult matter, on account of the uncertainty in the time of arrival of the impulse. The timing in this case must necessarily be automatic, the lightning impulse itself initiating the time deflection of the cathode-ray

* Devised by Mr. E. H. Lakey, B.Sc. Associate Member.

* See Reference (30). † *Ibid.*, (12). ‡ *Ibid.*, (31).

"spot." An ingenious arrangement for such a purpose has been devised by H. Norinder.* The arrangement employs a beam of cathode rays to perform the dual function of relay and oscillograph (see Fig. 11). The cathode stream is initially stopped by a small target. When a lightning surge arrives a proportionate deflecting potential is applied to the upper pair of deflecting plates and the beam moves off the target. Below the target the beam is bent back again by the same potential reversed by a second pair of deflecting plates. By suitable adjustment of the dimensions and spacing of these two pairs of deflecting plates the beam is caused to pass through a small orifice *whatever the value of the applied potential.* This orifice may therefore be regarded as the "pivoting point" of the cathode stream. A third pair of deflecting plates mounted below serve to provide the necessary "time-deflection." It will be seen that the cathode rays fall on the plate only during the passage of the impulse. The relay function is performed by the oscillograph itself, and a complete record is made of any transient whenever it may occur. This device has been used extensively in the study of lightning and spark discharges and of surge waves. It is suitable for the registration of random potential and current variations of whatever nature.

W. Rogowski, O. Wolff, and H. Schäffer† have also devised relay systems by means of which the passage of the surge wave is made to expose the photographic film. By a suitable choice of circuit constants the delay in putting the oscillograph into operation could be reduced to an interval of the order of 3×10^{-9} sec., during which time the surge has travelled only 1 metre.

In conclusion the author desires to express his indebtedness to the Admiralty for permission to publish this paper.

ACCURACY OF MEASUREMENTS MADE WITH HOT-FILAMENT CATHODE-RAY TUBES OF THE GAS-FOCUSED TYPE.

By Professor J. T. MacGregor-Morris, Member, and H. Wright, B.Sc.(Eng.), Graduate.

(*Paper first received 8th April, 1931, and in final form 6th January, 1932; read before the* Meter and Instrument Section *5th February, 1932.*)

Summary.

The rapid development of the hot-filament type of cathode-ray tube is outlined, and various sources of error which are encountered in its use as a measuring instrument are discussed, including errors inherent to the tube, especially those due to the effect of gas conduction, then errors of manipulation and those due to external influences are reviewed.

Recording is next dealt with, including photographic methods, and various methods of calibrating are considered. The chief part of the paper, however, deals with what is known as the "threshold effect," a quantitative examination of which is given, together with graphs showing its relation to the various variables, such as frequency and the effect of resistance in series with the deflecting plates.

Suggestions are put forward as to the cause of the threshold effect, and the paper concludes with recommendations for accurate working.

In an Appendix particulars relating to the latest pattern of low-voltage tube are given, and its sensitivity is discussed.

Table of Contents.

Introduction.

General Errors inherent to Tube.

Non-parallel plates; screen curvature; effect of gas conduction.

Errors of Manipulation.

Resistance in anode circuit; "threshold effect"; non-central zero spot; use of external deflecting plates; non-uniform field of deflecting coils.

External Influences.

Stray magnetic fields, including fields for centralizing spot; magnetic field from instruments; stray electrostatic fields.

Recording.

Tracing, gaslight paper and film, plaster-cast; typical data for camera; efficiency of methods.

Calibration.

General remarks; use of direct current, alternating-current, and both combined; simultaneous calibration and recording (Wilmotte's method).

Threshold Effect.

Introductory.

Prefatory remarks.

Method of experimenting.

Experimental evidence of existence of the "threshold effect."

Sensitivity: Equation connecting voltage and deflection.

Cause of the threshold effect.

Effect of frequency on the threshold effect.

Effect of resistance in series with deflecting plates.

General characteristics of the tube which have a bearing on the threshold effect.

Recommendations for accurate working.

Conclusion.

Appendix.—Particulars relating to later pattern of tube. Typical voltage/deflection graphs. Sensitivity.

Introduction.

The rapid development of the hot-cathode tube as an instrument for measuring electrical quantities is an interesting example of the assistance that pure physics is constantly giving to electrical engineering, and also of the fact that, unless the principles underlying the operation of the apparatus are clearly understood, erroneous conclusions may be drawn from the records obtained.

The Wehnelt cathode invented in 1905 was soon introduced into English and German types of cathode-ray tubes, and later was incorporated in the Western Electric type. Recently, it has been embodied in the von Ardenne tube (introduced in 1929) which, though quicker in recording, requires an intermediate third voltage of between 100 and 300 volts.

On account of the rapidly extending use of such tubes it appeared desirable to collect together the various methods used for recording results, and then to give a detailed examination of the causes of error, with a view to improving the precision obtainable and to increasing the speed of recording.

Many sources of error, for example those due to lack of perfection in manufacture and to external fields, are obvious. This paper, however, deals chiefly with the more obscure causes of such errors, e.g. the "threshold effect."

It should be noted that the word "error" is used rather as meaning a departure from simple theory than in the usually accepted sense. Obviously if a tube is calibrated all the "errors" are accounted for, except when the conditions of use change, when naturally a new calibration would be necessary. In the main, therefore, "error" here refers to the departure of the sensitivity of the tube from the theoretical sensitivity, this departure, of course, including any non-linearity in the relation between voltage and deflection.

General Errors in Measurements.

Inherent to Tube.

Non-parallel plates.—The tubes now available seldom have serious faults due to defects in manufacture, and in consequence the likelihood of obtaining a tube with deflecting plates which are not parallel is small, although plates may distort after some time has elapsed. The errors associated with this fault in construction are only apparent when deflections are being made in two direc-

tions mutually at right angles, i.e. when both pairs of plates are in use.

In Fig. 1, if the beam has already had a displacement along the line AB the displacement produced by the pair of plates under consideration would be different when in the position A than when in the position B. If x is the displacement of the cathode stream from the

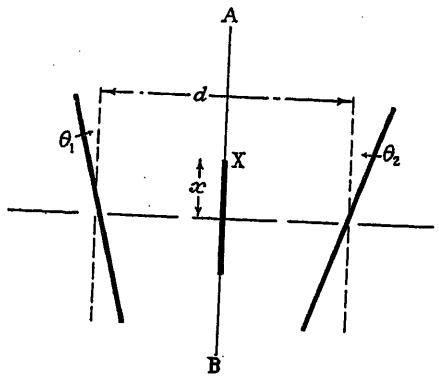

FIG. 1.

centre, and a voltage V is applied between the plates the potential gradient at X will be

$$\frac{V}{d + x(\tan\theta_1 + \tan\theta_2)}$$

The potential gradient if there were no distortion of the plates would be V/d.

Hence the error is

$$\frac{\frac{V}{d} - \frac{V}{d + x(\tan\theta_1 + \tan\theta_2)}}{V/d} \times 100 \text{ per cent}$$

$$= 1 - \frac{d}{d + x(\tan\theta_1 + \tan\theta_2)} \times 100 \text{ per cent}$$

If the deflection in the direction AB were varying sinusoidally, the difference between the deflection at right angles to AB, and at the extremes of the motion in the direction AB, would be twice this amount.

In the case of the Standard Telephone Co.'s tube:*

$d = 0{\cdot}5$ cm; $b = 2$ cm; and assume $x = 0{\cdot}2$ cm, and $\tan\theta_1 + \tan\theta_2 = 0{\cdot}1$ ($\theta_1 = \theta_2 = 3°$), then error between two extremes

$$= 2\left(1 - \frac{0{\cdot}5}{0{\cdot}5 + 0{\cdot}2 \times 0{\cdot}1}\right) \times 100 \text{ per cent}$$

$$= 2(1 - 0{\cdot}962) \times 100 \text{ per cent} = 7{\cdot}6 \text{ per cent}$$

Error of Curvature of Screen.—When the radius of curvature of the fluorescent screen is not equal to the distance between the deflecting plates and the screen or the centre of curvature is not at the deflecting plates, an error up to a few per cent may occur at large deflections, and reference should be made to the manufacturer's handbook.

The Effect of Gas Conduction between Deflecting Plates.—Owing to the fact that the gas in the tube is ionized when the cathode beam is in action, there is a conducting path between the plates. The effect of this is only apparent under two sets of conditions: (1) When the amount of energy for producing a deflection is extremely small; and (2) When a resistance is placed in series with one of the deflecting plates, in which case the error is always present, no matter what amount of energy is available.

In the first case, if the resistance is R, and the deflecting voltage V, the power loss in the gas is V^2/R watts. If the source of energy is a charged condenser of very small capacitance, as soon as the condenser is connected to the plates the voltage will decrease exponentially and no true deflection will be recorded. Another effect apparent in such a case would be due to the capacitance between the plates if the tube is being used on radio-frequency voltages.

If R is the resistance between the plates, and R_1 is the resistance in series with one of the plates, the actual voltage across the plates will be $RV/(R + R_1)$, where V is the deflecting potential.

The error is therefore

$$\frac{V\left(1 - \frac{R}{R + R_1}\right)}{V} \times 100 \text{ per cent}$$

and if $R = kR_1$ the error is

$$\frac{R_1}{R_1(k + 1)} \times 100 \text{ per cent}$$

$$= \frac{1}{k + 1} \times 100 \text{ per cent}$$

As R is not constant, but varies with the deflecting voltage, this matter is dealt with more fully under the Section entitled "The Threshold Effect."

ERRORS OF MANIPULATION.

The Effect of Resistance in the Anode Circuit.

The makers of hot-cathode tubes recommend the use of a resistance between the anode and the positive of the high-tension supply, so as to limit the emission in the event of over-voltage on the anode, or over-heating of the filament, or in the much more remote case of the formation of an arc between the anode and the filament. As the emission current is carried by this resistance a drop in voltage occurs, so that the anode does not receive the voltage of the source of supply. The effect of this difference in increasing the sensitivity of the tube is not mentioned in the makers' instructions, and in the case of the No. 4224 tube the following figures are typical:—

Nominal anode voltage	= 200 volts
Series resistance	= 2 000 ohms
Emission current	= 0·5 milliamp.
Error for electrostatic deflections	= ½ per cent
,, ,, electromagnetic ,,	= ¼ per cent

The importance of not exceeding this value of limiting resistance will therefore be seen.

* In the remainder of the paper this tube will be designated as the No. 4224 tube, and in the Appendix the later pattern tube will similarly be referred to as the No. 4018A tube.

Threshold Effect.

This effect was described by Captain P. P. Eckersley,* who stated that a certain " threshold " value of deflecting voltage had to be reached before any deflection took place. The result of the present investigation goes to show that this is only approximately true, as the sensitivity although lower is not zero, for very small deflecting voltages. For electromagnetic deflections, however, no such effect is apparent. This subject is dealt with more fully in the latter part of the paper.

Error due to Non-central Zero Spot.

This error only appears when the zero spot is near the edge of the screen, and then the curvature error comes into evidence in what are really small deflections. The curvature correction would have to be applied to the zero position as well as to the deflected position.

The Use of External Deflecting Plates.

The use of a pair of metal plates fixed outside the tube in order to obtain deflections by applying a voltage to the plates has been suggested. With a cold-cathode, high-vacuum tube, results with this may be possible, but with the type under consideration deflections are not possible. This is because of the comparatively large quantity of gas in the tube, which, when the tube is in operation becomes highly ionized by electronic collision of the electrons from the cathode stream and the gas molecules in the tube. By placing plates outside the tube and applying a difference of potential to them, the ions in the tube segregate under the influence of the electric field thus set up, and charges collect on the walls of the tube, largely reducing the potential gradient across it and so producing very little deflection of the spot.

As a result of work done by H. Whitaker at East London College on the use of external deflecting plates, if was found that for a cold-cathode tube the ratio of deflections using internal and external deflecting plates was about 111:1. The value found for the 4224 tube was 117:1. From a formula given by A. G. Webster† relating to the screening effect due to the high permittivity of glass, the field strength inside an infinitely long tube having $\frac{1}{16}$-in. walls and $\frac{5}{8}$-in. external diameter is 0·72 of the field outside, and for a tube $1\frac{5}{8}$-in. external diameter and walls of the same thickness, it is 0·92, assuming that the tube is placed between parallel plates of infinite extent. Hence it seems that only static charges will account for the greatly reduced deflection for potentials applied to external plates.

Non-uniform Field of Coils.

No actual measurements have been made of the field distribution in the space between the coils. There is, however, nothing to point to any non-uniformity of the field over the small area enclosed by the extreme positions of the beam.

† "Theory of Electricity and Magnetism" (Macmillan & Co., 1897, p. 378).

EXTERNAL INFLUENCES.

The Influence of Stray Magnetic Fields.

It is customary to bring the spot to a convenient part of the screen by means of one or two horseshoe or bar magnets. This is usually done by arranging a magnet situated at the end of the tube beyond the screen. It is generally necessary to have the magnet fairly close to the tube in order that it may have sufficient effect. The necessary corollary to this is that at least the end of the beam must be in a widely diverging magnetic field, so that as the beam is deflected

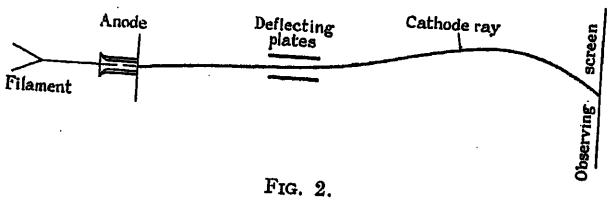

FIG. 2.

it is moving across this non-uniform field, which produces a force which will either add to or subtract from the applied deflecting force. The error which would be produced by this is under certain conditions very great. When the tube supplied by Messrs. Edwards is considered, another magnet has to be introduced. Owing to the heavy filament current used, it is seldom that the cathode stream from the lime spot on it goes through the hole in the anode. In this case a magnet has to be used to cause the stream to enter the hole, and when it

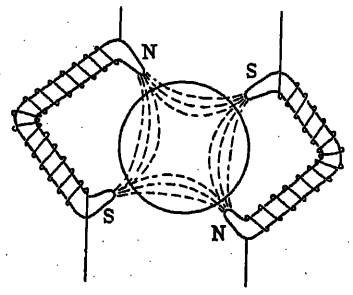

FIG. 3 (diagrammatic).

emerges it is usually found that the spreading field from the magnet causes the stream to strike the wall of the tube at some point along it. This necessitates the introduction of the magnet considered above, and this causes the beam to take the form shown in Fig. 2. Owing to the beam impinging on the screen at an angle, it is scarcely possible to obtain a small spot, and the deflection is unlikely to be proportional to the deflecting force. Several methods were tried by the authors and the most successful was the following.

A pair of small electromagnets were made as shown in Fig. 3 with $\frac{3}{16}$-in. iron rod flattened out at the ends and bent at right angles. These were mounted on a piece of paxolin sawn across the middle, having a hole in the centre to fit closely around the tube, the two halves being held together by screws. When the two windings were connected in series with two variable resistors and

supplied from a 2-volt cell, it was found easy to control the cathode stream and make it enter the hole by varying the resistances and rotating the paxolin carrier around the tube.

The stray field from this arrangement is relatively weak, and by reversing the direction of the current through the coils, either in one or both, it is only necessary that the mounting should be able to rotate through 90°. It was found that after the current had flowed through the coils there was sufficient remanent magnetism in the iron (which had not been annealed after flattening and bending) to do away with the battery. It has been used in this way for about a year without a battery.

The position of the tube with respect to any stray magnetic fields, e.g. from instruments or the earth's field, must obviously remain unaltered during calibration and use.

External Electric Fields.

It is unlikely that the tube would be subjected to any strong electric field, and in case of doubt it would be a simple matter to surround the tube with a suitable earthed metallic cage or screen.

If deflecting coils are used at a potential differing greatly from that of the anode, there is a possibility of electrostatic action occurring, so that the preferable way of using the coils is to connect them to the anode, but if this cannot be done a layer of tinfoil round the tube under the coils is sufficient to act as a screen when connected to the anode. Although it is difficult to produce a deflection by a potential applied outside the tube when a steady voltage is used, it is possible to get a movement of the spot when the voltage is alternating.

Recording.

Tracing.

The simplest method of obtaining a true record of any paths traced out by the spot is to use tracing paper and make a tracing of the curve obtained. There are two objections to this, one being that in the case of a tube like that supplied by Messrs. Edwards, where the fluorescent screen is not on the end of the tube, but on a separate mounting, it is impossible to trace it accurately. The other objection is that where the phenomenon is not repeating with regularity it is extremely difficult to reproduce the mean curve. The first difficulty can be overcome by using a camera with a focusing screen, and tracing the image produced on it. This is not possible where the speed of travel of the spot is too great to produce a very intense line on the fluorescent screen. A further difficulty is that it is necessary to have complete darkness in order to be able to see the trace on the camera screen.

By Direct Photography.

By Film or Gaslight Paper.—An alternative to tracing by hand is to do it automatically by laying a photographic film on the end of the tube and developing the latent image. Gaslight or bromide paper can be used in place of the film. It is difficult to state definitely which of the two, film or paper, is the better, as the conditions cannot be specified. It is, however, much easier to form a damp piece of gaslight or bromide paper to the end of the tube than to adapt for this purpose the comparatively unyielding film. On the other hand, the film is far more rapid photographically than the paper. The H. & D. numbers for the film and paper would be about 300 and 20, or relatively 15 to 1. The film, even if panchromatic, is more sensitive to blue or green light than to yellow, and the opposite is the case with the paper. This will make the relative speeds still more unequal. Any number of copies can be printed from the film, while it would only be possible to do this with the paper after a considerable amount of trouble.

By Plaster Cast.—This method, although interesting, is difficult to realize in practice. A photographic emulsion is made and run on the surface of a plaster of paris mould of the end of the tube. When the emulsion has set, the mould is used in the same way as the film, development being carried out by pouring the fluid into the cup of the mould. The trouble entailed by this method renders it unsuitable for obtaining a large number of records. The fact that the emulsion with the image is stuck to the cast renders the method cumbersome, and it is not known whether stripping solutions would remove it in order to transfer it to a glass plate. The possibility of using a pantograph has been suggested.

Camera Photography.

The simplest way of recording is by means of the camera. A darkened room is not necessary in this case, as the tube and the camera can be fitted into a small light-tight box, the camera shutter being operated from outside. The one great objection to this method is that only a small fraction of the photographic energy of the trace on the screen is available for producing an image on the plate, therefore making a long exposure a necessity.

Typical Results.—Using a camera with an aperture of F/7·7, and obtaining an image reduced about two-thirds, and an ordinary plate with a speed of 1 400 H. & D. with the Edwards tube, which has a mica screen, the exposure necessary for a mean speed of travel of the spot of 3 metres per sec. is about 40 seconds when the tube exciting voltage is 350 volts.

With a tube having the fluorescent material mounted on a mica screen, only about $\frac{1}{2}$ per cent of the total light energy is received on the sensitized emulsion, while with the glass mounting the value is about 4 per cent, this figure having been calculated and confirmed experimentally. It should, however, be mentioned that the direct-contact print does not yield a sharp record, owing to the thickness of the end wall of the tube being interposed between the luminous spot and the film.

Methods of Calibration and Evaluation.

General Remarks.

If the connection between the deflecting force and the deflection were of a strictly linear nature, it would be a simple matter to evaluate the traces, as all that would be necessary would be to obtain two points to establish the constants of the law. Unfortunately it is not so simple, and practically the only way of evaluating the results is to resort to preliminary calibration.

The authors found that the best way of measuring-up

records was by means of a co-ordinatograph, but dividers and scale are more simple to use, though not so accurate. In the case of a truly linear calibration a pantograph could be used for enlarging from the photographic image to a curve on squared paper. Once a calibration curve is obtained connecting the co-ordinates of a point and the quantity to which it relates, it is a straightforward matter to apply the calibration. Several methods of calibration follow, and in addition a brief description of a method which does away with preliminary calibration.

Methods of Obtaining a Calibration Record.

Using Direct Current or Voltage.—One method is to produce a deflection of the spot by a known value of voltage on the deflecting plates, or a known current through the coils, and record the position of the spot by one of the methods described previously.

Should it be desired to check the value of the deflection produced by a given force as the beam is moved transversely to the direction of deflection, all that is necessary

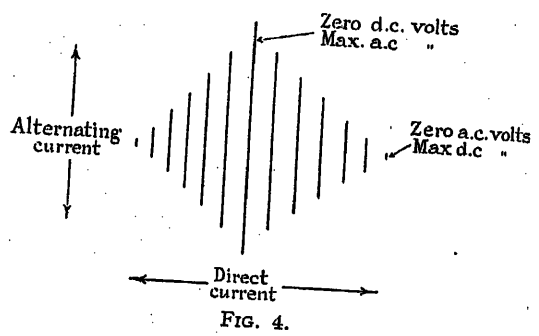

FIG. 4.

is to apply a steady deflecting force in the transverse direction and repeat the process.

Using Alternating Current or Voltage.—No advantage is obtained by the use of this method, which uses the peak of an alternating wave, while it has several disadvantages. Either the quantity must be sinusoidal or its peak value must be known, two conditions which it is sometimes difficult to fulfil, and the time for tracing, photographically or otherwise, is longer than it is for the spot. It is scarcely possible to use the relation between the sinusoidally varying quantity and time to obtain the relation between force and deflection, as it is seldom that the time base of such an arrangement can be calibrated in terms of time.

Calibrating in Two Mutually Perpendicular Directions.—Where it is desirable to calibrate along two axes at right angles simultaneously, it can be done if a sinusoidal alternating quantity is available. If direct current is applied in one direction and alternating current applied to produce deflections at right angles to this, the resultant record would be a series of spaced straight lines, and as the alternating part is varied as well as the steady part a diagram is obtained which would resemble Fig. 4.

If there is doubt as to whether a given relationship between force and deflection holds over all parts of the screen, the above method can be so modified that a constant alternating quantity is applied in one direction and a steady quantity varied in the other direction, these two being finally interchanged and the process repeated. In this case a grille pattern is obtained, either with all the lines parallel or some diverging, depending on the constancy of the force/deflection relation (see Fig. 5).

By doing this and then superposing any other trace required, the whole becomes, by the insertion of a few numbers corresponding to the value of the cross lines, a complete graph. It should be mentioned that this is not easy photographically, because the ends of the lines are distinctly brighter than the middles, and, owing to stray parts of the beam in the tube producing a halo round the spot, fogging of the negative occurs.

Simultaneous Calibration and Recording.—An interesting method due to R. M. Wilmotte* evaluates any point on a stationary trace on the screen directly. By means of two rotating commutators, one for each pair of plates, the voltages under analysis and a d.c. voltage are applied alternately to the two pairs of plates, the commutators being so proportioned that for a large part of a revolution the voltage under analysis is applied, the direct current being applied for the remaining part. By varying separately the values of the d.c. voltages the spot produced by them can be made to move over the screen until it is coincident with the trace, so that the co-

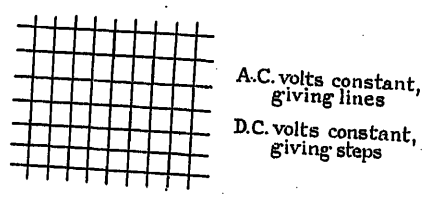

FIG. 5.

ordinates of any point of the trace can be measured in volts. By this means the necessity of preliminary calibration is dispensed with, but on the other hand it is only suitable for use where the trace under analysis is repeating exactly for as long as it takes to evaluate in this way. This method has been tried out by Mr. C. A. Luxford at East London College, and has been found to work excellently.

THE THRESHOLD EFFECT.

In the paper by Captain P. P. Eckersley quoted previously, a common use of the cathode-ray tube for radio-frequency measurements is described, and a statement to the effect that the tube appears to be insensitive to low values of deflecting voltage is made, and that voltages less than 8 to 12 volts apparently produce no deflection. This voltage was called by Capt. Eckersley the "threshold voltage." It was also stated that the effect would be diminished by reducing the filament current or the anode voltage.

The existence of this effect was proved by the present authors in the case of a simple form of tube of German manufacture, and it was found that the tube, though less sensitive to voltages below about 10 volts than it was to voltages above this figure, still gave measurable deflections.

* *Journal of the Franklin Institute*, 1930, vol. 209, p. 809.

Introductory Remarks on the Experiments Made.

A photographic method of recording was decided upon and a No. 4224 tube was housed in a black box in which was also a camera, so that all the work could be done in an undarkened room. It has previously been found in the course of some other work that the relation between deflection and current when coils were used for producing deflections was linear. Use was therefore made of this fact for producing a reference base for the electrostatic deflections. A pair of coils were fixed to the tube so that they would produce deflections in a horizontal direction, while a pair of plates were used for producing vertical deflections.

Experimental Evidence of the Existence of the "Threshold Effect."

A number of photographic records were first made with a view to determining whether the threshold effect was one of geometry, in that the effect may be due to the position of the beam in the tube, any stray effects being possibly due to charges on the tube walls. The records were made in the form of (*a*) spaced dots, these being produced by a series of steady deflecting potentials; (*b*) spaced parallel lines; and (*c*) a grille pattern. The values obtained from this last record are given in Table 1.

TABLE 1.

Voltage	Deflection, mm	
	P_x plates	P_y plates
+ 7·8	6·34	6·49
+ 5·2	3·74	4·32
+ 2·6	1·72	2·05
0	0	0
− 2·6	− 1·67	− 1·83
− 5·2	− 3·99	− 4·10
− 7·8	− 6·63	− 6·52

The fact that the lines neither converge nor diverge at the ends shows that the position of the beam in the tube does not influence, to a measurable extent, the deflection produced by a given voltage. This was further confirmed as follows. The beam was deflected simultaneously by two forces at right angles, one electrostatic and the other electromagnetic, and a diagonal trace with a kink at zero was obtained. A biasing voltage was then applied in series with the alternating current in two opposite directions successively, the three traces being recorded on one negative, and the kink was found to move along the axis of zero voltage. If the threshold effect happened only in the zero position of the beam, the kink would move at right angles to the line of voltage deflection.

The Development of the Equation connecting Voltage and Deflection.

The equation which was found to connect the deflection and voltage was of the form

$$\delta = KV - k\sqrt{[\pm (i - i_0)]}$$

where δ = deflection in millimetres,
V = deflecting potential,
i = conduction current at the voltage V,
i_0 = ,, ,, ,, zero voltage,
K = sensitivity constant as derived theoretically,
k = constant.

The alternative sign under the root is explained by the fact that the space charge must disappear at one plate and appear at the other as the voltage on the deflecting plates changes sign, so that by this means a simple way of taking account of the relative nature of the potential on the deflecting plates is obtained.

Four examples of experimental curves are given in Fig. 6 with the corresponding conduction currents in Fig. 7, for anode voltages of 350, 320, 280, and 250 volts, and in addition Fig. 6 shows points obtained from the equation above. The results obtained are summarized in Table 2, and the values were derived from simultaneous equations formed by substituting in the equation values obtained from the experimental curves.

TABLE 2.

Anode voltage	k	Sensitivity, K	Theoretical sensitivity	Error
				per cent
350	1·118	0·828	0·841	− 1·5
320	1·04	0·917	0·920	− 0·4
280	1·112	1·063	1·051	+ 1·0
250	1·56	1·212	1·178	+ 3·0

The Cause of the Threshold Effect.

Having obtained a relationship between the threshold effect and the conduction current it is desirable to attempt some explanation of this effect. This can be done very briefly. As a current can be made to flow between the deflecting plates free ions must be in existence. These ions are produced by electrons in the cathode stream which has penetrated beyond the anode, partly by the escape of electrons from the stream and partly by collision with gas molecules.

All these electrons have quite a high velocity, so that, even when there is no potential gradient between the deflecting plates, some ions will reach them by their own velocity. If a potential difference is set up between the plates, however, a definite drift will be set up, electrons going towards the positive plate and positive ions towards the negative. The great difference between the mobilities of the two kinds of ions causes a concentration of positive ions, i.e. space charge, near the negative plate, thus causing the potential gradient to be greater over this part than over the rest. As the p.d. between the plates is increased, the potential gradient over the part occupied by the space charge does not increase so rapidly as that over the rest, owing to the limited supply of positive ions to form the space charge. Hence it is that when more than, say, 5 volts

is applied between the deflecting plates the deflection becomes proportional to the voltage. This is the value for 350 volts on the anode, but at 250 volts on the anode this figure is reduced to about 3·6 volts, bearing out Captain Eckersley's statement regarding exciting conditions.

does not alter between 0 and 10 000 cycles is useful, as this covers most of the range of audio-frequencies.

The Effect of Resistance on the Threshold Effect.

The effect of placing a resistance of 1 megohm in series with the deflecting plate is seen in Fig. 9. The

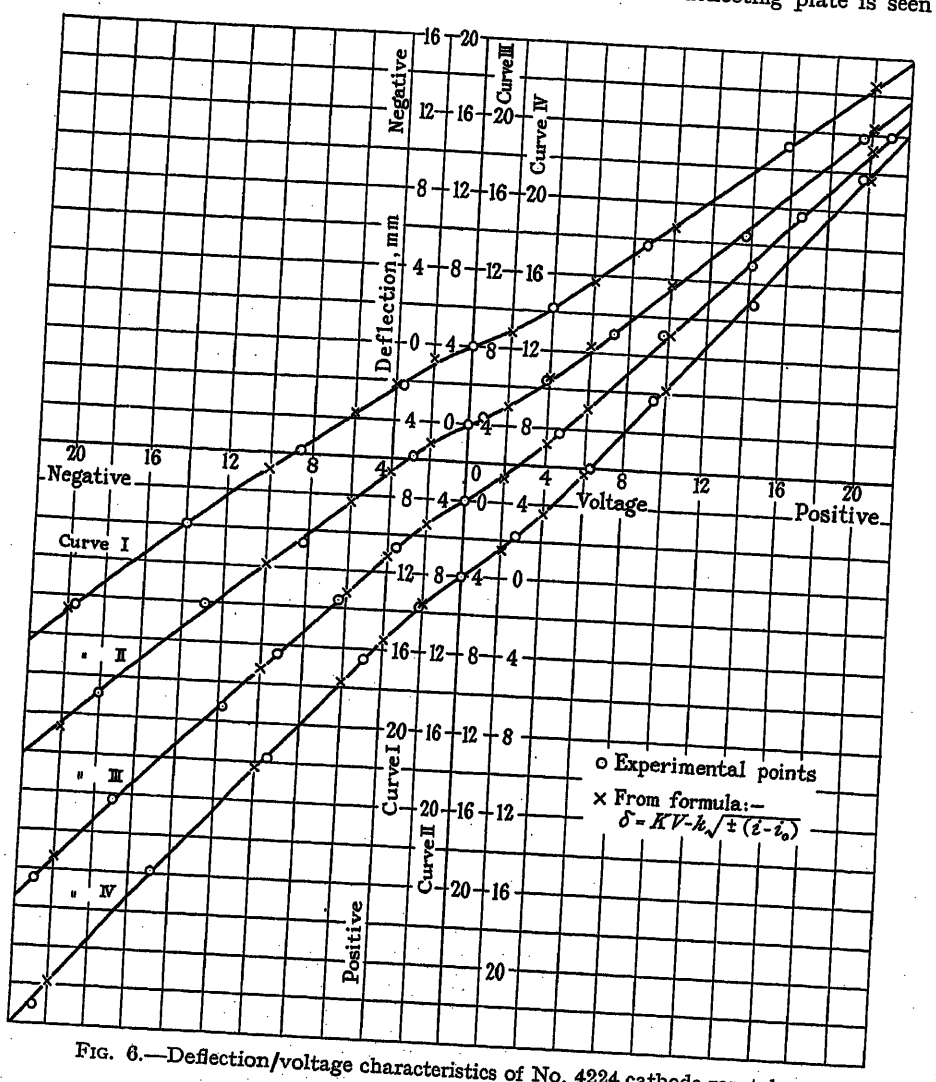

FIG. 6.—Deflection/voltage characteristics of No. 4224 cathode-ray tube.

The Effect of Frequency on the Threshold Effect.

A series of records were obtained connecting deflection and voltage with constant excitation for alternating voltages varying in frequency from 10 to 9 000 cycles per sec. The two lower frequencies were obtained from an alternator and the three higher from a valve oscillator. All five are set out together in Fig. 8, showing that all follow the same voltage/deflection curve as far as can be estimated. Consideration must be given to the fact that it was not possible to obtain all the records with the same scale relations between the two quantities, so that they all had to be reduced to a common scale in order to show them. It was not possible at the time to investigate the matter at still higher frequencies, but the knowledge that the effect threshold effect is apparently increased for positive deflecting voltages, but this is due entirely to the drop in voltage in the resistance. This is substantiated by evaluating the equation

$$\delta' = K\left[V \pm (i' - i'_0)R\right] - k\sqrt{\left[\pm (i' - i'_0)\right]}$$

and the values so obtained are shown on the curve. This also seems to indicate that the potential distribution in the space between the deflecting plates is dependent on the voltage applied to the plates and independent of the current flowing between the plates, for a given state of ionization in the tube.

The Characteristics of the 4224 Tube.

The connection between the various factors of tube

excitation when the electron stream is correctly focused is seen in Figs. 10 and 11. The decrease in the emission necessary when a deflecting voltage is applied is probably due to the removal, by the charged deflecting plates, alternating voltages, while with steady deflections some mean value of focus will have to be found.

The emission characteristics of the tube, Figs. 12 and 13, are those of an ordinary diode. Fig. 14 appears to indicate that the conduction current between the deflecting plates is proportional to the anode voltage for a given value of filament current, but Fig. 15 shows definitely that the conduction current is not independent of the anode current. The linear relation in the former is probably an accidental feature due to the emission current being near saturation value. It is a difficult matter to draw any definite conclusions, as they can only be based on the knowledge of the number of electrons reaching the anode, and not on that of the number passing through, these latter being those which are effective in producing the ionization, and so causing the conduction current.

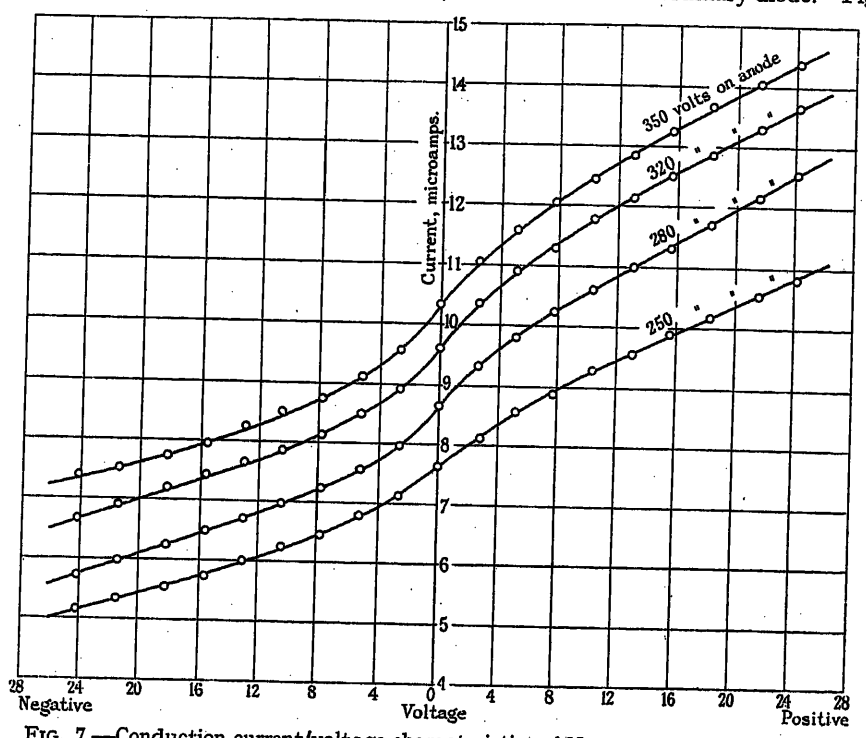

FIG. 7.—Conduction-current/voltage characteristics of No. 4224 cathode-ray tube.
These current curves are all displaced upwards by the presence of conduction currents external to the tube, but this current is independent of the deflecting voltage.

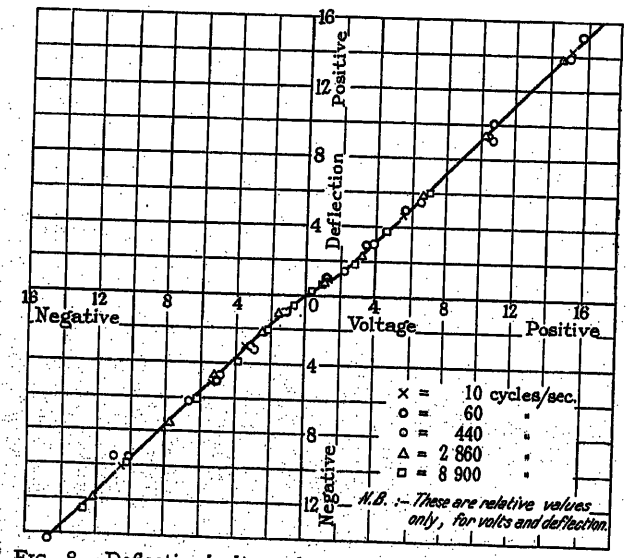

FIG. 8.—Deflection/voltage characteristic at various frequencies of No. 4224 cathode-ray tube. Anode voltage = 320.

of some of the ions surrounding the stream, so that the number of electrons in the stream must be diminished to restore a state of balance. The practical importance of this is that the electron stream should be focused with the deflecting voltage applied when used with

Method of Obtaining Most Accurate Results.

In view of the foregoing information the following suggestions are put forward as a guide when accurate work is being undertaken with this type of tube.

A correct calibration is essential, and this for preference should be done photographically, and should be carried out over the greater part of the surface of the fluorescent screen, and not only for two lines at right angles. This second precaution is made necessary by the presence of stray magnetic fields, and, if a magnet is used for bringing the spot to its zero position, large errors will result if it is neglected. It is not desirable to have to calibrate each time the tube is used, so that it must be used under the same conditions, one of these being that of position. The remaining conditions are those of excitation. Bearing in mind the large

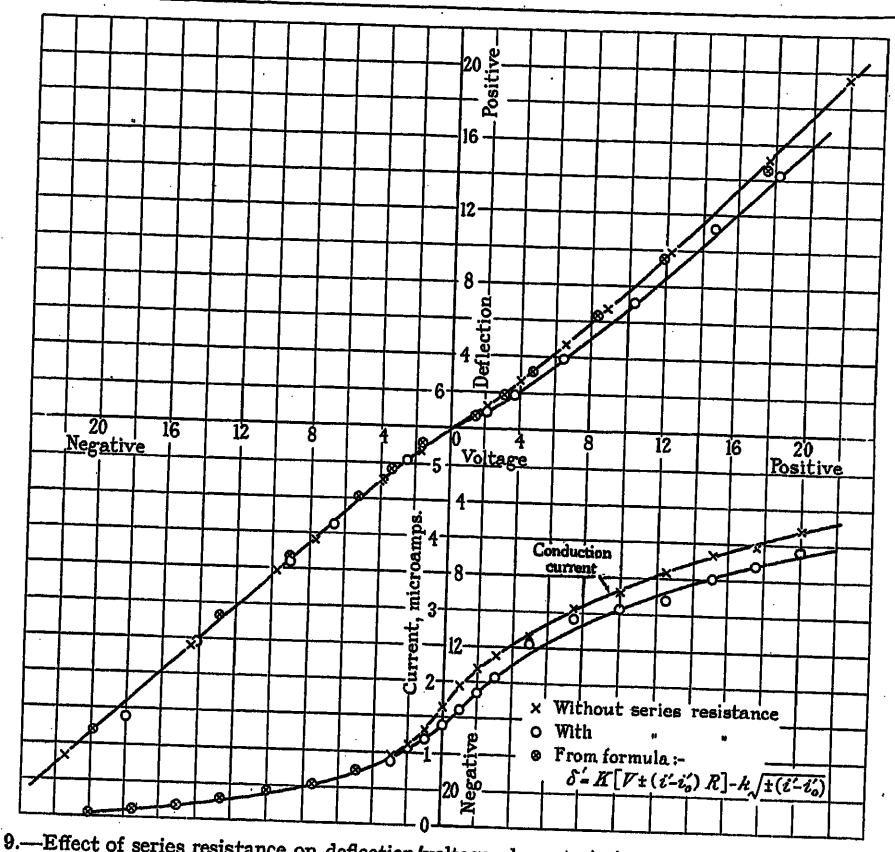

FIG. 9.—Effect of series resistance on deflection/voltage characteristics of No. 4224 cathode-ray tube.

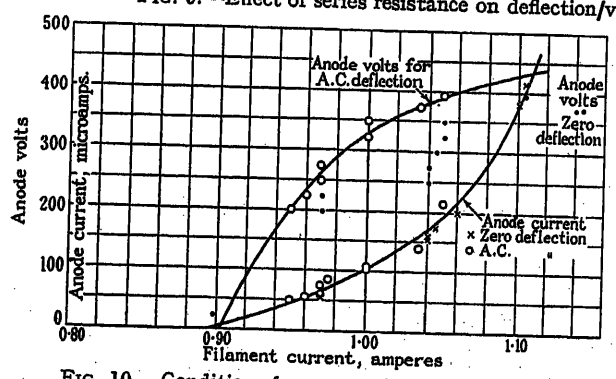

FIG. 10.—Conditions for correct focus of No. 4224 cathode-ray tube.

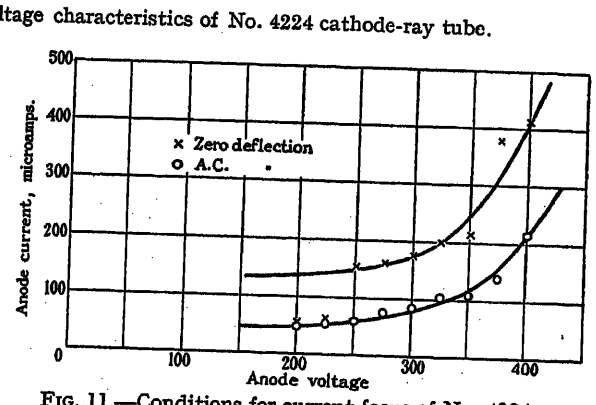

FIG. 11.—Conditions for current focus of No. 4224 cathode-ray tube.

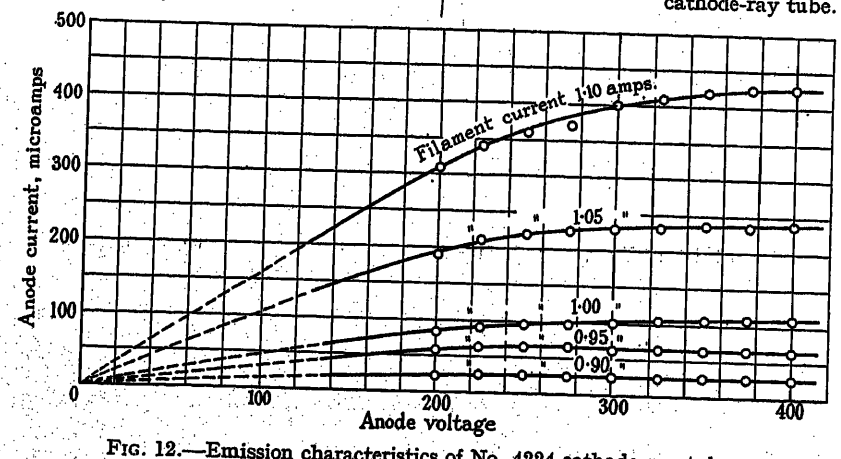

FIG. 12.—Emission characteristics of No. 4224 cathode-ray tube.

errors introduced by the threshold effect, the two factors which must be repeated exactly are the anode voltage and the conduction current between the plates, the first affecting the sensitivity, and the second the amount of threshold error. If the anode voltage is first fixed, the filament current can be adjusted to make the conduction current between the plates correct. As the emission current is only a measure of what is happening between the cathode and anode, and therefore can be only an indication of what happens beyond the anode, it is recommended that for the greatest accuracy the conduction current should be measured. This involves the use of a sensitive microammeter. With reasonable care it is possible to replace this by a milliammeter to measure the emission, but where a centralizing magnet is used it is essential that the field due to this should remain

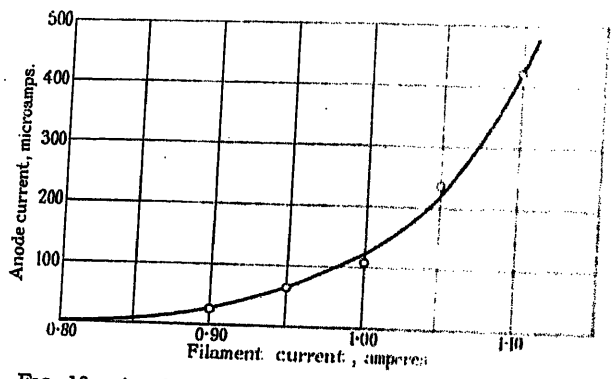

FIG. 13.—Anode current saturation curve of No. 4224 cathode-ray tube.

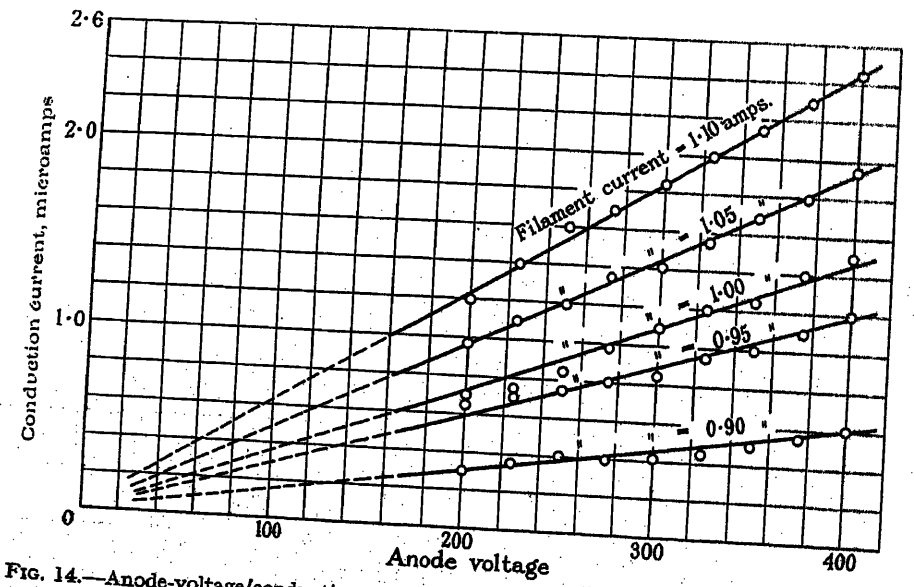

FIG. 14.—Anode-voltage/conduction-current characteristics of No. 4224 cathode-ray tube.

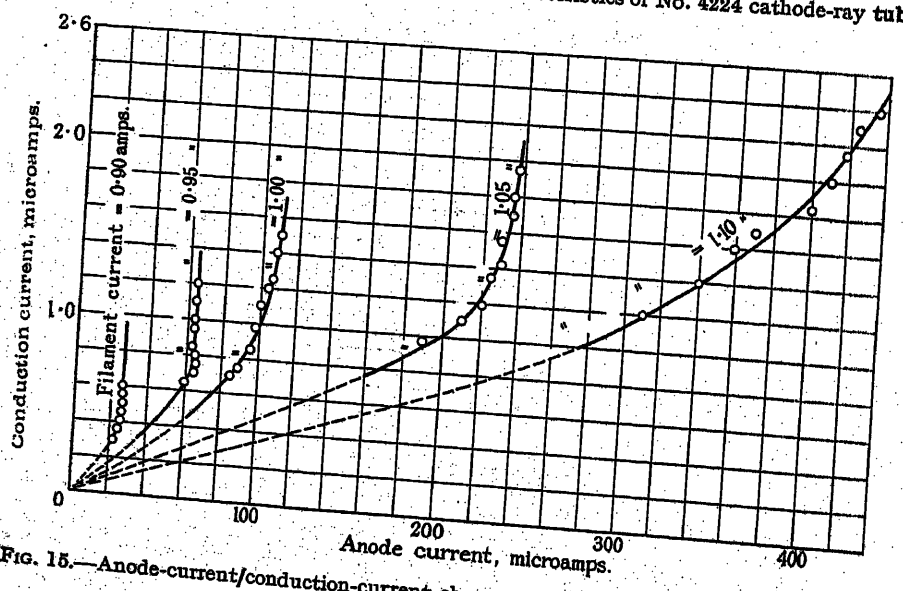

FIG. 15.—Anode-current/conduction-current characteristics of No. 4224 cathode-ray tube.

constant. It has been suggested* that the threshold effect can be overcome by deflecting the spot off the screen electrostatically and then bringing it back again by means of a magnet. The strong field from the magnet necessary to do this is seldom likely to be uniform, and consequently the image will be distorted. Owing to the beam striking the screen at an angle, a sharp focus will not be obtained.

A cathode-ray oscillograph built up from a tube costing under £6, and of less refined construction than the No. 4224 tube, has been in more or less continuous use for visual work during the past 12 months at East London College. During this period the calibration has not altered appreciably, while some 90 photographic records have also been made.

Conclusion.

In conclusion it is clear that valuable information could be obtained by still further investigation in this field. There is still need for knowledge of the effect of frequency, while the physical explanation of the threshold effect requires to be fully developed. The determination of the relation of the "space charge constant" k to the gas pressure and other controlling factors, would materially assist in the development of a sound theory.

A close study of the behaviour of hot-cathode tubes of many types extending over a considerable period leads the authors to the belief that the field of use of such apparatus will continue to expand more and more, especially in those cases where rapidity of response is essential. The simplicity of action, the ease of visual observation, and the absence of risk make the low-voltage tube an instrument of general utility in the laboratory. Correct interpretation of the results involves, however, an intimate knowledge of the principles underlying the action of such tubes.

The authors are glad to acknowledge here the debt they owe to Prof. E. H. Lamb for his kindness in loaning a Coradi co-ordinatograph for an extended period. Without this instrument it would have been difficult and tedious to make full use of the photographic records. Thanks are also due to the Council of the East London College for certain assistance from the Research Fund.

APPENDIX.

Particulars Relating to Later Pattern of Tube.

Introduction.

Since the completion of the paper, the Standard Telephone Co. have placed on the market a new type of tube, known as the "4018A" tube. The authors felt that if some facts concerning this could be added the scope of the paper would be materially widened and at the same time the subject would be brought more up to date.

The new tube is almost identical in construction to the older one, but it depends on a shield round the cathode stream for its focusing, and is designed for a higher anode potential. With this method of focusing, the size of the spot becomes independent of the filament current over quite a wide range, so that it is possible to use a high anode potential with a low filament current, thus reducing the magnitude of the threshold error and at the same time obtaining a brighter spot, which has also been still further improved by providing a better fluorescent material.

Typical Voltage/Deflection Graphs.

In Fig. 16 are shown four voltage/deflection graphs, whilst the corresponding conduction-current curves are given in Fig. 17. It will be seen that they are of the same general character as those for the 4224 tube, but it should be noticed that the deflection/voltage relationship for the 560-volt case is linear for negative voltages. At lower filament currents with lower anode voltages, the relationship is also linear and even extends to positive voltages, although the slopes of the positive and negative parts of the curve may be slightly different.

In order to make quantitative comparison easy, the threshold errors under various exciting conditions are given for both tubes. In the case of the 4018A tube, the filament current is higher than would be normally used with the lower anode voltages, so that the error would usually be less than this.

Table 3.

Anode voltage	Percentage error				4018A Tube	
	4224 Tube		4018A Tube			
	+ 20 V	− 20 V	+ 20 V	− 20 V	Theoretical sensitivity	Derived sensitivity
250	10·5	9·6	7·8	7·1	0·909	1·40
280	10·8	8·3	—	—	—	—
320	13·3	9·2	—	—	—	—
350	11·3	10·1	13·4	8·6	0·649	1·10
450	—	—	7·8	5·3	0·505	0·776
560	—	—	4·7	2·5	0·406	0·613

The error, which is the amount by which the experimental results fall short of the theoretical values, is less in the case of the newer tube than in the case of the older, due to the lesser ionization, because the emission current is reduced, and in addition it is understood that the quantity of gas in the tube is less.

The Sensitivity of the Tube.

On examining the curves of Fig. 16 some rather unexpected results are obtained, as shown in the last two columns of Table 3. The figures in the column headed "Theoretical sensitivity" have been obtained from the generally accepted formula

$$\text{Deflection} = \frac{V_d l_1 l_2}{2 V_a d} \text{ cm},$$

where V_d = deflecting potential,
l_1 = length of deflecting plate,
l_2 = distance from plate to screen,
V_a = anode potential,
d = distance between plates.

250	1·22	10·5	36
350	1·22	12·5	45
450	1·22	16·5	50
560	1·22	35·0	74

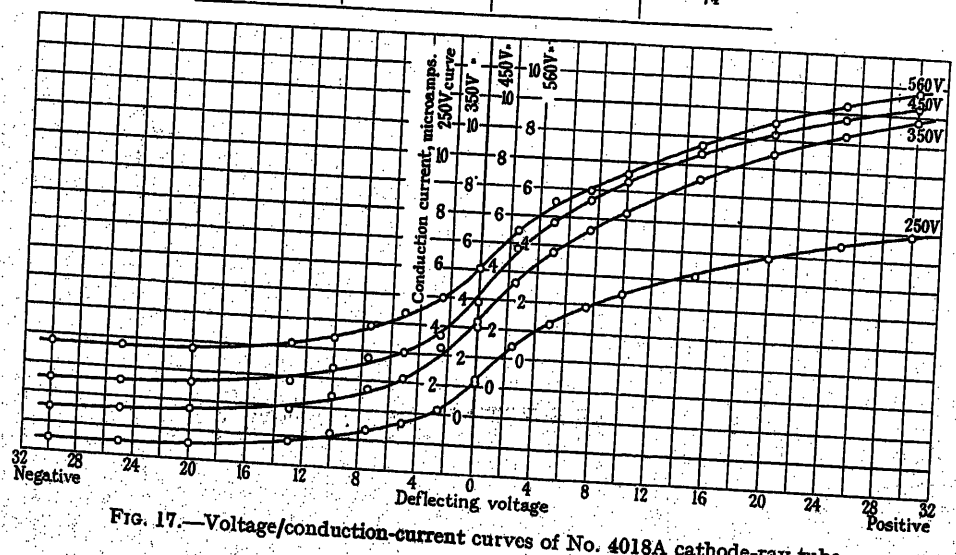

FIG. 17.—Voltage/conduction-current curves of No. 4018A cathode-ray tube.

while those in the last column have been derived from the experimental curves given, and are corrected to allow for the threshold error. It is seen that the tube has, the gas pressure in the 4018A tube is stated by the manufacturers to be one-tenth of that in the older pattern 4224 tube.

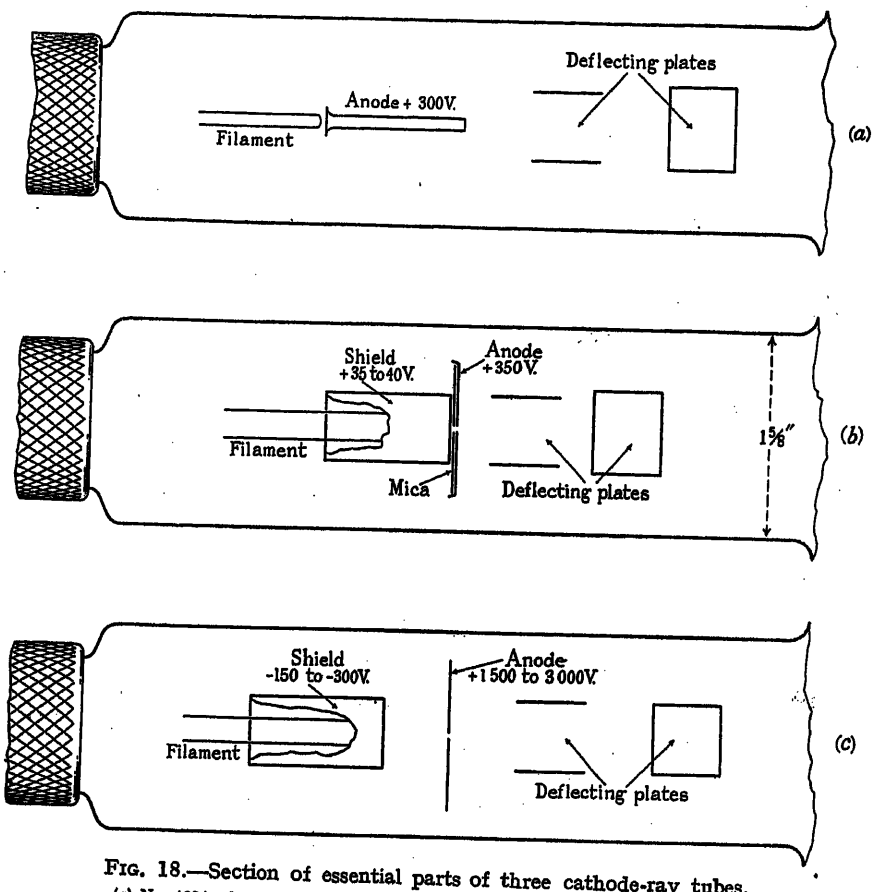

FIG. 18.—Section of essential parts of three cathode-ray tubes.
(*a*) No. 4224 tube. (*b*) No. 4018A tube. (*c*) Von Ardenne tube.

even when the decrease due to the threshold error is not allowed for, a sensitivity some 40 per cent higher than would be predicted by simple theory. This result has been confirmed by two other independent experimenters using the same tube. This difference is confirmed by the manufacturers who, when using another tube, obtained about 10 per cent difference. At present the authors are at a loss to account for this difference, and the matter is still under investigation.

A sectional view of the important parts of the several tubes under investigation is given in Fig. 18 with the appropriate working voltages. It should be noted that

To sum up, the following points should be noted in reference to the newer pattern of tube:—

(1) The possibility of obtaining a linear response of the spot to the deflecting voltage.
(2) A large increase in the average life.
(3) A brighter and better-defined spot.
(4) A reduction in the cost of the tube.

When due weight is given to these points, it will be clear that the field of use of the low-voltage cathode-ray oscillograph will be greatly extended.

[The discussion on this paper will be found on page 70.]

DISCUSSION BEFORE THE METER AND INSTRUMENT SECTION, 5TH FEBRUARY, 1932, ON THE PAPERS BY DR. WOOD (SEE PAGE 41) AND PROF. MACGREGOR-MORRIS AND MR. WRIGHT (SEE PAGE 57).

Dr. C. V. Drysdale: With regard to Dr. Wood's paper, the cathode-ray oscillograph is undoubtedly a tool of great importance. Within the last 10 years it has come more and more into vogue, and it seems obvious that its use will greatly extend in the future. Although the old types of oscillographs will still have a great field of application, the cathode-ray oscillograph has given us powers and opportunities of exploring phenomena which we could not have investigated by other means. The author has been the pioneer in this country of the hard internal-photography cathode-ray oscillograph, and he has not only given the instrument a simple and portable form but has also carried the details of the technique to a high pitch of perfection.

Turning to the paper by Prof. MacGregor-Morris and Mr. Wright, while there can be no question that the unsealed type of cathode-ray tube has many advantages as regards internal photography, it nevertheless involves always using a complete evacuating outfit. The fact that for each series of exposures one has to let in the air, withdraw the plates, and then evacuate again, militates against the portability of the apparatus. Furthermore, the advantage of having a tube which can be used for external photography is that it enables one to obtain a continuous record extending over a long time, whereas internal photography is only capable of a comparatively short range over a very small plate. When we were first concerned with the use of the cathode-ray oscillograph, I considered that a sealed form would be the ideal one, and more than 10 years ago I sketched out a design the main features of which seem to be almost identical with those of the von Ardenne tube. On the other hand, there are various difficulties associated with the sealed form of instrument. First, there is the question of the gradual decrease in the emission of the filament, which is not very serious; but I felt at the outset that the great difficulty in the way of the development of a sealed form of tube with sufficient intensity for external photography would probably be the luminescent compound. Unfortunately, luminescence under strong bombardment seems to be always accompanied by the disintegration of the luminescent material. All the luminous compounds which are used for luminizing dials have a fairly long life, but they do decay materially, and, naturally, the heavier the bombardment the greater the rate of decay. Only recently I saw a tube which had been in use for a comparatively short time; when it was switched on, the central portion of the fluorescent screen was seen to be less luminous than the remainder, probably owing to the fact that the illumination was more usually confined within that area. We really want a tube which we can seal and keep sealed for years. If we have periodically to open the tube, renew the luminescent screen, and re-evacuate, the advantage over the pump form is much less. An investigation with the object of obtaining luminescent materials of greater resistance to disintegration would be very valuable, not only in the case of the cathode-ray oscillograph but also in connection with luminous compounds. The radium or other exciting salt generally has a very long life, but the luminescent substance (e.g. zinc sulphide) begins to deteriorate after a comparatively short time. Concerning the relative value of hard and soft tubes, I think on the whole the advantage lies with the former. While soft tubes have certain advantages as regards sensitivity, ionization of the gas which they contain gives rise to many difficulties and errors, as Prof. MacGregor-Morris and Mr. Wright have described.

Dr. Wood has shown us how extremely sensitive the hard type of tube with internal photography is, and there is no doubt that for very high-frequency work we shall be forced to use this type for a long time to come. It is unfortunate, also, that even with the sealed tubes a record cannot be satisfactorily obtained without using very wide-aperture photographic equipment, which is costly and involves additional trouble in setting up. If we could only get a perfectly plane and very thin end to the tube there might be a chance of obtaining a sufficiently sharp image by means of a film running in close contact with it, and I think that this is what we should aim at achieving. One difficulty associated with most cathode-ray oscillographs is that of getting more than one trace. Dr. Wood showed one film on which there was a time trace, and I should like to know whether this trace was a simultaneous record. In oscillograph working it is very valuable to obtain not only a time trace but also a simultaneous record of two or three phenomena. How this can possibly be done by means of the cathode-ray oscillograph I do not see, but it is a problem to which those engaged on the subject should devote their best talents. It might, of course, be attempted by having two or more screened systems in the same tube, but the registration of the spots would probably involve difficulties.

Mr. J. E. Calthrop: I should like to make a few comments on the paper by Prof. MacGregor-Morris and Mr. Wright, with particular reference to the method of plotting the results. In view of the fact that the plates may be slightly inclined and hence the lines of force may be curved, there will be great difficulty in sending the beam through the centre, and I think the following method of plotting the results would be preferable. Taking a few figures from Table 1 as an illustration, I think we ought to plot for ± 2, ± 5, and ± 7 volts the mean deflections obtained. The positive voltages give rather large and the negative voltages rather small deflections, but in the case of the higher voltages the results come close together, and in order to find the law which is being obeyed we have to take the mean of the observations. This method gives a straight line which does not go through the origin, so that the expression for the deflection comes out to be

$$\delta = 0{\cdot}91(V - 0{\cdot}8)$$

I read off the deflections from the curves in Fig. 6, plotted them according to this plan, and obtained the following result. On plotting against V one gets for the four anode voltages a series of four straight lines which intersect at the same point (where $V = 1$ volt). I will not attempt to explain why this point does not fall at the origin; it seems, however, that the whole of the applied voltage is not really effective in deflecting the beam, so that the formula which is applicable is of the type:—

$$\frac{\delta}{V - V_0} = K$$

The deflection is also given by

$$\delta = KV\left(1 - \frac{V_0}{V}\right) \quad \text{or} \quad \frac{\delta}{V} = K\left(1 - \frac{V_0}{V}\right)$$

This equation shows that for low voltages the correcting factor is important, and therefore we must not expect the deflection to be proportional to the voltage. At higher voltages, however, the correcting factor becomes very small and the sensitivity approaches the expected value. As regards the variation of the sensitivity with the anode voltage, I plot S against $1/v$, where v = anode voltage and $S = \delta/(V - V_0)$ = sensitivity. Although sinple theory would lead us to expect a straight line through the origin, plotting the sensitivities as described above gives a straight line which does not pass through the origin, but which has an equation of the form:—

$$S = K\left(\frac{1}{v} - \frac{1}{v_0}\right)$$

By putting the two together I derive the following formula, which at least fits the author's observations.

$$\delta = K(V - V_0)\left(\frac{1}{v} - \frac{1}{v_0}\right)$$

This gives reasonably accurate values for the deflection, for any deflecting voltage and any anode voltage. This slide shows a typical calculation [Mr. Calthrop here exhibited a lantern slide], for which the equation is

$$\delta = 332{\cdot}5(V - 1)\left(\frac{1}{v} - \frac{1}{1\,750}\right)$$

Taking a point at random for which $v = 280$ volts, $V = 14$ volts, and $\delta = 13$ mm, I find that the calculation gives δ as 12·96 mm. Fig. A(b) illustrates the above treatment. I have recently been endeavouring to find an equation for the sensitivity curve which would take the above form for higher voltages and yet give no sudden discontinuity near the origin. The equation

$$\delta = KVe^{-V_0/V}$$

has been tested for one of the sensitivity curves, and has been found to fit the observations very well. This may be expanded, and only the first few terms of the resultant series retained. Thus

$$\delta = KV\left(1 - \frac{V_0}{V} + \frac{V_0^2}{2V^2}\right)$$

$$= K(V - V_0) + KV_0^2/(2V)$$

Hence for higher voltages, the equation takes the form found above. The advantage of this expression is that it shows the so-called zero-point anomaly not as a sudden discontinuity but as a bend near the origin, which straightens out more and more as higher voltages are

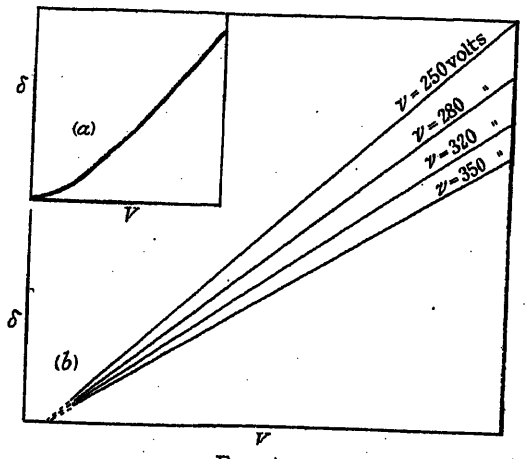

FIG. A.

(a) $\delta = KVe^{-V_0/V_0}$ (b) $\delta = K(V - V_0)$

approached. This curve is depicted in Fig. A(a). I do not know the theoretical explanation of this behaviour.

Dr. F. Simeon: I should like to ask Dr. Wood whether it is necessary with all types of photographic recording instruments to use the kind of silver-iodide plate which he has had developed at the Admiralty laboratory, and also whether this is a particularly difficult type to produce. Are these plates as difficult to make and as necessary for this kind of work as the Schumann plates are for ultra-violet photography?

Dr. T. E. Allibone: I shall refer first of all to Dr. Wood's paper. Speaking for those users of oscillographs who are engaged on the examination of transient phenomena on high-tension transmission lines of all voltage ratings and their effect on terminal apparatus, lightning arrestors, etc., I should like to say that for us the distinguishing and only valuable characteristic associated with oscillographs is their maximum writing speed. We are not interested in voltage sensitivity in general, because the transients which we observe occur on high-tension lines and therefore a sufficient voltage is always available; nor are we especially concerned with portability, since all the apparatus with which we deal, even if it weighs a few hundredweights, is easily transported in the field. Let us therefore consider for a moment the approximate writing speed which we need for recording transients. The figure can be arrived at by studying the records obtained on American transmission lines, on which much work has already been done. To obtain a clear photograph of a transient of 1 or 2 in. amplitude on a linear time-base of the order of a micro-second or less, we need a convenient writing speed of about 500 km per sec. If one wishes to work on the physics of spark-gaps, it will be preferable to have a shorter time-base than 10^{-7} sec. I have had experience of both low-voltage and high-voltage oscillographs. I found that the low-voltage type, such as that described by Dr. Wood,

was entirely unsuited to the transient phenomena which I wished to investigate, for the following reasons. In the first place, the energy of the cathode rays is too small, so that it is necessary to use special forms of Schumannized photographic plates; even so, the energy is still too small for high writing speeds. Incidentally, any form of special technique for dealing with photographic films is rather a disadvantage, because it complicates the operation of the oscillograph. Secondly, the electrostatic focusing of low-voltage electrons is inherently poor; it is no doubt influenced by the magnetic field round the filament, though this effect has been overcome by one or two ingenious methods. The use of hot cathodes in discharge tubes is also generally discredited, because the emission current from a suitably small area is too small and it is impossible to use a large area of emission since this will increase the minimum size of the spot on the plate. An advance in the direction of using hot filaments is only likely to come through the use of, for example, the ingenious device developed by Prof. Rogowski, who employs much higher temperatures for his emitting source and therefore obtains a much greater emission current without increasing the area of the source. The third disadvantage of the low-voltage oscillograph is that it dispenses with magnetic focusing of the beam, with a consequent loss of intensity. I cannot support Dr. Wood's remark with regard to the use of a solenoid to focus a beam of electrons. The mathematical treatment of the subject was worked out in 1928 by Busch,* who showed that such a solenoid has all the physical properties of a lens. Prof. Rogowski had observed the action of a solenoid (which must be short compared with its diameter) before Busch published the mathematical solution, and it is now well established that for a given distance between source and screen the solenoid allows a large angle to be used, with a consequent increase in the number of electrons. Finally, the intrinsic luminosity of a fluorescent screen is so much greater in the high-voltage oscillograph than in the low, that it is an easy matter to photograph this fluorescence with a camera. Attempts to intensify the ultra-violet light component emitted by the screen are of great value, since they enable a greater writing speed to be obtained; with the high-voltage oscillograph Rogowski has achieved writing speeds of several hundred kilometres per sec. The use of the Lenard window becomes possible with the high-voltage oscillograph, because the window can be as thick as 10^{-3} cm and can easily be obtained free from holes. Higher electron energies enable one to use asymmetrical circuits for deflecting the electrons, an important feature from my point of view. To observe the magnitude of a surge on a transmission line, one of the pairs of deflecting plates in the body of the oscillograph is connected through the potential divider to the line, the other being connected to earth, and the resultant electrostatic field between the plates is a measure of the surge voltage. In asymmetrical circuits one is liable to encounter difficulties in connection with the beam of electrons, because one of the plates is at the potential of the case and the other is not. These difficulties become less as the speed of the electrons is increased. Using 75 kV on the discharge tube of the oscillograph, Prof. Binder (of Dresden) has been able to apply 100 kV to the deflecting plates of the oscillograph. Dr. Wood remarks that Knoll has dispensed with magnetic focusing. This is true in so far as it applies to the discharge tube, where both Knoll and Binder have developed good electrostatic focusing, but they use a solenoid to focus the electrons between the anode and the photographic plate. Rogowski maintains that better results can be obtained with two solenoids. Fig. B is an oscillogram of an impulse lasting a few micro-seconds. In this case the electron beam is switched on to the photographic film just at the moment when the transient arrives. A very short time afterwards two other calibrating records are added to the picture: (*a*) the permanent voltage on the deflecting plates, and (*b*) a time scale measured in micro-seconds. These are recorded by mechanical switching, but it could be done electrically. The impulse is applied to a point-plane spark-gap set for 700 kV; the voltage rises to a maximum, is maintained almost constant,

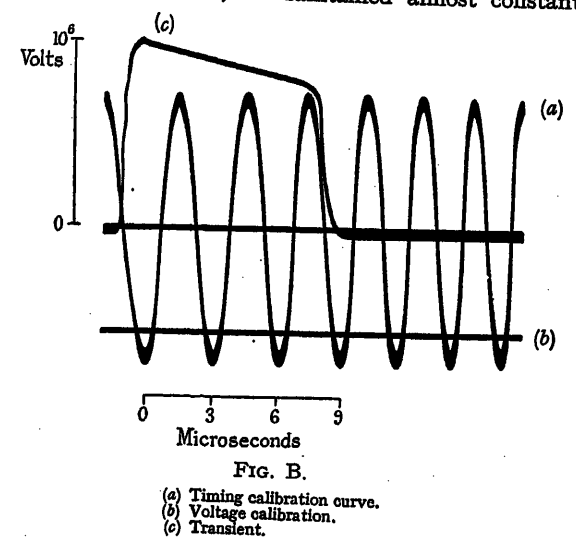

FIG. B.

(*a*) Timing calibration curve.
(*b*) Voltage calibration.
(*c*) Transient.

ionization occurs in the gap, and breakdown ensues after about 9 micro-seconds. A resistance is placed in series with the impulse generator so as to vary the rate of rise of voltage. The voltage rises in 0·5 micro-second, which represents a moderately slow impulse, and decays to half value in 20 micro-seconds. [Dr. Allibone here exhibited an example of high-speed writing recording, the pictures having been taken in 0·4 micro-second.]

With reference to the paper by Prof. MacGregor-Morris and Mr. Wright, if in the case of the sealed-off type of oscillograph it was very necessary to get rid of the threshold effect, could not this be done by separating the deflection plates from the discharge-tube portion of the oscillograph by means of a diaphragm with a small hole in it and maintaining a difference of pressure between the two chambers of the oscillograph by means of a sealed-on pump?

Mr. J. F. Herd: With regard to Dr. Wood's paper, I think the author's classification of oscillographs into two groups, high-voltage and low-voltage, is rather arbitrary, and that in his presentation of the case he does not pay sufficient attention to the medium-voltage

* *Archiv für Elektrotechnik*, 1927, vol. 18, p. 583.

sealed-off type, for which there is undoubtedly a great future and a wide range of uses. It could be made as convenient in operation as the ordinary wireless valve. In fact, with properly-designed auxiliary apparatus, it has now practically reached that state. The medium-to-low-voltage oscillograph is numerically the most important, even if we impose the distinction that an instrument which is limited to visual observations should really be called an " oscilloscope." The same tube may well be used for both low and medium voltages, the main point of difference being the material of the fluorescent screen. Incidentally, I think the author wrongly describes as " phosphorescence " what should rather be termed " fluorescence." In the present state of fluorescent materials a sealed-off low-voltage tube would be primarily used for visual observations or the photography of quasi-stationary images, and zinc silicate seems to be the best material for the screen. The great increase obtained in the intensity of fluorescence on increasing the voltage from 300 or 400 volts to 3 000 or 4 000 volts gives the medium-voltage tube a wide field of use in many forms of external photography and as an oscilloscope. With regard to the advantages of external photography with a medium-voltage tube, on one occasion we obtained 1 100 records in a recording period of only 4½ minutes, whereas using visual methods on precisely the same type of work our previous speed was about 150 to 160 records per hour. It would undoubtedly be an improvement if medium-voltage tubes could be made with higher vacua, thus minimizing many of the ionization problems which arise. Other desirable improvements in the tube are more sensitive fluorescent materials and greater sharpness of the spot. External photography has of recent years greatly benefited from the development of lenses and of film-emulsions for cinema purposes, but improvements are still possible, especially in the lens system. One other possibility, to which reference is made in the paper, is that of a quartz end—or even a quartz window over a limited portion of the end—to permit of better penetration of the fluorescence. For instance, calcium tungstate has a fluorescence which extends well into the ultra-violet, and obviously a great deal of this may be lost in a glass tube and glass lens-system. The fact that a voltage of 3 000 to 4 000 volts is required to operate these tubes is not a serious difficulty, because the anode currents are so small that they can be derived from an eliminator of simple type. The currents are generally much less than 1 mA, and a half-wave rectifier with simple smoothing system is quite sufficient. Considerable advances have recently been made in the construction of oscillographs, some of these being embodied in the new low-voltage instrument produced by Standard Telephones and Cables, Ltd., the medium-voltage oscillograph due to von Ardenne, and the model on generally similar lines developed by the Edison Swan Electric Co., Ltd. A new British oscillograph intended for either low-voltage or medium-voltage operation has also recently been produced by Messrs. A. C. Cossor, Ltd. I have used an oscillograph of this type quite satisfactorily at all voltages from 300 or 400 volts up to over 3 kV. I think the list of references in Dr. Wood's paper should include a paper describing a new time-base circuit, using a mercury-vapour valve, due to A. L. Samuel.* Another recent bibliographical addition is a paper† by J. B. Johnson on the general theory and uses of cathode-ray oscillographs. In connection with single-traverse time-bases, I have had occasion recently to use a simple method employing a condenser with a saturated diode, after the manner of the recurrent base shown in Fig. 7 of Dr. Wood's paper. The arrangement is shown in Fig. C. The condenser C is charged by the battery B, deflecting the spot to the left side of the oscillograph screen. Release of the key K allows the condenser to discharge through the diode D in a manner that can be caused to follow a law practically linear with time. During this period the spot travels in a corresponding manner across the screen, giving a timing voltage for any transient phenomena applied to the other pair of plates. The battery B_1 serves to maintain saturation of

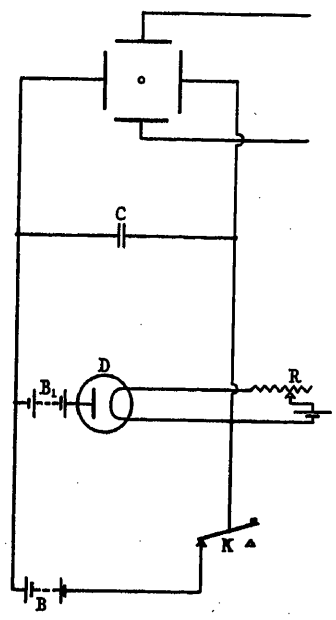

FIG C.—Circuit for single-sweep linear time-base

the diode, with consequent improvement of linearity. The speed of the time stroke is governed jointly by the capacitance of C and the adjustment of the diode filament, and is capable of a wide and easy range of control.

With regard to the paper by Prof. MacGregor-Morris and Mr. Wright, I am particularly interested in the threshold effect mentioned by the authors. I think a rather better name for it might be " origin-distortion." We have a neat method of testing for it by means of apparatus developed for another purpose. This is a potentiometer giving voltages proportional respectively to cos θ and sin θ on the two pairs of plates, as θ is varied in 10-degree steps. When the potentiometer is supplied with alternating current this gives a pattern in the form of a line tilted to the vertical axis at the angle θ. Rotation of the potentiometer revolves the line and reveals this type of distortion wherever it occurs. I have noticed that, among a batch of otherwise similar

* *Review of Scientific Instruments*, 1931, vol. 2, p. 532.
† *Bell System Technical Journal*, 1932, vol. 11, p. 1.

tubes, many show an abnormal amount of distortion in those quadrants which lie adjacent to the vertical deflection. The ionic-cloud theory to which reference has been made is no doubt largely substantiated in practice, but I doubt whether it represents the whole of the story. To give a concrete example, when using one of the Standard Telephones and Cables "4018A" tubes referred to by the authors I found that with a certain filament current and anode voltage which gave an excellent visual focus, the potentiometer method showed no trace of origin-distortion. If the focus was reset by increasing the filament current and readjusting the shield voltage, a well-focused spot was obtained, coupled with definite origin-distortion. As regards the effect of magnetic fields, when calibrating the tube one must ensure first of all that the spot is in a uniform field. Secondly, if the calibration is one which, for its use, demands that the spot should be restored to a certain position, it is essential that it should always be returned by means of precisely the same field as was used for this purpose at the time of the calibrations. An excellent method of shielding these small tubes from stray magnetic fields, including that of the earth, is by means of a mumetal screen, or, more cheaply, with an ordinary piece of drainpipe! As regards the difficulty mentioned by the authors that the von Ardenne tube necessitates the use of a third voltage, this is not a serious drawback if the tube operates with a negative cylinder, since the third voltage can be obtained without any increase of current-load by the well-known method of introducing a bias derived from a resistor joined between the cathode and the h.t. negative return lead. I have used this arrangement regularly both with von Ardenne oscillographs and with the new Cossor oscillograph, and have found it to be very satisfactory in operation.

Mr. G. A. Whipple: In view of the rapidly increasing demand for cathode-ray oscillographs of all types, it would be useful to formulate some definite standards by means of which the relative capabilities of various types of tubes could be judged. Such standards would be of service to both the user and the manufacturer. Setting aside considerations of cost and auxiliary apparatus, the criteria by means of which the user selects a tube are voltage sensitivity and photographic sensitivity or maximum linear recording speed, both these figures of merit being given at a stated accelerating potential and with stated anode and conduction currents flowing. The voltage sensitivity is readily determined, and is stated in millimetres per volt on the deflecting plates. The photographic sensitivity seems to present a more difficult problem. Some manufacturers and workers maintain that their tubes will record up to certain stated frequencies, an assertion which has no meaning until the amplitude of the wave and the width and intensity of the trace have been specified. What is required is a specified maximum recording speed corresponding to a certain defined blackening of the photographic surface at this speed; in fact, a recording speed formulated on the basis of a standard oscillogram relative to which any given oscillogram will have a figure of merit. M. Knoll* has comprehensively defined maximum linear recording speed. The first step is to take a definite minimum darkening of the photographic plate. This intensity of darkening is derived photometrically and should be given by

$$\log_e (I_0/I_T) = 0{\cdot}1$$

where I_0 and I_T are the intensities of light transmitted through the unaffected and the trace-darkened portions of the photographic negative respectively. Then, assuming always that this photographic intensity condition is fulfilled, the standard oscillogram is taken as one having a ratio of amplitude to trace width of 50 : 1. If a recording speed of $r_{max.}$ is attained on any oscillogram, say by impressing a square-peak travelling wave on a line of known length and measuring the speed from the record of the wave front, then the true maximum linear recording speed ($r_{s\,.\,max.}$) referred to standard conditions is given by

$$r_{s\,.\,max.} = r_{max.} \times \frac{1}{50} \times \frac{a}{d}$$

where a is the amplitude and d the width of the trace. It would be of interest if Dr. Wood or Prof. McGregor-Morris could suggest methods by means of which the performance of cathode-ray oscillographs could readily be judged.

Mr. F. S. Robertson: With regard to the paper by Prof. MacGregor-Morris and Mr. Wright, their statement that some of the errors of manipulation are due to charges on the walls of the tube is borne out by the fact that in experiments where very highly-exhausted quartz tubes are employed it is often necessary to place earthed metal shields round the inside of the tube in order to prevent effects due to electrons which may otherwise become attached to the inner wall. If in these cases the screen is put outside instead of inside the tube, the effect is often worse than with no screen at all. The authors have clearly shown that the so-called "threshold effect" is not really a threshold effect in the true sense of the word. Any phenomenon which makes the potential gradient in volts per cm over the centre portion of the space between the plates less than (Volts applied to plates)/(Distance between plates) is likely to cause this effect. What we have to consider is not merely the potential gradient in volts per cm, but the volts per cm in the vicinity of the cathode ray per volt applied to the plates. The force acting on the electron is determined by the true potential gradient. Any effect such as space charge or difference of contact potential due to dissimilar conditions at the surfaces of the plates, which will cause the true potential gradient in the vicinity of the cathode beam to be less than (Applied voltage)/(Distance between plates), will cause the true potential gradient per applied volt to be small for very small values of the applied voltage but after passing zero applied voltage to increase rapidly at first and then to become practically constant for the larger values. The authors seem somewhat diffident in pressing their explanation as they find that the effect persists even at frequencies of the order of 10 000 cycles per sec.; but, after all, the effect is due to moving electrons, for which the necessary speed would be a matter of small consideration.

Mr. R. Mines: I should like to refer to the von Ardenne

* *Zeitschrift für Technische Physik*, 1931, vol. 12, p. 54.

tube, which I have had occasion to use. In connection with the ionic focusing, at a high velocity of traverse of the spot one can observe a blur which is produced by the continuous movement of a very much finer spot. It is suspected that this phenomenon is actually taking place all the time. In recording 10 000 cycles per sec. with a wavelength and an amplitude on the record of about 1 cm, one can definitely observe that the spot has an epicyclic (or hypocyclic) movement; it moves in a circle as though in the ionic focusing process the beam of electrons were rotated about an axis. It is highly desirable to eliminate this rotation for the purpose of recording at high speeds. If the rotation can be eliminated, this tube is capable of giving a very fine trace. Using these tubes we have observed the phenomenon of failure of the screen material. When a voltage up to the maximum recommended by the makers (4 000 volts) is used, a few seconds' exposure to the stationary spot will cause a brown or even a black spot to appear on the white screen, which loses its fluorescence at that particular point. In practice this trouble is evaded by making sure, in the case of single-trace recording, that the spot never remains stationary on the screen, or else by focusing the spot near the edge of the screen and setting the time-scale deflection so that it traverses a piece of clean screen afterwards. It would be an advance to produce a fluorescent material which is not subject to this disadvantage. In connection with external photography, I have successfully employed a photographic lens having an aperture of $f/2{\cdot}9$. This is much larger than the size of photographic lens usually available, and due to its being very accurately corrected it costs a good deal in comparison with the total outlay on the oscillograph equipment. A cheaper form of lens, less highly corrected, with either one or two pieces of glass (perhaps plano-convex), might be good enough for the purpose, however. Such a lens could be made with a bigger aperture, even as large as $f/1{\cdot}0$. Dr. Allibone suggested dividing the tube into two compartments by means of a diaphragm of small aperture, the compartment in which the deflecting plates are placed being exhausted to a higher vacuum so as to eliminate the threshold effect. It seems to me, however, that in the tubes where this effect occurs it is impossible to apply such a device, because the essential point of the method of ionic focusing adopted in such tubes is that the cross-section of the ray is kept down to a low value throughout the whole length of its path. If that constraint is relaxed over two-thirds of its path, or at any rate over its path between the deflecting plates and the screen, obviously it will be impossible to prevent the scattering which it is desired to avoid. If a single trace of the spot is used, when the spot is deflected off the screen it is found to be necessary to ensure that its deflection is many times the diameter of the latter. If the ray is deflected so that it glances on to the side walls of the tube, reflection of the electrons takes place to a very considerable extent and causes illumination of the screen and fogging of the exposed plate. If the ray can be bent round so that it strikes the parallel and not the conical portion of the tube, at an angle approaching 90°, this effect causes no trouble.

Prof. J. T. MacGregor-Morris: I should be glad if Dr. Wood would put forward his views on the focusing system of the new Standard Telephones and Cables type of tube. The difference between the new tube and the von Ardenne type is that whereas in the one the focusing cylinder is positively charged, in the other it is negatively charged. In 1928, at Purdue University, I had the privilege of examining Mr. R. H. George's electrostatic focusing tube, the negatively-charged cylinder of which was moved up and down by means of a rack and pinion, so that one could focus the cathode beam as easily as a microscope. In connection with phosphorescent materials, I should like more information regarding the statement that "Rogowski and Ruhlemann obtained at 55 kV a value of 35 lumens per watt for the luminous output of the screen of a high-voltage tube." This is nearly equal to the efficiency of an arc lamp. Can we regard the cathode-ray tube as ultimately becoming an efficient source of light? In connection with the capacitance of the leads and deflecting plates of the oscillograph, recent measurements of the dielectric losses in liquids appear to indicate that the losses in the leads and plates amount to about one-fifth of the total loss, and, therefore, if cathode-ray oscillographs are to be used at very high frequencies this factor will have to be carefully considered. In conclusion, the author refers (page 54) to a simple switch the contact arms of which fall into mercury cups. Many years ago I used this arrangement for rather lower speeds, and I found that when the contact arm first made contact the mercury rebounded, and broke and remade the circuit two or three times.* A mechanical extension was applied so that this was permanently in the mercury, with the result that when the actual electric contact entered the mercury it closed the circuit satisfactorily.

Dr. A. B. Wood: In the Summary to their paper Prof. MacGregor-Morris and Mr. Wright state that the chief part of the paper deals with what is known as the "threshold effect," and then they give a theory of this effect which is based on the fact that the tube contains gas. I think a better title for the paper would have been "Accuracy of Measurements made with Gas-Filled Cathode-Ray Tubes." Their remarks about the threshold effect do not apply to high-vacuum tubes. The general explanation of the focusing action in gas-filled tubes is that a column of positive ions is formed along the axis of the beam and that a diffused cylinder of negative electrons surrounds it, thereby producing a radial field which focuses the beam. If this is the correct explanation, would it not be much simpler to use a high-vacuum tube, which has no complicated gas corrections, and a simple focusing device consisting of a thin positively-charged wire running down the axis of the tube, surrounded for some distance by a negatively-charged cylinder? The latter should then have the same effect in a hard tube as the gaseous ionization has in a soft one.

Mr. L. H. Bedford (*communicated*): The opinion that the "inter-plate current" in the gas-filled cathode-ray oscillograph is due solely to ionization seems to be quite generally held, but the following facts are sufficient to show that this view must be erroneous. (*a*) The "inter-plate current" persists practically unaltered in a high

* See *Electrician*, 1907, vol. 59, p. 292.

vacuum. (*b*) The mean free path of the electrons is usually several times the length of the bulb, from which it may be deduced that the amount of ionization is not nearly sufficient to account for the observed plate currents. (*c*) The currents remain "electronic" even for quite high negative plate voltages (see Fig. 7 of the paper by Prof. MacGregor-Morris and Mr. Wright). We believe that the explanation of these facts will be found by following up a point which has largely escaped attention in the literature of the subject. This is the question: How do the electrons which pass through the gun get back to it? In the early days this point was slurred over by saying that, in the first place, only a very small proportion of the electrons actually passed through the gun, and those which hit the screen got home partly by leakage over the glass and partly by ionic conduction. This argument is quite fallacious, more especially when applied to modern tubes with disc anodes and Wehnelt-cylinder focusing; for in these tubes it is quite possible for the entire anode current to go through the gun hole and down the beam. Since the mean free path is several times the length of the bulb there are only enough ions to take care of a small proportion of the current, and this leaves far too big a residue to be accounted for by leakage. The true state of affairs appears to be that the electrons get home by means of secondary emission from the fluorescent screen. If this is the case, then, since the number of secondary electrons falls off to zero as the speed of the primaries is reduced, we should expect to find that on progressively reducing the gun voltage a point would be reached where the tube would suddenly fail to function; this is actually observed, and the mode of failure is exactly in accordance with the supposition that the screen is piling up negative charge. Accordingly it is suggested that what has been looked upon as "inter-plate current" would be better described simply as "plate current." When one of the plates has its potential changed, what happens is really a redistribution of the return space current amongst the four deflector plates and the gun. In the Cossor oscillograph, which was referred to in the discussion by Mr. Herd, this state of affairs is recognized and the anode is provided with a shielding extension which embraces the deflector plates as completely as possible and intercepts a very large proportion of the return space current. The effect of this shielding is very striking (see Fig. D). It will be noted that the plate current is very greatly reduced and the ionic current is no longer masked by the electronic current, but shows up clearly on the negative side. The fact that "origin distortion" still persists with this tube in spite of the much reduced electron plate currents, indicates that the space-charge effect is ionic and not electronic in character, a conclusion which was also reached independently by calculation; the electrons produce no measurable space-charge effects of this sort. An attempt has been made to investigate mathematically the matter of origin distortion, but in its complete form the problem was found intractable. However, a good deal of light can be thrown on the problem by considering it in the following manner. The electron beam passing between the plates may be regarded as a virtual emitter of ions and electrons; owing to their high mobility the latter produce no measurable space-charge effects and they may be ignored for the present purpose, but of the former we may inquire what negative voltage on a deflector plate is required to "saturate" this virtual ionic emission. Unfortunately, even now matters are too complicated to allow of an accurate solution, but by means of sufficiently violent approximation one may arrive at least at the order of the effect to be expected. Curiously enough, a first calculation gave a "threshold value" of 5 volts, exactly the figure arrived at independently by Prof. MacGregor-Morris and Mr. Wright. The term "threshold value" is here exactly appropriate, for it is that value of deflector-plate voltage which is required before any field appears at the beam. Actually, of course, this treatment is only approximate and the threshold value is no more sharply defined than is the transition from temperature to voltage saturation in a diode. That this view of the threshold effect is substantially correct is confirmed by the observation that the effect decreases with reduced gun current and with increased beam diameter, the latter being measured in the neighbourhood of the deflector system. A beam which is very thin where it passes through the deflector plates gives a much more pronounced threshold effect than a thicker beam carrying the same current. Unfortunately, a thin beam is necessary for other reasons, and a compromise has therefore to be made. Reference was made in the discussion to the longitudinal effect of deflector-plate voltage. This is usually only observable when very large deflections are involved, but in any case it can always be completely suppressed by operating the deflector plates symmetrically in push-pull, a point which adds to the already known advantages of tubes in which all four deflector plates are brought out separately. Mr. Mines mentioned that he had observed certain types of internal oscillation in the oscillograph

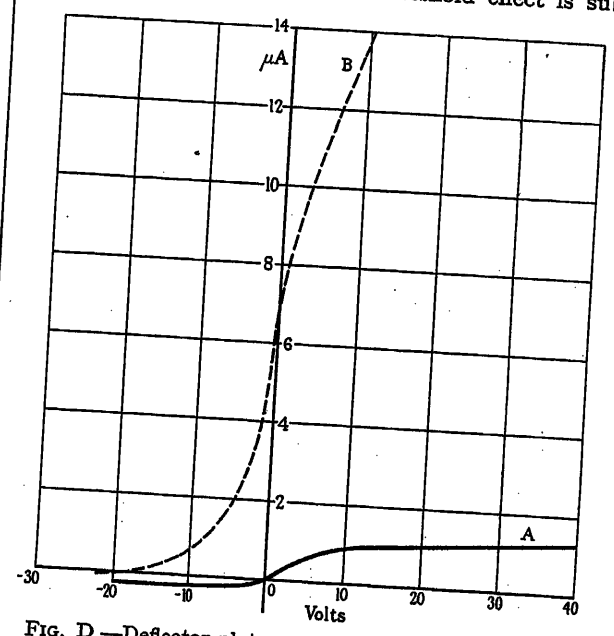

FIG. D.—Deflector-plate current at 50-μA gun current.

Curve B. Similar structure without shield.

tubes. We have experienced more than one variety of this effect, and have found that it appears to be associated with glass charge effects in the neighbourhood of the deflector plates, and particularly on the portion where the conical part of the bulb joins the parallel neck. A piece of tinfoil wrapped round this portion will generally stop these oscillations. In the case of the Cossor tube it was found necessary to extend the anode shield beyond this portion in order to suppress oscillations completely without resorting to external shielding. Although this appears to effect a complete cure of the trouble, we are really at a loss to visualize the mechanism of these oscillations.

Mr. R. Davis (*communicated*): I should like to supplement to some extent Dr. Wood's remarks on the development in the design, and the technique of the use of, the cathode-ray oscillograph for high accelerating voltages. The first step in this direction was taken by Dufour. He was followed by Norinder in Sweden, and soon after by Rogowski and his co-workers in Aachen, and Gabor in Berlin. Their instruments were similar generally in design. The discharge tube was of glass and the rest of metal. Accelerating voltages of 60 to 70 kV were used, with a cold cathode, and the cathode current was of the order of 1 mA. In order to have as high a vacuum as possible in the deflection chamber and sufficient gas in the discharge tube to provide the requisite cathode current, the oscillographs were operated with two separate vacua; continuous pumping was resorted to in the deflection chamber, while the gas pressure in the discharge tube was controlled by a suitable leak. It was found that the gas discharge tube was not always suitable for continuous operation. The glass walls near the cathode developed surface discharges leading to irregularity in the cathode stream. Further, the electron discharge caused heating in the discharge tube with a release of gas molecules, and a consequent fluctuation in the discharge-tube vacuum. This led to the use of the metal discharge tube, or its equivalent, by Berger, who required the oscillograph for continuous operation in lightning studies on transmission lines. Knoll, in Berlin, also used the metal discharge tube and furthermore made a success of external photography through a Lenard window, as described by the author. Knoll was able to dispense with the fore concentrating coil used by Rogowski, and to achieve similar results largely through being able to use a much larger cathode current. Further improvements in this construction consisted of mechanical refinements whereby the deflectional sensitivity could be varied under vacuum, and in addition the shape of the deflection plates was designed to give maximum sensitivity. Later, Binder and his co-workers produced a cathode-ray oscillograph which consisted of a large metal tube 30 cm in diameter and about 2 metres long. The discharge tube was at one end of the tube, separated from the rest of the oscillograph by a suitable diaphragm. The high voltage applied to the cathode was brought in through a porcelain bushing. The advantage of this type of tube over the previous metal discharge tubes was (*a*) the large volume, which prevented sudden fluctuations in the pressure, (*b*) the remoteness of the walls of the tube, and their disturbing effects, from the cathode, and (*c*) the fact that the field through which the beam passed was approximately uniform. To localize the discharge on the surface of the cathode, a cylindrical electrode, the potential of which was left floating, was placed concentrically with it. An additional important feature of this oscillograph was the design of a pair of ordinate plates for a voltage of 200 kV. Previously the deflecting plates of oscillographs had been designed for voltages of from 5 to 10 kV. With deflection plates for this high voltage much work can be carried out without the aid of voltage-dividers and their attendant sources of error, and the properties

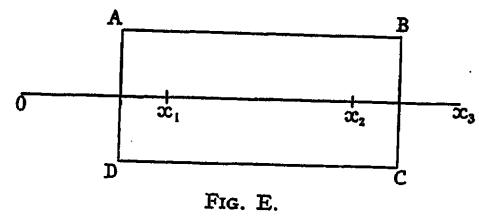

FIG. E.

of dividers for use in registering very rapid transient phenomena can be investigated practically. On the question of recording technique, the author outlines some of the methods which have been used for synchronizing abscissal and ordinate deflection so as to enable a satisfactory record to be obtained on the photographic plate. The function of the timing circuits in recording single transients is to move the beam from some position O (Fig. E) so that at the onset of the transient it takes up a position such as "x_1" on the photographic plate ABCD. During the time occupied by the transient the beam moves from "x_1" to "x_2" at a constant abscissal speed, this speed being controlled by the time-constants of the timing or abscissal plates. Their subsequent motion in the abscissal direction takes the beam to the position "x_3." Arrangements must

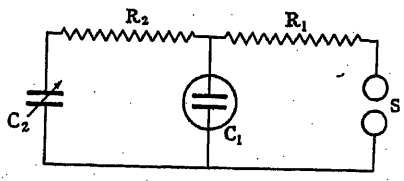

FIG. F.

be made to remove the beam to the initial position O without blackening the exposed film, before a further record can be made. Many arrangements have been used to suit different experimental conditions, as the author points out. The first rapid jump Ox_1 may be obtained by the sudden charge or discharge of a special pair of timing plates through a circuit of very small time-constant. This operation may be initiated simultaneously with the normal time deflection through a spark-gap common to the two circuits. An arrangement due to Krug* avoids the necessity for a special pair of timing plates to produce the initial motion of the beam and bring it on to the photographic plate. The arrangement is shown in Fig. F, in which C_2 represents a variable condenser, C_1 the time deflection plates

* *Elektrotechnische Zeitschrift*, 1930, vol. 51, p. 605.

of the oscillograph, R_2 and R_1 resistances, and S a spark-gap. A d.c. supply is connected across the spark-gap. When the gap breaks down, the voltage on C_2 falls to a value $VR_1/(R_2 + R_1)$, V being the trigger voltage, in a time given approximately by $C_1 R_1 R_2/(R_1 + R_2)$, where C_1 represents the capacitance of the timing plates. The subsequent abscissal motion is controlled by the time-constant $C_2 (R_1 + R_2)$, where C_2 is the capacitance of the variable condenser. By using a charging voltage instead of a discharging voltage to deflect the beam, the final position of the latter can be made to coincide with the initial. There then arises the problem of synchronizing this deflection with the ordinate deflection due to the phenomenon under investigation. When the latter is controlled and its voltage is the same as that which operates the timing circuit, the two can be released by a common spark-gap. Further control can be exercised by varying the length of the conductor connected to any one pair of plates. Generally the ordinate voltage differs from the value used to operate the timing plates. In such a case it suffices to allow the spark-gap which releases the time sweep to be placed near a gap which is released by the transient, so that when the latter breaks down the former is disturbed and breaks down also. This modification is readily adapted for registering uncontrolled transients such as those occurring on transmission lines, as well as the controlled transients of the laboratory. The voltage divider presents a special problem in high-voltage cathode-ray oscillography owing to the very high speeds frequently involved, with a consequent tendency to distortion and delay. I should like to refer to two points in this connection. The oscillograph cannot always be placed close to the test object or transmission line, and consequently a long lead or cable may be required to join the high-voltage arm of the divider to the low-voltage end across which the ordinate plates are connected. If such a divider is to divide the voltage correctly and without distortion, no reflection of the fraction of the surge which travels along the connecting cable must occur at the low-voltage end of the divider. To ensure this, the equivalent surge impedance must form part of the low-voltage arm of the divider. Such a divider has been used and described by Gabor.* For use on transmission lines carrying the working voltage at power frequencies the divider can be made insensitive to low frequencies. A considerable quantity of literature has accumulated in Europe and America on the subject of the recording of high-speed transient phenomena. Dr. Wood's paper is welcome as showing that in this country the importance of such developments is not being overlooked.

Dr. J. L. Miller (*communicated*): We have recently developed a cold-cathode type of oscillograph for the measurement of high-speed transients, and some remarks based on our experience may be of interest. Except in the Introduction, Dr. Wood's paper makes little mention of cold-cathode discharge tubes, despite the fact that most of the transient measurements by the General Electric Co. and the Westinghouse Co. in the United States, Norinder in Sweden, and Berger in Switzerland, have been made with high-voltage cold-cathode type instruments. Obviously, therefore, these instruments form quite a large and important section of the subject of cathode-ray oscillography. We found it a troublesome matter to build a discharge tube that would operate quietly at 60 000 volts for long periods, would have the inherent property of giving a finely-focused cathode ray, and would not cause pitting of the cathode surface after too short a time. Quite a lot of experimenting had to be carried out before the laws governing the design were understood. It is obvious that the diameter of the beam can be controlled by the size and shape of the cathode and of the discharge tube round and behind the cathode, and we made considerable efforts to use these data so as to provide good electrostatic pre-anode focusing. In addition, of course, main electromagnetic focusing takes place some distance below the anode. The necessity of good pre-anode focusing is sometimes questioned, but obviously it is essential in some form or other, and all cold-cathode instruments have it by accident if not by design. The only real question is: How good should this focusing be? Our experience is that from the point of view of fineness of trace on the photographic plate it is better to use good pre-anode focusing and a small anode hole, rather than poor focusing and a larger anode hole. Thus, although it would appear from the few details given from time to time in the foreign technical Press that some designers do not particularly concern themselves with this question, it is worthy of note that many of them do. For instance, Rogowski is the great advocate of pre-anode electromagnetic focusing, and he uses a concentrating coil above the anode; Knoll designs his later discharge tubes so that the cathode and anode are very near together, and, in addition, the cathode is surrounded by an anode tube; and Binder obtains very good electrostatic focusing by surrounding the cathode with a metal cylinder which is free to take up any potential. Berger tells me that his cathode is surrounded by two or three concentric glass cylinders of gradually increasing length. It is also possible to obtain quite good focusing by means of a cylindrical glass shield whose periphery is just below that of the cathode; in addition, a suitably shaped hollow cathode can be used. Another question which frequently arises is whether it is better to have a glass or a metal discharge tube. When a glass tube has been in operation for some time, a layer of metal may be deposited on the inner surface of the glass due to the pulverization of the cathode. Even when this deposit became excessive due to an accident, it could not be ascertained that it had any detrimental effect, and this view is confirmed by Dicks.* We can therefore state that the glass discharge tube has a useful life of many hundreds of hours, all that is required being a periodic renewal of the cathode. The metal tube is better for mechanical reasons because it lends itself more easily to accurate centering, and because it is more readily adaptable to the use of devices giving still better electrostatic focusing. Regarding photographic films or plates, high-voltage rays will record photographically on almost any emulsion when inside or direct photography is used, but it is quite a

* "Forschungshefte der Studiengesellschaft für Höchspannungsanlagen" (Vol. 1 of the Research Organization for the Study of High-Voltage Problems).

* H. Dicks: "Glass or Metal Discharge Tubes?" *Archiv für Elektrotechnik*, 1931, vol. 25, p. 523.

different matter when it is desired to employ external direct contact photography by utilizing the luminosity effect of cathode rays falling on a phosphorescent material like calcium tungstate. In all our earlier work inside photography was employed, but for the sake of convenience and ease of operation we decided to explore the possibilities of outside photography. Using an ordinary commercial plate, an excellent record of an oscillation having a frequency of 200 000 and superimposed oscillations of 10^7 cycles per sec. on one part of it, could be obtained with one single sweep of the time base, the cathode potential being 60 000 volts. Using external photography and a similar photographic plate in direct contact with the glass sheet 0·25 mm thick, coated with calcium tungstate and supported by a suitable grid, the main oscillation was easily discernible on developing, but the superimposed oscillation was very difficult to follow. Rogowski's external records show a similar fault at very high frequencies. In order to get good records of higher frequencies with outside light blackening photography, it seems that one must employ the minimum thickness of glass to prevent blurring, and have rather more current in the post-anode beam than is necessary for internal photography. Eventually, when the cathode potential becomes high enough, the glass will transmit a reasonable percentage of the electrons striking it, and I am interested to see that the author estimates that at 160 kV, using glass 0·17 mm thick, there would be a 50 per cent transmission. A further difficulty with external glass contact-photography lies in the fogging produced on the photographic plate when records are taken at short time-intervals, because the fluorescent material is liable to emit light for some considerable time after the ray has been removed from it. Although our development work in this direction is not yet complete, at this stage we agree with the author that the direct effect is many times greater than the indirect effect. Probably, if the inconvenience of breaking the vacuum in order to change plates is to be avoided, it may be necessary to use a real Lenard window employing thin aluminium sheet for recording very high frequencies. In his remarks on the timing of single impulses, the author draws attention to the ingenuity and skill required to synchronize the unknown transient and the timing or sweeping movement. Actually, the problem is a little more difficult than that indicated by his statement, because with the notable exception of the Norinder instrument all oscillographs require the synchronization not of two, but of three circuits, the additional one being the ray-withdrawing circuit. This operates in such a way that the beam is prevented from passing through a small hole in a diaphragm in the upper part of the oscillograph by means of a potential applied to one pair of deflecting plates. Closure of a switch automatically destroys this potential, allowing the beam to pass through the hole in the diaphragm; after a very short time-interval, variation of the potential on the second pair of deflecting plates causes sweeping to commence, and then, after a predetermined delay, the unknown transient arrives at the third pair of deflecting plates via a short line or delaying cable. When the beam has completed its traverse, the potential is re-applied to the first pair of plates and the beam is withdrawn. The whole operation may be over in something of the order of a few micro-seconds, and we have successfully used the arrangement to record artificial transients having a total length of $1{\cdot}7 \times 10^{-6}$ sec. Some experimenters are in favour of employing in the withdrawing circuit a valve the grid potential of which can be controlled by the surge current flowing in the timing circuit, so that withdrawal of the ray cannot occur until the current in the timing circuit has fallen to a predetermined value, thus causing the ray to be withdrawn automatically at the end of its traverse. It is our experience, however, that it is difficult to overcome the capacitance effects to earth of the supply transformer for the valve. We find it preferable, therefore, to use a connection where the withdrawing circuit is directly in parallel with the timing circuit; if care be taken in the choice of capacitances, damping resistances, and resistances to absorb reflections, this connection is capable of giving very satisfactory operation. Time bases which sweep across in, say, 1 micro-second or less, are liable to grave errors unless due precautions are taken, and occasionally one has the unhappy experience of finding that time is going backwards! Also, the damping in the circuits in which the transients under examination exist, must not be overdone. The author describes a mechanical switch of a very simple type which he has used to good effect. We have used an even simpler one which consisted of a large mousetrap with just one or two additions, and it worked very well! I am glad to see that the author draws attention to the fact that resistance-type potentiometers are liable to give rise to distortion when used for high-speed work. I support this view, and think that their use is to be deprecated. I should also be glad to know his opinion of the insulator-string-type potentiometer.

THE AUTHORS' REPLIES TO THE DISCUSSION ON THEIR PAPERS (SEE PAGES 41 AND 57 RESPECTIVELY).

Dr. A. B. Wood (*in reply*): The enthusiastic discussion is a sufficient indication of the increasing interest which is being taken in the development of cathode-ray oscillographs. Such a response is very encouraging to those taking an active part in this development. I am particularly grateful to Dr. Allibone, Mr. Davis, and Dr. Miller, for their remarks on high-voltage oscillographs used to record transients at very high speeds. Little work of this character has hitherto been reported in this country, and I was therefore forced to refer somewhat extensively in my paper to the results obtained by Continental and American workers. As shortage of space prevents me from replying adequately to all the speakers, I must ask their indulgence if I have overlooked any of the points they have raised.

Dr. Drysdale refers to a few of the desirable features of cathode-ray oscillographs and mentions in particular sealed tubes with external photography. I have indi-

cated in the paper how far these desiderata have been achieved up to the present, but there is still much to be done. The two traces obtained on one plate were not made simultaneously by two independent cathode streams. They were made independently with a single stream of cathode rays. Dufour describes a double tube for such a purpose, but I do not know whether it has proved successful.

Replying to Dr. Simeon, ordinary gelatine plates are sufficient for many purposes, depending on the recording speed and the generating voltage of the cathode rays. At low recording speeds, low-voltage cathode rays will record on ordinary plates. Cathode rays generated at high voltages (30 kV or more) will record sufficiently well on ordinary plates at the highest speeds of traverse. The silver iodide plates which I have used are not difficult to make; they are similar in many respects to Schumann plates and may be prepared in somewhat the same manner.

Dr. Allibone and I are working at opposite ends of the cathode-ray "scale." He requires the maximum recording speed irrespective of voltage sensitivity, whereas I want both voltage sensitivity and high recording speed. As I have pointed out in the paper, these two desiderata are not easy to obtain simultaneously. The "lens action" of the solenoid is very interesting, and my statement in this connection refers to a long solenoid with a magnetic field which is assumed to be uniform. The focusing action to which Dr. Allibone refers is apparently due to the radial component of a distorted field produced by a short solenoid.

I would draw Mr. Herd's attention to my remarks at the beginning of the paper, explaining that the division of cathode-ray oscillographs into two groups—high- and low-voltage—is purely arbitrary. It is impossible to draw satisfactory lines of voltage division to distinguish between the various types. While opinions seem to vary with regard to the use of the words "phosphorescence" and "fluorescence" in connection with a material like calcium tungstate or willemite, I think Mr. Herd has got hold of the less popular definitions. The name "fluorescence" is generally applied to the phenomenon exhibited by such substances as fluorescene (an aniline derivative), paraffin oil, and a solution of quinine sulphate, which when illuminated by violet or ultra-violet light emit green or blue light (of longer wavelength than the incident light). Fluorescene emits a brilliant yellowish-green light when exposed to daylight or an arc. The phenomenon of fluorescence was investigated by Sir George Stokes, who framed the law relating to the degradation of wavelength. Fluorescence continues only so long as light is incident on the fluorescent substance. Certain substances, e.g. the sulphides of calcium, barium, and strontium, continue to emit light, however, when the existing source of light is removed. This effect is termed "phosphorescence." Balmain's luminous paint contains a mixture of these sulphides. Calcium tungstate, willemite, etc., also exhibit phosphorescence. The effect may continue for a period varying from 10^{-4} second to several hours, depending on the nature of the substance. Glass is phosphorescent under the action of cathode rays. All solid fluorescent substances are found to be phosphorescent also, and it may be due to this fact that confusion has arisen. Both phenomena are quite distinct, of course, from the faint greenish-white luminosity which phosphorus shows when exposed to moist air in the dark. This effect is due to chemical oxidation (slow combustion) of the phosphorus. I am obliged to Mr. Herd for details of the simple arrangement using a condenser and diode which he has devised, and for the reference to A. L. Samuel's paper on a new time-base.

Mr. Whipple raises the important point that in view of the large variety of cathode-ray oscillographs it would be an advantage if some common basis of comparison (e.g. a figure of merit) could be devised. The principal difficulty which would be encountered in formulating such a standard arises from the fact that the "merit" of an oscillograph depends upon the object in view. Thus Dr. Allibone requires a high recording speed and is not in the least concerned with voltage sensitivity. I, on the other hand, regard this as very important. There is no common ground of comparison in these two cases. The matter is, however, sufficiently interesting and important to warrant further consideration.

In reply to Prof. MacGregor-Morris, I cannot venture an opinion regarding the difference in the focusing action of the gas in the Standard Telephones and Cables tube and the von Ardenne type. In both cases gas is used to produce the focusing action. There must be other ways of focusing which do not involve the objectionable features associated with the introduction of gas into the tube. As to the high luminous efficiency of the phosphorescent screen of Rogowski and Ruhlemann, while the result is very striking one cannot imagine any known phosphorescent material withstanding such a bombardment for more than a few minutes. With regard to the mercury switch, I have not experienced such troubles as those to which Prof. MacGregor-Morris refers.

Prof. J. T. MacGregor-Morris and **Mr. H. Wright** (*in reply*): Although the higher-voltage hard-vacuum tubes are rapidly developing in the direction of higher recording speeds and so are finding new fields of application as well as extending the older ones, we feel that the lower-voltage tube has a field of at least equal breadth and freshness. The sealed-off tube is an instrument easy to handle and can be set up almost anywhere in a laboratory in a short time, costs little in time or money for maintenance, and is ready for use as soon as the circuit is complete. Until the hard tube can be handled in this way the sealed-off gas-focused tube will continue to hold sway in its own wide province in spite of the errors and possible troubles due to the presence of the gas.

Dr. Drysdale suggests that the most promising direction for development is the production of better fluorescent materials for the screen. Hitherto efforts have been made to obtain screens giving light which is brilliant for visual work and actinically active for photographic work. It is now possible to obtain photographic plates which are many times more sensitive to yellow light than any other plate is to light of wavelength extending from the blue to the ultra-violet region. Were it possible to produce a fluorescent material giving a yellowish or faintly green light there would be no

need to use quartz either in the tube or in the camera lens.

The almost simultaneous recording of current, voltage, and time-base was regularly carried out for over a year at East London College. The records were made at power frequency by means of a commutator arrangement which successively put each trace on for one cycle. In many phenomena under investigation the change occurring over three cycles is very small, so that in these cases this method can be applied. It may be noted here that time intervals down to 10 micro-seconds could be measured on photographic traces obtained with this apparatus, and the measurement of shorter times would have been possible had the phenomena under investigation been sufficiently constant to allow of longer exposure.

Mr. Calthrop has developed a formula which certainly gives a good approximation, but we cannot agree with him that the asymmetry of the deflection/voltage curve is due to experimental error. As the plate-current curve is not symmetrical and the space-charge effect will be closely related to this current, it is only reasonable to suppose that the space charge will be different when the plate is positive to that which it is when negative. Unfortunately, the equations given by Mr. Calthrop do not hold at the lower voltages. It does not seem likely, in view of the complicated nature of the current, that any simple equation can be obtained which will fit the curve at all working values of the voltage. The difference is probably due to the asymmetrical arrangement of the deflecting plate circuit, as one plate is connected permanently to the anode and the other is either at a higher or lower potential. This can be overcome by arranging the plates in "push-pull" as has been suggested, but this would not be possible with a tube of the Standard Telephones Co.'s pattern. It is not out of place to remark here that there is a difference of opinion regarding the exact manifestation of the threshold effect. Johnson states that there is no deflection for the first few volts, while Bedell and Kuhn depict the deflection as being produced in steps over about the same range of voltage. In the work under discussion the effect has always been observed as a continuous one, as the curves show.

It is pleasing to note Mr. Herd's remarks, which so strikingly show the possibilities of recording with the sealed-off gas-focused tube. Now that so much interest is being taken in this type of tube, as is borne out by the comparatively large number of new types which have been put on the market recently, it is to be hoped that still further developments will be forthcoming to make recording more easy. The potentiometer method of detecting the "origin distortion," as Mr. Herd suggests calling it, would lead one to the conclusion, from considerations of the actual results obtained, that the distortion disappears entirely at certain conditions of focusing. The sensitivity of one pair of plates is different from that of the other, and the distortion effect is also different. The distortion which is observed can only be the difference in the distortion produced by the mutually perpendicular deflecting pairs, so that, due to their different distances from the screen, there are likely to be a large number of combinations of filament current and anode voltage which makes the distortion/sensitivity ratio the same for both pairs of plates, and so the trace appears undistorted although the threshold effect is still present, and may even be increased and not diminished. With regard to the best name to use for this effect, there are four terms which are used by different experimenters:—(1) The threshold effect, (2) space-charge effect, (3) zero-point anomaly, and (4) origin distortion. Of these the space-charge effect is the only one which suggests a possible cause. For the present, however, until the effect is completely understood it is probably wiser to use the term "origin distortion."

We agree with Mr. Whipple that a factor of merit for tubes would be a highly desirable thing to have. At the moment, nothing can be suggested, other than his proposal, which would afford a true comparison. The one drawback associated with any method involving relative photographic sensitivities is that the actinic light from the fluorescent screen is concentrated in certain parts of the spectrum. This would mean that the specification of a given plate as a standard might conceivably penalize one tube because its fluorescence was green and not blue, whilst if another plate were used it might completely reverse the results. Another point which would have to be taken into account would be the fineness of the trace, as a thick one could lead to fairly large errors in measurement.

The trouble with the blurred spot and parasitic looping described by Mr. Mines has also been experienced by us. In our case we found it to be due to insufficient smoothing of the anode supply. In the presence of an external field this will cause the beam to oscillate slightly, owing to the change in sensitivity with anode voltage, and this produces the blur. When the tube is used under certain conditions this oscillation becomes "locked" with either the time-base or the applied oscillatory deflecting force, and appears as a steady figure on the screen.

We should be interested to hear of experiments embodying Dr. Wood's suggestion of the focusing wire. Would not the trouble be that, due to the comparatively long time it takes for the electrons to travel from end to end of the tube, the repulsive force between the electrons in the stream would have time to make itself evident by lack of focus? The reason that the term "gas-filled" did not appear in the title was because it was felt that the term had been so long associated with the half-watt lamp that it implied a high gas pressure instead of a fairly good vacuum. We suggest that the term "gas-focused tubes" might be used as being nearer the mark, and we have now altered the title of the paper.

Mr. Bedford's contribution to the discussion has certainly gone a long way towards explaining the mechanism of origin distortion. He rightly states that the means of ridding the screen of its negative charge has too long been overlooked. On analysing the curves shown in Fig. 17, i.e. those for the plate current in the 4018A tube, it was found that they had the general form

$$I = A + BV^n + C \operatorname{arc\,sinh} DV$$

the values of the constants varying for each curve, and it is interesting to note that this falls in line with Mr. Bedford's analysis. It would seem that the term A

represents the normal drift of electrons returning from the screen to the anode, and the last term shows how these redistribute themselves between the two plates as the potential difference between the plates is increased, the total number arriving at the plates being constant. The exact significance of the middle term is not too clear, as it gives positive values of current for negative values of voltage, although the form of it is somewhat as would be expected for a diode, corresponding to the current produced by the removal of ions from the beam.

The remarks of speakers have definitely indicated the direction in which improvements in this type of tube are desired, and they are, in brief, speedier recording and the elimination of origin distortion. With the wider interest and augmented experience of increased usage, it is to be hoped that these improvements will not long be delayed.

A CIRCULAR TIME-BASE GIVING RADIAL DEFLECTIONS, FOR USE WITH THE CATHODE-RAY OSCILLOGRAPH.*

By The Staff of the Radio Research Station, Slough.

(*Paper first received 25th February, and in final form 18th April*, 1932.)

Summary.

In the study of electromotive forces varying with time, the electromotive force under examination is caused to modulate similarly and simultaneously two voltages which are applied in quadrature to the deflecting plates of a cathode-ray oscillograph. The resultant screen-image on the oscillograph consists of a circular time-base, on which are superposed radial deflections delineating the wave-form and the time relationships of the applied electromotive forces.

Introduction.

Perhaps the most frequent of all the applications of the cathode-ray oscillograph in experimental research is in the study of the variation of an electromotive force with respect to time. The electromotive force may be in itself the primary object of study, or it may be derived from electrical or mechanical phenomena which may conveniently be converted into a proportionate electromotive force. The use of a piezo-electric crystal in association with a cathode-ray oscillograph for the study of pressures may be cited as an example of investigations of this latter class. Now that sealed-off cathode-ray oscillographs can be obtained in a comparatively inexpensive and reliable form, it may reasonably be hoped that this remarkably flexible tool will find applications in still wider fields of investigation. The purpose of the present paper is to describe a convenient accessory circuit for use in such applications.

Linear Time-Bases.

In the earlier applications of the cathode-ray oscillograph to the study of varying electromotive forces, it has been customary to trace out the time curve of variation in Cartesian co-ordinates, the ordinates being proportional to the electromotive force under investigation, and the abscissæ being made to vary in accordance with a known and controlled function of time by means of special time-base circuits. The inconvenience of the sinusoidal time-base has been avoided by the introduction of a variety of linear time-bases, in which the indicating spot is made to move at a substantially uniform velocity from left to right, and then to return quickly to the left. This form of time-base is produced by the application to the time-base electrodes of an electromotive force of " saw tooth " wave-form. One such linear time-base† derives the required electromotive force from the fluctuations of the potential of the grid of an intermittently oscillating (" squegging ") valve using a saturated diode as the grid leak. This device, originally introduced for the study of the wave-form of atmospherics, has recently been used for the study of the retardation time of echo signals returned from the ionized layers of the upper atmosphere.‡

Circular Time-Bases.

In some investigations it may be convenient to delineate time relationships in polar co-ordinates instead of in Cartesian co-ordinates. Even when polar co-ordinates are not required, it may be convenient to refer the electromotive forces under study to a time-base of circular form rather than to one of linear form. An example of such an application is found in the harmonic comparison of frequencies.§

In previous applications of the circular time-base with truly radial reflections, the deflectional sensitivity of the oscillograph has been modulated in accordance with the variations of the electromotive force under investigation, by applying this electromotive force in series with the

e Papers Committee invite written communications, for consideration view to publication, on papers published in the *Journal* without being : a meeting. Communications (except those from abroad) should reach cretary of the Institution not later than one month after publication of er to which they relate.

anode battery.* If, however, the electromotive force to be studied varies rapidly, this method is unsatisfactory when used with cathode-ray oscillographs of the sealed-off variety, in which the residual gas pressure is relatively high. The changes in the effective anode voltage which result from the modulation process alter the sharpness of focus of the indicating spot, since such sharpness is a function of the filament current, the anode voltage, and the gas pressure.

In experiments on the retardation time of wireless echoes, Goubau and Zenneck† utilized a circular time-base obtained by applying equal timing voltages in quadrature to the two pairs of deflecting plates in the oscillograph. The electromotive force under observation was superposed on the electromotive force applied to one pair of plates, thus producing vertical departures from the circular time-base. If the echo signal arrived when the indicating spot was moving with a considerable horizontal component of velocity, its time of incidence was easily determined, but if it arrived when the spot was moving nearly vertically, the departure from the circle was nearly tangential and the order of accuracy of the determination of time of arrival was relatively low.

In an editorial comment‡ on these experiments, it was suggested that the experimental technique might be very greatly improved by the use of a radial instead of a vertical movement of the spot. The particular electrode system suggested in the editorial note would not, however, give the desired result. Circuits had previously been devised in this station for fulfilling these requirements, and it is thought that an outline of the method may be of value to other workers.

Description of the New Device.

If the electromotive force under observation is represented by $e = f(t)$, it is desired that the spot should move on a curve of which the polar co-ordinates are

$$r = a + b\,.f(t) \quad \text{and} \quad \theta = \omega t$$

where a and b are constants and ω is the angular velocity of the spot in radians per second.

The cycle of indication will be repeated $f\,[= \omega/(2\pi)]$ times per second.

Changing to Cartesian co-ordinates, we have

$$x = r\cos\theta = [a + b\,.f(t)]\cos\omega t$$
$$y = r\sin\theta = [a + b\,.f(t)]\sin\omega t$$

It will be seen that the desired result is obtained by applying to the plates voltages in quadrature, these being modulated by the electromotive force under observation.

Of the many modulating methods available the push-pull modulator described§ by Heising was chosen.

The voltages in quadrature are obtained by tapping off the voltages from a condenser and a resistance in series. The circuit, which is shown in Fig. 1, is nearly self-explanatory. C and R are adjusted to have the same impedance at the frequency f, and they supply two audio-frequency transformers with centre-tapped secondaries. Condensers C_1 are connected across the half secondaries, in order to provide a low-impedance path for the transient $e = f(t)$ which is applied between the centre points of the secondaries and the valve filaments. The anodes of the valves are connected to

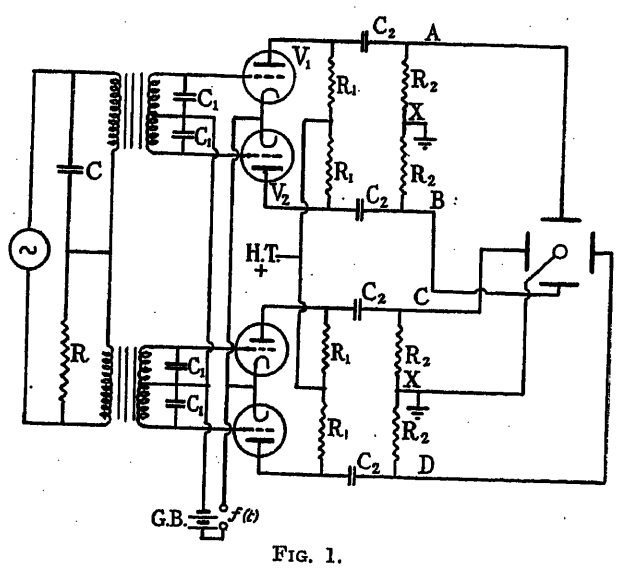

Fig. 1.

H.T. + through resistances R_1 and (through condensers C_2) to the four deflecting plates. (In the cathode-ray oscillograph employed, the four plates are separately accessible. This avoids the use of an output transformer with centre-tapped primary, which would probably distort high-frequency transients.)

The grids of the valves are biased so that the operating

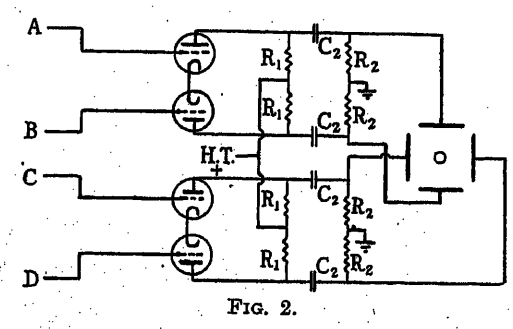

Fig. 2.

portion of the $i_a - e_g$ characteristics is approximately parabolic.

The theory of this modulator is given in Appendix 1.

Use of the New Base.

The use of the device may be illustrated by Figs. 3 and 4. In these the electromotive force $e = f(t)$, represented approximately in Cartesian co-ordinates in Fig. 3, was supplied from an intermittent (" squegging ") oscillator, the grid condenser discharging through an ohmic resistance. The variation of the time-constant of the condenser and its associated leak controls the

period of operation over a wide range. Fig. 4 is reproduced from a tracing of photographs taken with the intermittent oscillator working at 50, 100, 200, and 650 cycles per second. In each case a separate exposure was given in order to show the undisturbed circular base. It will be seen from Fig. 4 that the straight part of the trace, representing the extremely rapid charging of the condenser during high-frequency oscillation, is approximately radial, no matter at what point in the cycle it occurs.

Advantages.

The advantages presented by the time-base circuits just outlined include the following.

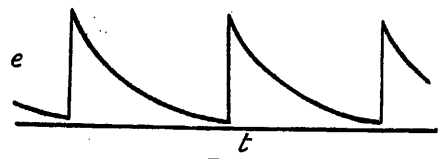

Fig. 3.

In common with other circular time-base circuits the length of base can be made nearly as great as the effective circumference of the oscillograph screen—in the present case 31 cm.

The circular time-base, by reason of the continuous angular rotation of the spot, lends itself well to permanent and accurate calibration as regards time; for example, by the application of a voltage of frequency nf in series with the voltage e. In these circumstances stationary ripples will appear on the circular base, dividing it into n parts representative of equal intervals of time. This subdivision is independent of the small departures from truly circular form which may result from imperfections in the oscillograph.

The circuits described eliminate the defects of focusing experienced with other circuits in which radial deflections are obtained.

Applications.

Among the many types of experiment in which the application of this form of time-base would be advantageous, a few typical cases may be mentioned.

It is unnecessary to add to what has already been said on the direct application of the circuits described in the study of the variation with time of transient phenomena, whether these occur periodically or not. It may, however, be useful to refer to other typical applications in which the circuits have special merit.

In the harmonic comparison of frequencies, for example, the methods described by Dye and others may be applied over a considerably extended range. The uniform sharpness of the spot over the whole trace enables comparisons to be made between the reference frequency of the time-base and a very high-order multiple of that frequency. Observations have been made on about 18 000 cycles per second against a time-base of 50 cycles per second. In this case the ripples are separated by one degree of arc which, on the circumference of 31 cm used in the experiment, corresponded to a distance of 0·8 mm, and the latter is sufficiently large compared with the effective diameter of the indicating spot to leave no ambiguity in the determination.

The circuits also lend themselves to the accurate comparison of two frequencies of very different orders when these frequencies are not in an exact harmonic relation. If the frequency f_1 is much greater than f_2, f_1 is applied as the time-base frequency while f_2 is caused to apply a short transient electromotive force. If f_1 is an exact multiple of f_2 the transient will appear always at the same point on the screen, while departures from the exact relation will result in displacements of the transient in the screen image. For example, if f_1 is made accurately 50 cycles per second and f_2 is derived from the alternate swings of a seconds pendulum, the apparent movement of the transient on the screen will show the departure of the pendulum frequency from uniformity. Since a movement of 1° of arc can easily be detected, a departure of $1/50 \times 1/360 = 1/18\,000$ sec., i.e. 1/36 000 (about 0·003 per cent) of the period, in the rate of the pendulum can be measured with ease. This departure corresponds to a rate of about $2\frac{1}{2}$ seconds per day, and the determination is made in a few seconds if the swings of the pendulum are themselves uniform. The details of any non-uniformity in swing can be quickly studied in the same way.

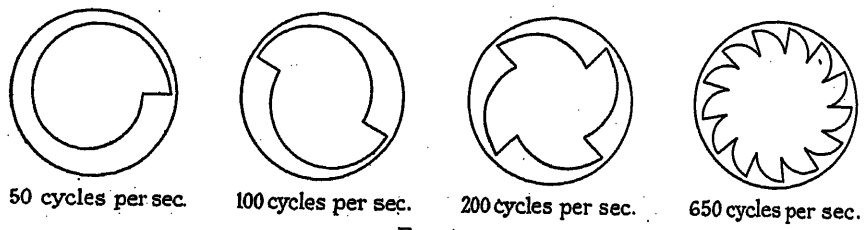

Fig. 4.

Thanks are due to the Department of Scientific and Industrial Research for permission to publish the details of this device.

APPENDIX 1.

The Theory of the Modulator.

It is assumed that the valve is working over a part of the characteristic which is parabolic, i.e. that the relation between i_a and e_g is of the form

$$i_a = c + de_g + he_g^2$$

where c, d, and h are constants.

It is only necessary to consider the upper half of Fig. 1.

The voltage applied to the grid of V_1 is

$$a \cos \omega t + b \,.f(t)$$

That applied to the grid of V_2 is

$$- a \cos \omega t + b \,.f(t)$$

The voltage across the resistance R_1 connected to V_1 is

$$R_1 i_a = R_1\left[c + d\left\{a \cos \omega t + b \,.f(t)\right\} + h\left\{a \cos \omega t + b \,.f(t)\right\}^2\right]$$

and in the case of V_2 is

$$R_1\left[c + d\left\{- a \cos \omega t + b \,.f(t)\right\} + h\left\{- a \cos \omega t + b \,.f(t)\right\}^2\right]$$

The resultant deflection on the "vertical" plates, due to the difference between these two, is therefore proportional to

$$R_1\left\{d(2a) \cos \omega t + h(4ab) \cos \omega t \,.f(t)\right\}$$

by expanding and subtracting term by term, and this is equal to

$$2aR_1 \cos \omega t\left[d + 2bh \,.f(t)\right]$$

which is of the form required.

APPENDIX 2.

Components for a 50-Frequency Time-Base.

The following values of components were used (in conjunction with a 50-frequency supply) in the time-base arrangements for a cathode-ray oscillograph with a deflectional sensitivity of about 1 mm per volt.

The valves should be matched; and this is best done by turning off the circular-base electromotive force and applying only the transient to be studied. When the circuit is balanced the spot should remain stationary, i.e. no trace of the transient should be detected.

The values of the components used were:—

$f = 50$ cycles per second; voltage, about 1·5 volts;
$C = 4\mu$F; $R = 800$ ohms; $C_1 = 0{\cdot}04\mu$F;
$C_2 = 0{\cdot}25\mu$F.
Low-frequency transformers, ratio 1 : 3·5.
Valves, L.S.5b, working with 4 volts L.T.
$R_1 = 50\,000$ ohms; $R_2 = 1$ megohm;
H.T = 180 volts; grid bias = 4·5 volts.

If greater amplification than that given in Fig. 1 is required, the leads are broken at A, B, C, D, and are connected as shown in Fig. 2, the points X in Fig. 1 being connected to a bias battery of about 6 volts.

DISCUSSION ON

"THE DESIGN OF A DISTRIBUTION SYSTEM IN A RURAL AREA."*

THE AUTHORS' REPLY TO THE DISCUSSIONS AT LONDON, GLOUCESTER, GLASGOW, SHEFFIELD, NEWCASTLE, MANCHESTER, LIVERPOOL, AND BIRMINGHAM (SEE VOL. 70, PAGES 235 AND 449).

Messrs. E. W. Dickinson and **H. W. Grimmitt** (*in reply*): In the first place we wish to express our appreciation of the way in which the paper has been received and to thank those who took part in the discussion for the constructive criticism which indeed was what it was desired to evoke, because the subject is admittedly a most thorny one. We had little idea that the paper would arouse such widespread interest and discussion, but it was clear from the first meeting that this was because the matter had been engaging the earnest attention of so many in the industry. We ourselves had considered that the paper was little more than a collection and a digest of information.

We are pleased to find that the main conclusions of the paper have not been materially affected by the discussion. It has been so great in volume—upwards of 70 speakers have taken part—that it is obviously impracticable to reply to each speaker individually, nor is it desirable, as with discussion at so many Centres the same point has been raised repeatedly. Hence we propose to answer points rather than speakers. We ask indulgence if any points have been overlooked.

Some important parts of the paper escaped discussion altogether, and it may therefore be inferred that these were generally accepted. Much of the discussion was devoted to detail of design and reduction in cost of construction, especially of the low-tension distribution. The question as to a proper form of tariff again evoked much interest, and we have been somewhat criticized for not carrying the matter further. We intentionally refrained from doing so, being fully convinced that a matter so highly controversial should not be introduced as though it were a subsidiary one, and contented ourselves with expressing the opinion, which we would reiterate very strongly, that a two-part tariff wherein the service charge rises and the unit charge falls with increased use is essential (see page 235). The subject is more fully dealt with later in our reply, but we would seize this opportunity to suggest that the subject of tariffs is one that might well be dealt with comprehensively by some member better qualified than ourselves and having more intimate knowledge of the problem. At any rate the conclusion reached in the discussion was generally to approve of the unit charge being kept in as close a relationship as possible with actual running cost. Although a great variety of opinion was evident as to what the basis of the "Service charge" (based on the fixed costs) should be, it seems clear that the industry is still seeking for a method of charging which bears some closer relationship to the quantities sold, namely, kilowatts and kilowatt-hours, than has so far been the custom. If electricity is to become a commodity of universal use its sale price should not, for instance, be made mysterious by a reference to amenities of a certain district or the ability of the consumer to pay what might be inferred from the use of rateable value as a basis. The basis of floor area is for the same reasons incorrect as only a portion of a dwelling may be occupied.

Several speakers emphasized what we said as to the importance of keeping down fresh capital expenditure to a minimum and the necessity of making better use of the capital already invested in order to afford progressively cheaper supplies to consumers.

On the question of costs of equipment as shown in the schedules on pages 226, 230, and 232 and adopted in the paper, opinion seems to be divided, some considering the estimates much too low, while others found them too high. We conclude, therefore, that the figures we have taken may be regarded as a fair average throughout. Since writing the paper we have been confirmed in our belief by the fact that large contracts have been placed at prices approximately equal to, if not less than, those given in the paper.

As was to be expected, the paper was approached by some speakers from the point of view of their own undertakings, or of their own particular experiences, and their criticism went to show how local physical conditions affect detailed design.

Modifications of Conclusions.

Referring to the conclusions set out on page 234, it can be said that no exception was taken to the accuracy of the statistics and the deductions therefrom, on which the earlier part (Conclusions 1 to 5) was based.

Nothing was advanced to rebut the conclusion that the present radius of supply of electricity can be extended materially so as to include areas of less population density than at present provided for—roughly 375 persons per square mile at the time the paper was written (Table 6)—and that this can be done with confidence.

No argument has been adduced to show that Conclusion (7)—that in rural areas any reduction in the charge per unit to consumers will lead to increased sales and greater gross revenue—is untrue.

As regards Conclusion (8), we admit that "application of a tariff under which the charge for electricity is reduced *pro rata* to consumption, it can confidently be hoped to tap large sources of revenue" is rather a bald statement and should be modified as it is applicable to domestic supplies, for which load factor can roughly be

* Paper by Messrs. E. W. Dickinson and H. W. Grimmitt (see vol. 70, page 189).

gauged. For power purposes the price should be a matter of agreement based on a kilowatt and unit charge, if possible modified for off-peak load supplies.

In regard to Conclusion (9) the discussion has not led us to depart from the view that development should take place on a comprehensive design and not sporadically (see page 191). Much that was cogent was advanced in the discussion in favour of a creeping development outward on a flexibly designed network, always giving time for revenue to accrue to justify further expansion. We are satisfied, however, that the comprehensive design will be more and more adopted as time goes on, and we merely cite, as the most recent examples, those for Dumfriesshire and Northern Ireland.

As to the extent of the area that should be considered, we quite realize that areas of much smaller extent than 400 square miles exist, but it seems obvious that they should be amalgamated with neighbouring areas.

Conclusion (10)—that the best pressure for the distribution in rural work with scattered loading is 11 000 volts, 3-phase—has been generally conceded, and is desirable both from the point of view of uniformity and of interchange between areas. As to the system of supply, we recognize that a case has been made out for single-phase working in those areas where there is little hope of industrial loads or where the load is purely domestic.

Conclusion (11)—that the cost of overhead lines and equipment can be reduced to a minimum by standardization, bulk purchase of material, and such preparations as will ensure continuation of construction—has been accepted without real question, although it has emerged that financial considerations, especially in small, struggling undertakings, militate against development in this way.

As regards Conclusion (12), we admit the force of the criticism that we have been too sweeping in stating that electrification should proceed in all areas over which powers of supply are held. Obviously the statement should be read in conjunction with the finding arrived at that it does not appear economically possible at present to attempt electrification in areas where the density is less than 75 persons per square mile. Moreover, just as in the case of densities of 100 and 150 persons per square mile, the rural areas should for purposes of more effective control and development be associated with an established urban undertaker, as clearly adumbrated in Figs. 5 and 11.

Conclusion (13)—as to goodwill and co-operation between all concerned in development even in areas of population having densities little above 75 per square mile—was challenged on the grounds that it was probable that such a meagre population would not be sufficiently wealthy to give the estimated revenue of £10·06 per consumer. We would ask these critics to await further results which, we are confident, will justify our figures, especially if allowance be made for the extended use of electricity for water and space heating and cooking which experience shows does follow upon a wisely devised tariff (see Table 10). The wording "goodwill and co-operation" was introduced designedly, and more particularly because we know how difficult it appears to be for companies and local authorities to work together for their mutual benefit.

Having now referred to the salient points that emerged from the discussions, we propose to proceed to reply to certain matters in greater detail. We find that it is convenient to summarize our replies under separate headings.

Units sold per £ of Distribution Capital Expenditure.

Notwithstanding the advance in the distribution of electricity, the number of units sold per £ of distribution capital invested is not increasing (see Table 3), and we considered this to be a serious matter, but some exception was taken to this view. Mr. Phillips argued that it might indicate that wise and greater provision than usual was being made in anticipation of future demand. Taking the figures for 1928–29 (Table 3), it will be seen that 50 units at 0·97d., being a total of 1·38d. per unit sold (as shown in Table 2) minus 0·41d.—i.e. the cost of electricity sent out of the generating stations and of bulk supplies—is about 4s., or a return of 20 per cent on the distribution capital invested. If we attempt to reduce the sale price to 0·75d. less, say, 0·35d. per unit for generation and bulk transmission as a desirable objective, the return on the distribution capital would be only 1s. 8d. in the £, or just over 8 per cent, which is clearly insufficient. It follows that the number of units sold per £ of capital must be made to increase and the price per unit sold to the consumer to fall, but for the past 7 years this is shown not to have happened. We still hold, therefore, that this is a serious matter, and Mr. Kennedy's and Mr. Phillips's remarks have made it abundantly clear.

Size of Model Scheme Area.

Our conclusion was that an area of not less than 400 square miles in extent should be considered for electrification, and multiples of unit up to 3 or 4 times might conceivably give better results. Mr. Phillips thinks that an area of 400 square miles is too large to be administered from one organization, while Mr. Siviour agrees with our choice of a hypothetical area. Although Mr. Britton sees no justification for stating that the size of an area should be 400 square miles or any other figure, he agrees that they should, for reasons of economy, be as large as possible. He thinks that rural electrification should be linked with a fully operated established undertaking in an urban area, because when so attached more rapid expenditure of capital is possible, owing to the financial support obtainable during (presumably) the earlier stages of rural development. Mr. Margary's attitude generally confirms Mr. Britton's views. In these remarks we seem to detect a clash of interests, or rather a difference in point of view as between local authorities and companies engaged in tackling the problem of rural electrification. When deciding upon a suitable size of area we had only in mind a practical and economical solution and, as a matter of fact, we have contemplated centring our scheme on an established urban centre, as we thought would be evident from a careful inspection of Fig. 5, in which the centre of the Model Scheme area is a town provided with a grid supply. We cannot make it too clear that we have considered our Scheme as being controlled from an urban centre where electricity is available and where a company or local authority is charged with the business of distribution. In these circumstances we contend—and there has been no sufficient evidence to

refute our contention—that the surrounding rural area can be electrified to an extent much greater than has so far been deemed possible without adding to the town dwellers' responsibilities, except temporarily in the shape of credit facilities to finance the project. When that period has elapsed, we have shown that a scheme of expansion will prove to be an asset. In the case of a company this responsibility would be borne by the shareholders. We have contemplated sharing in the distribution and management expenses in a way one might assume to occur in practice, and we shall refer to this a little later in our reply. Where the rural areas surrounding a town are in the hands of companies we see no reason to modify our general assumption as to control and management from some convenient point at the costs shown.

Mr. Britton suggests spheres of operation centred on existing urban points of supply well chosen so as to cover the whole of our occupied areas more or less uniformly, having regard to minimum distribution costs. To this we would agree as being an ideal arrangement, provided some commonsense agreement could be come to between local authorities and companies, both of whom are engaged in this important public service. It may happen in these circumstances, as it does now, that the best placed local authority undertaking operating, say, a small urban supply is neither wealthy nor feels itself in a position to launch out into rural electrification. In such circumstances confidence is absent and the spirit of adventure is damped. Some financial backing is required in the form of a guarantee from a central fund or from the reserves of amalgamated interests dependent on development work for their existence and steady progress.

Density of Population.

Population per square mile has been said to be not quite the most convenient basis for the purposes of computing estimates for a rural area. Mr. Fennell and Mr. Britton both suggest "consumers per mile of line." This unit is quite satisfactory when considering l.t. distribution as shown in Fig. 13(*a*), but it is unwise to include the length of h.t. line in this figure as it bears no relation to the number of consumers. We have gone to some length to explain the dispersion of the rural population in relation to the electrical load, and it must be understood that when a population density is referred to we must imagine an area normally split up into parishes, each parish consisting of 4 square miles. A parish is assumed to contain one village in which roughly 80 per cent of the people in the parish are living, and the varying sizes of the villages are in the proportions set out in Table 22.

Lay-Out (*Fig.* 11).

Fig. 11, in which are shown 33 000-volt radial feeders, is purely diagrammatic and is drawn simply to indicate that a supply of electricity at 33 000 volts is available at the centre of each 100-square-mile area. In actual practice these feeders will either be duplicated or in the form of a ring main.

In answer to Mr. Biles and others, the voltage at these four points has been assumed to be controlled. It would not, of course, be possible to have a voltage variation of 12 per cent at these points and to keep within the statutory requirements at consumers' premises.

Tariffs.

At least fifteen members have referred to the question of tariffs applicable to domestic use—some at considerable length. We pointed out in the paper to the need, if schemes were to be successful, for a suitable tariff, and by a suitable tariff we meant (*a*) a simple one, (*b*) one having some relation to the demand made on the capital and service of the undertaking, (*c*) one inducing the consumer to use more electricity, and (*d*) one that studies the consumer in respect to payment, etc. From the examinations made and recorded in Figs. 9 and 10 we came to the conclusion that a tariff for domestic purposes under which the charge for electricity is reduced in some relation to consumption would perhaps, in all the circumstances, be the best to adopt. That there is need for revision cannot be doubted. Mr. Macleod says that in his opinion there is a great need for the simplification of tariffs and that when a reasonable and readily understood tariff is available custom automatically and rapidly develops. Mr. Siviour is definite about the need for a suitable and attractive tariff; Mr. Nimmo's chief criticism is that the paper lacks a model tariff; Mr. Hetherington refers to the prevailing wide diversity of tariffs and the necessity for uniformity so as to avoid clash and confusion at the borders of contiguous or neighbouring areas, and thinks that at any rate the form at least of the tariffs should be the same throughout; while Mr. Mounsdon hopes for our further remarks.

It may be as well to explain at once that the form of the curves shown in Figs. 9 and 10, on which our estimates of units sold and price per unit for the Model Scheme revenue are based, show the position for 1929–30 only. In the course of time the curves in Figs. 9 and 10 should drop little by little to correspond to the average revenues per unit sold (given in Table 2), but whether the curves will tend to tilt downwards at point B with the point A more or less fixed is a debatable point. It should do so, we think, with improving load factor and increased units used per £ of capital (Table 3).

We felt safe in using the figures we did when they were those of a year that had passed. Mr. Woodward thinks it dangerous to have mixed up power units and domestic units. A separate curve covering sale price and consumption for electricity sold for "domestic purposes only" was derived from the same 221 returns and was found to coincide closely with the left-hand portion of the curve. The industrial unit readings were found to follow the flatter part of the curve shown on the right-hand side with the average revenue of 0·72d. per unit sold (see prices assumed for Model Scheme, Table 16B).

Referring to the formula (1 140d./units sold) + 0·73d. for the Fig. 9 curve, further investigation tends to show that the figure of 0·73d. is higher than, and bears no close correspondence to, the actual running cost of the unit to the consumer. With bulk supply at £3·25 + 0·2d., the average running cost is calculated to be about 0·4d. Mr. Porter's remarks in this connection are interesting and instructive. It seems clear that the unit charge as now made usually carries with it about 45 to 50 per cent of

fixed charges. This, we think, is generally realized and is confirmed by Mr. Long's remarks.

This mixture of fixed and running costs as usually reflected in the running component of our 2-part tariffs does not by any means do what supply engineers want, i.e. increase the number of units sold per consumer or per £ of capital expended. It indicates rather that we are still in a transitional stage as regards tariffs, and are moving slowly from a flat-rate unit charge, which was more suitable for the days when electricity was sold for lighting only, towards a 2-part tariff suitable for all domestic purposes, including small domestic power, and cooking, water- and space-heating, in which, after fixed charges are satisfied, every additional unit is sold at a figure closely approximating to the actual "running" cost of producing and distributing it. If we admit a transitional stage then it follows the right course to take,

TABLE A.

An Example of a Domestic Two-part Tariff, the Fixed or Service Charge being computed on a Proportion of the Units Metered being sold at 8d., and the Unit Component Charge being graded. Minimum Fixed Charge 6d. per week or 26s. per annum.

Annual consumption		Fixed or service charge for range given in cols. 1 and 2	Actual fixed or service charge for range	Unit charge on full quantity metered	Average total bill to consumer for range given in cols. 1 and 2
From	To				
kWh	kWh	per cent	£ per annum	d.	£

For Consumers on 2-part Tariffs:—

For quarterly charge multiply quarterly consumption by 4 and use the corresponding service and unit charge.

For monthly unit charge multiply monthly consumption by 12 and use the corresponding service and unit charge.

whenever the occasion arises to reduce tariffs, is to make the reduction on the unit component of the 2-part tariff. All that we intended in suggesting the form of 2-part tariff shown in Table 19 was that whatever the basis of the ascending "fixed or service charge" might be—whether room area; kilowatts actually measured or allowed for by means of graded sizes of meters; lamps installed; or finally by unit consumption; it should be smoother in ascent, and so formed that the unit component charge descends so as to be an encouragement to increased consumption. In the light of the discussion, and having in mind the fact that electricity for lighting is a marketable commodity at 8d. or 9d. per unit, cooking at round about 1d., and water- and space-heating at about ½d., we now suggest a slightly modified alternative form of quantity tariff to that shown in Table 19, based as before on unit consumption (see Table A). It is true that graded tariffs with the fixed charge based on other than unit consumption are now in force—*vide* Northampton where the fixed charge is based on net rateable value duly graded, and a unit charge also graded in two steps at ⅞d. and ½d.; Bedford, with a somewhat similar scheme but more roughly graded as to service charge with seasonal variation in the unit charge fixed at ½d. for the urban zone, and North Ireland, with a fixed charge based on aggregate floor area (external measurements) duly graded on a unit of area basis, with a stepped unit charge of ¾d. and ½d.

Notwithstanding Mr. Fennell's remarks, this domestic tariff is feasible and the service charge is based on something tangible in the shape of a percentage of units sold. It is easily understood and could be clearly indicated on the back of the meter card and as clearly explained. With the exception perhaps of graded meter sizes it is better, to our mind, than other domestic tariffs in respect to the service charge, because it pays some regard to the load factor that might reasonably be expected with increased output, and consequently to the consumers' kilowatt demand on the system, allowing for diversity. Both components could be slightly increased as the radius of supply was extended if tariff "zoning" were adopted by the supply authority. We think that a tariff of this kind should apply generally at the consumer's terminals whether he is isolated or not. Any further charge in cases of long service or spur lines should be, if regarded as essential (which we do not), a definite amount per annum calculated on capital expenditure as recommended by Mr. Long (see the remarks on spur lines later in reply).

Choice of H.T. Voltage.

Mr. Phelps suggests the use of 22 000 volts for the h.t. network shown as working at 11 000 volts in the paper. His chief reason for advancing this view is that this voltage eliminates the use of much of the more expensive 33 000-volt mains, and the cost of 22 000-volt lines is little in excess of that of 11 000-volt lines. The general consensus of opinion in the discussion is that in this country 11 000 volts is by far the best pressure for local transmission in rural areas, with a 33 000-volt transmission system for bulk suppliers. Throughout the paper we endeavoured to keep to generally accepted standards endorsed by the Electricity Commissioners, but in the case of the North East Coast, where conditions are such that the proportion of industrial load is greater than that taken for the Model Scheme, and where the size of the area and average conditions differ from those which we assumed, we would not suggest that, considering the year in which it was designed, 22 000 volts may not have been the best pressure to use. We feel, however, that if the system were to be re-designed in the light of present experience and practice, the transmission and distribution arrangements suggested in the paper might greatly influence the mind of the designer.

Spur Lines.

The means suggested in the paper of reducing the cost of 11 000-volt spur lines, namely by using a small copper conductor in conjunction with short spans, has

been severely criticized. This method of construction is almost universal outside this country, and the cheap Continental lines referred to in the discussion are of this type. The whole question hinges on wayleaves. If wayleave troubles are absent then a line built up of a small copper conductor, say No. 6 S.W.G. with spans of 180 ft., strung entirely on pin insulators, will invariably prove cheaper than a steel line with a longer span. On lines feeding an isolated consumer (and this is the kind of line that is under discussion), wayleave troubles are more likely to be absent because the line often runs over the land belonging to the consumer.

The problem of connecting up isolated consumers is a difficult one from both the technical and economic points of view. It can only prove lucrative if the undertaker is in a position to offer a tariff that urges the consumer to make full use of electricity, and every assistance should be given to the isolated consumer, always provided that consumers of other categories do not unduly suffer. From the statistics in the paper the average revenue per farm is approximately £11 per annum. This is lamentably low, and it is obvious that electricity is employed for little else but lighting. The judicious application of electricity to agricultural problems affords immense scope. The load factor of an individual farm at its best will be poor, but diversity among farms should be high. There is therefore every reason for connecting up as many as one can, and the possibilities are that the maximum demand for this class of consumer will occur at a different time from that of the town load. Mr. Phillips has shown that the maximum demand of his rural area may occur in the summer months; this, of course, improves the general load factor—a result highly to be desired.

For isolated consumers Mr. Long indicates a satisfactory way of arriving at an annual charge on special local expenditure incurred, to which must be added the usual consumers' 2-part tariff with a unit charge carrying a high proportion of fixed costs. We agree, provided the course recommended on page 216 of the paper was deemed unsuitable. It is perhaps unfortunate that every isolated consumer should actually be treated differently as regards payment for a supply. Mr. Long's method is no doubt the fairest. The other alternative is to base a tariff on the size of transformer. This appears to be reasonable in most cases and works well in practice, but it does not take into account the length of spur line, i.e. the cost entailed in reaching the consumer, which is usually a matter of a separate charge and checks business.

Mr. Perks raises an interesting point in this connection. It is not at all safe to assume, he says, that any proposition is a paying one if the revenue is fixed at 20 per cent of the capital cost. Whether it pays or not, he continues, will depend on the average price at which the unit is sold. A low-priced unit, he points out, inducing large sales, gives no greater total revenue than may be expected from the sale of a few units at a high price, calls for greater capital expenditure, and may only be satisfied by a higher return than 20 per cent on the capital expended. He therefore stresses the advisability of some revision of the Clauses Act. The argument put forward involves questions of policy as to how developments should proceed, and in the circumstances we can only direct attention to our considered view as expressed on page 216.

Mr. Coe and Mr. Lisle ask what is the best method of dealing with isolated supplies to farms, hamlets, and country residences in patches of sparsely populated areas (say about 65 per square mile). We would refer these speakers to the final paragraph of Section (*f*) on page 217 and say that we would consider this a special circumstance and would probably advocate single-phase galvanized-steel conductor interconnection at 11 000 volts. For dealing with the densities and loadings taken for the Model Scheme we would adhere to our conclusions given in the paper and use 3-phase lines.

Earthing.

The question of earthing has been raised by several members. There is perhaps some confusion in the minds of certain engineers as to what constitutes "earthing." "Earthing" should, we think, be distinguished by reference either to (*a*) the earthing of the l.t. neutral, or to (*b*) apparatus earthing. With regard to the former, the Commissioners' Regulations require that an earth be made at one point only and that the insulation of the neutral be preserved throughout. The regulation was made to avoid any interference with the operation of telegraph and telephone circuits. In these conditions, i.e. earthing at one point only, there may obviously be a considerable voltage-drop along the length of the neutral in the event of a short-circuit occurring at the end of the l.t. line remote from the earth. Consequently it is possible under certain circumstances for the voltage to rise sufficiently to make the line dangerous to touch. The answer to Mr. Kennedy is, therefore, that so long as multiple earthing is prohibited we cannot advise the use of an uninsulated neutral conductor under eaves or elsewhere. We fully realize the danger of a badly insulated neutral earthed only at one place.

In our opinion it is imperative that all low-tension apparatus should be well and securely earthed, either to the water supply system or some tested earth on the premises. Where, in unusual circumstances, this is found to be impossible, we recommend a local continuous earth wire, earthed wherever most convenient.

As to high-tension line earthing, we can only reiterate the opinion that we expressed in the paper. As to the remarks made on this subject by Mr. Babb, Mr. Fennell, and Mr. H. W. Taylor, we realize that in exposed hilly country a continuous earth wire placed above the h.t. conductors will tend to eliminate lightning troubles, and in such circumstances we would advocate its use. Mr. Biles raises the question of the best type of earth electrode to employ. This is still a moot point but from recent investigations it appears that an iron rod about 8 ft. long by $\frac{3}{4}$ in. diameter gives as good a result as any of the other types. The use of crushed coke has been discredited because it has been found that as good an earth can be made without it as with it. It may be interesting to note that where lattice steel towers are used with earth grillage foundations, the foundations offer a lower resistance to earth than the usual earth electrode.

Acts and Orders.

Mr. Siviour questions our assertion that the Acts and Orders are no impediment to development, and says that they require clarifying, and Mr. Woodward is of the opinion that the option to purchase by a local authority forms a definite bar to progress. This may be so in cases where the option to purchase is near at hand, and no doubt some of the Acts and Orders would be better for revision, so putting the authorized undertakers on a sure footing and inducing expansion. We are heartily in agreement with Mr. Siviour when he suggests that a codifying Act would be a useful addition to our book-shelves.

Commissioners' Regulations.

In the paper we stated that the Commissioners' Regulations do not offer any obstacle to the cheap erection and design of overhead lines, and we see no reason, as the outcome of the discussion, to modify those views.

As Mr. Nimmo points out, many h.t. lines are erected in excess of the requirements of the Regulations, thus unnecessarily increasing cost. With regard to general criticism on the score of cost, it may be pointed out that in the case of l.t. lines it is usually found essential in practice to erect larger-diameter poles than the Regulations actually demand, in order to enable service lines to be taken off neatly.

As to h.t. lines, Mr. Fennell, Mr. H. W. Taylor, and Mr. Hill emphasize the necessity of the continuous earth wire, but in our opinion, as given in the paper, it is not always necessary, and saving can frequently be effected by omitting it.

It is not within our province to express any definite views as to whether any relaxation of the Regulations in respect of factors of safety, etc., is necessary or desirable. Whatever variations may be made from time to time we do feel that, as a practical point, reliability should under no circumstances be sacrificed by those engaged in supplying rural areas.

L.T. Distribution Networks.

Village Distribution Networks.—Mr. Fennell suggests that the lay-out of pole transformers, substation, and low-tension 3-phase 4-wire 400/230-volt network, as fully described in the paper, is or will be generally unsuitable and uneconomical, because he says that the whole tendency is towards ribbon growth in rural areas. Although we think he is mistaken in assuming that no check will be placed on ribbon growth, an h.t. and l.t. system with suitably spaced transformers is most suitable and flexible for this kind of housing development. There is no doubt that in some spoilt areas this system of distribution is the best, and here we would endorse Mr. Fennell's suggestion, but it cannot be said to be of general application. It is usually found that a long, straggling village can be well catered for by two substations, the chief point governing a lay-out being the voltage-drop. The position of the substation is more often than not governed by geographical and wayleave considerations.

We admit that the use of No. 8 S.W.G. copper conductors for l.t. mains can only be justified in the smallest of hamlets; the poles should be such that a larger size of conductor may be strung on them at a later date. The saving in using No. 8 S.W.G. is very small and we further admit the argument that it might be well in practice to have 0·05 sq. in. as a minimum size, as so little will be added thereby to the cost of equipment.

It is impossible to say that no l.t. lines should exceed a certain length; such a ruling may be possible in an urban area where consumers are more or less evenly spaced, but for rural work it appears to us to be out of the question. It must not be assumed that the length of l.t. main shown in Table 24 represents long, straight runs. The length may be made up in shorter star-shaped amounts.

As to the point raised by several speakers, including Mr. Fennell and Mr. Turnbull, whether a very definite saving might not be effected by the use of single-phase 3-wire distribution in the smaller villages, we are in agreement, where there is an absence or no likelihood of power load. It has several real and obvious advantages, including cheapness, but it should be adopted with great caution as one can never foresee what industrial development may arise in a rural area. We do not advocate its almost general use as does Mr. Turnbull, but for small hamlets at the end of spur lines it is perfectly satisfactory. It was not included in the paper, because it would have been difficult to assume exactly where single-phase and 3-phase supply should be used, but a scheme such as the Model Scheme with some single-phase networks would have been cheaper. We felt we were right and safe in budgeting for a 3-phase system.

Voltage Regulators.—Mr. Norris and Mr. Ayres raise the question of automatic voltage regulators. The chief difficulty in a rural network when it becomes fully loaded or the load in a portion develops more than is estimated, as is often the case, is regulation, and it is in such circumstances that an automatic voltage regulator appears to us to be a sound proposition. In this connection the question of voltage variation at consumers' terminals must also be considered. The maximum variation permitted by the Regulations is $\pm$ 4 per cent of the declared voltage. Mr. Britton suggests that a greater variation should be allowed. We do not hold this view, because if a cooking load is anticipated, as it must be, nothing can be more harmful to the reputation or the usefulness of electricity than a severe voltage-drop at the cooker.

There are two aspects of the question as to what saving can be effected by the use of voltage regulators. The first is whether greater saving could not be made by installing them to cope with excessive voltage-drop as and when unexpected demands occur in the later stages of development. In this case it is purely a question of balancing the advantages of (*a*) the cost of erecting new or larger mains, (*b*) an extra feeder, (*c*) a new substation, and (*d*) a regulator. It is fairly certain that unless the increase in load is excessive the regulator will give the greatest saving. The other aspect is as to whether it would not be better to install a regulator at the commencement, so compensating for all the h.t. voltage-drop. From this point of view the engineer would, from the start, be able to work out his network for a higher density than would be possible without one. Fig. 29 illustrates this point. Owing to the reactive

drop a conductor larger than 0·1 sq. in. is not economical, so that there is a definite limit to conductor size on this basis. Should the estimated load call for higher current densities, an automatic regulator may be considered at the start. The extent to which one should go with a regulator should be influenced by Kelvin's law.

H.T. Lines.—Mr. Siviour and Mr. A. B. Mallinson question the economic span suggested in the paper for the 11 000-volt single-conductor line. On page 212 of the paper we have stated very fully our reasons for adopting 350 ft., but we quite agree with these speakers under the conditions they assume. We can only repeat that so much depends on local conditions and we adhere to our general conclusion.

Two speakers are of the opinion that the extra precautionary measures at road crossings required by the Regulations are unnecessary, and that the abolition of road-crossing construction would be an effective means of cheapening overhead lines. The need for increased safety at public roads is generally recognized throughout the world, and some measures are required by practically all countries on the Continent. The prevailing practice is to increase the factor of safety of the support at the roadside. The Commissioners' Regulations are lenient on this point.

Pole-Top Fittings.—The pole-top fittings illustrated are representative types, and many variations of and improvements on these types exist. The one which we suggest, shown in Fig. 18, has some marked advantages over others enumerated in the paper. A tipped triangular spacing, as represented by Fig. 21, is the best. This type of spacing, as Mr. Phillips points out, has a slight advantage which none of the others possesses, viz. the pole is concentrically loaded. This, however, is not of any real importance, because the vertical weight is so little as to be negligible compared with the transverse wind load which acts at right angles to the pole. The most efficient type of pole top is a variation of Fig. 22, giving a tipped triangular spacing; but this type of construction is more difficult to erect and is of less general utility than that of Fig. 18.

Mr. H. W. Taylor is of the opinion that at medium-angle positions it is cheaper to fit a strap at right angles to the cross-arm and put the insulators in that. We agree and would say that this is quite satisfactory, provided the strap and single cross-arm are sufficiently strong.

Foundations.—With regard to pole foundations, we suggest that on such sizes of h.t. lines as are recommended in the paper it is necessary to fit kicking blocks on all intermediate poles, except in the case of rock foundations, so as to be assured of a firm hold. The design of pole foundations requires judgment, and much must be left to the engineer who is erecting the line. It can, however, be generally accepted that kicking blocks are essential for lines having spans of over 300 ft. Where they are used the advantage of using a machine auger for digging the holes is, of course, negatived. It has been suggested that the pole should be planted 1 ft. deeper instead of using kicking blocks, but this depends entirely on the ground in which the poles are to be planted. We would not suggest that this could be accepted generally.

Low-tension Construction.—Low-tension overhead line construction is rapidly becoming standardized in general practice, and the construction shown in Fig. 32 is being adopted almost universally. Mr. Turnbull says that the Aylesbury type is superior, but this type can only be used at straight-line and small-angle positions. At section, large-angle, terminal and junction-poles, one is forced to resort to "D" irons, and as straight runs are rarely met with in low-tension work we fail to see the advantage of this type of construction. It also has not the facility for taking off services that a "D" iron has.

Mr. H. W. Taylor's Fig. H is undoubtedly an improved variation on the "D" iron construction, and his suggestion clearly illustrates the facility with which services may be taken off.

Several speakers, including Mr. Kennedy, question the advisability of placing l.t. lines at the backs of houses. We made this suggestion with certain reservations. Mr. Britton has, however, erected a complete l.t. network in a village in which all the lines are at the backs of the houses. It is a most excellent job, the lines being scarcely visible from the road.

Substations.—The substation designs indicated in the paper represent types of construction which are in general use, each type having advantages and disadvantages, and, as usual with designs of this description, being a compromise. From the discussion several very definite points have emerged on which nearly all the speakers were unanimous. The fuse links shown in Fig. 25 have proved to be of little practical use, owing to the difficulty of operation. We fully realized that this type of link is not all that could be desired, but we felt that for such a small load as 5–15 kVA it scarcely warranted the more expensive pull-down type. The main factor influencing our choice was cost. We are of the opinion that if a better type can be used without unduly influencing the economic aspect this should be done. In Fig. 26 the position of the l.t. fuse box has been much criticized. Mr. Phelps, Mr. Lisle, and Mr. A. B. Mallinson have suggested that this box should be in such a position that it can be easily reached by an operator standing on the ground. This is undoubtedly the best position. A cabinet either of timber or iron can be fixed to the pole leg and it can contain fuses, links, and plugs for fitting a meter and perhaps a maximum-demand indicator. This is an undoubted improvement.

A certain amount of controversy has ranged round the question as to whether h.t. air-break switches, oil fuses, or oil circuit-breakers should be used. Obviously the choice largely depends on the position in the system where the apparatus is to be employed. For sectionalizing purposes an air-break switch is all that is required, as well as at those definite points on the system where fairly large loads are tapped off. For tappings for 100 kW or over, a resetting oil circuit-breaker is undoubtedly the best. At less important positions oil fuse-switches may be used successfully and these should be of the type in which, if one phase breaks down, all three phases are tripped out. Furthermore, with overload oil circuit-breakers at selected points on the system a certain amount of protective discrimination may be arranged.

We were interested to learn from Mr. Coates that the cost of these switches is comparable with that of oil switch-fuses. We realized that the main disadvantage of fuses is that they require more or less skilled persons to replace them. On the other hand it must be remembered that they do not blow out unless something radically wrong has happened, such as would necessitate the presence of a skilled man.

There is a certain amount of disagreement as to whether the h.t. side of transformers should be fused. Mr. H. W. Taylor, Mr. Turnbull, Mr. Burton, and Mr. Siviour are definitely of the opinion that h.t. fuses to protect transformers are essential, while Mr. Phelps and Mr. Lisle deprecate their use. It is difficult to reconcile these conflicting opinions, but it appears to us that h.t. fuses are essential in nearly all cases for rural work.

Mr. Lisle makes the interesting suggestion concerning the standardization of transformers that the idea of a transformer of a smaller size than 25 kVA should not be entertained, and that when the load grows another 25-kVA transformer should be added and worked in parallel. It would undoubtedly prove useful in certain areas to have one size of transformer, but it is doubtful whether the idea could be applied generally.

We stated that transformers of over 50 kVA should be placed on the ground. Mr. Latham has placed 125-kVA transformers on a pole platform: here again this type of construction may prove successful in particular circumstances, but generally we do not think it would prove satisfactory.

Dr. and Mr. Ekstrom's Communication.

The mathematical analysis of the problem of electrical transmission in sparsely populated areas is useful and instructive. The main difficulty, however, in approaching this problem is the uncertainty of practically all the constants. Consequently, after making a complete survey of an area and estimating, as accurately as one can, the likely electrical load and then designing the schemes on the lines laid down by Dr. Ekstrom, the very first thing that would happen would be an enormous load development where it was least expected, and the economies he anticipates from the tapering of the conductor size would be seriously miscalculated. The main difficulty that we foresee in starting off with a large-diameter conductor and tapering down as the line goes to the outskirts, is the variety of size of pole and the variety of span length that will be needed. This, of course, would increase erection costs enormously. One point to remember is that in the United Kingdom great care is always taken to utilize the most economic spans for the conductor on wooden pole construction, whereas in most other countries where timber is cheap this is not so evident. Abroad, use is made of two or perhaps three standard sizes of poles. They do not depart from these standards, nor as a rule from the length of span; and on these poles they string whatever conductor they wish—in some cases irrespective of what the pole will really stand. Dr. Ekstrom's scheme would be quite satisfactory for a uniform span, where a uniform pole could be used and where the only variation would be the size of conductor, but we do not think a lay-out on his lines would be cheaper than the usual practice now followed in this country.

Capital Costs.

The tables on page 226, in which the capital expenditure is set out, give costs of overhead lines and equipment on the basis of copper at £55 per ton. For this paper to be of use one must vary costs to suit local conditions. The costs of h.t. lines in the paper must not be compared with the costs of short lengths of line erected over particularly bad country in particularly bad weather. Mr. Matthews and Mr. Coates have given particulars of some very cheap lines. Such costs are apt to be very misleading. Price must be qualified by the line pressure, conductor size, type of support, and the Regulations to which the line is designed and erected. Again, the cost of erecting lines in a highly developed country like the United Kingdom is quite a different matter from that associated with the erection of lines in a new and undeveloped country. From the discussion it can be concluded that the majority of speakers regard the costs in the schedule as reasonable.

Our figure of £2 per overhead service is perhaps the most often criticized item. It includes only a loop-in from the l.t. pole to the consumer's premises, and this estimate includes insulators, bracket, one insulated service wire, and one bare neutral, leading-in tube, meter board, and fuse. It is assumed that a number of consumers in terraced houses may be connected from one service. What might be termed a long service line is not included in this figure as it is amply covered in the l.t. distribution costs.

We have found that the estimates for substation equipment, etc., are on our further revision quite reasonable. The large increase in cost of a 75-kVA installation over a 50-kVA installation is entirely due to the fact that at the former size we have allowed for three sets of switches as shown in Fig. 27, and that the low-tension arrangements permit of more than one circuit being taken off. As it is essential to have sectionalizing switches at suitable intervals in the network, these have been arranged for at points where loads of 75 kVA and above are estimated to be available. This can only be regarded as a method of allocation adopted as a precautionary means of including all necessary apparatus for the Model Scheme.

Mr. Hill points out that no allowance has been made for Post Office and railway crossings, but it should be noted that a sum of £11 730 has been allowed for 8 miles of h.t. cable. This will only be used in short lengths, chiefly at the entrance to large villages and awkward railway and Post Office crossings.

Revenue Account Expenses.

A considerable amount of criticism has been levelled at the "expenses" side of the revenue account shown on page 227. As to the cost of electricity purchased, we have indicated that the cost, taken at £3 5s. per kW at power factors between 0·8 and 0·9 and at 0·20d. per unit, was simply an estimate based upon what should shortly be the cost of production at our large power stations where, with 90 per cent of plant in use, costs at £2 5s. per kW and 0·110d. per unit should not be un-

common, with a small margin added for the Board's main transmission and other expenses. The cost of bulk supply will naturally, for some time, vary in different parts of the country, but we hope and expect that we have struck a quite possible and happy mean. We are inclined to think so notwithstanding Mr. Purse's references to contracts at £4 7s. 6d. + 0·22d. and £6 5s. + 0·22d. Maybe these tariffs are of quite a temporary nature and due for further investigation, or perhaps they apply where conditions are somewhat extraordinary. We are the more disposed to think that one or the other or both suppositions are true because Mr. Scott observes that he is amused at the criticism of the bulk supply charges as he has actually had a quotation almost identical with the figures quoted in the paper. Mr. Clegg observes that although he can agree with £3·25 he is afraid the figure of 0·2d. is a little lower than most engineers can anticipate. If the supply industry is to prosper, we must be eager to obtain supplies at the absolute minimum because sales prices, and therefore development, depend upon this vital and (for years) immutable factor.

As to the expenses of distribution and management, it has already been explained that in setting out our Model Scheme we contemplated centring our scheme either on an established area of distribution, under either a company or a local authority, or alternatively as part of a larger organization such as may now be found in control over large areas embracing villages, small country towns, etc. Mr. H. S. Ellis acknowledges this assumption but goes on to ask whether we had assumed that the rural scheme would be subsidized by the urban area. The word "subsidized" is, we suggest, wrongly used in this connection. Sufficient has been said in the paper and in our reply as to the revenue side of this account to show that it is a matter of meeting the first 2 or 3 years' deficits by means of a sum on credit duly honoured, as the scheme proceeds, by interest and the return of the loan—an everyday transaction. Mr. Ellis doubts whether the figures taken for distribution expenses and management are sufficient. Mr. Clegg says that the distribution costs are lower than those prevailing in town supplies. Mr. Purse gives a set of figures derived from the Commissioners' Electricity Returns for 1930–1931, extracted by him to prove that we are completely wide of the mark in our estimates of distribution and management expenses. Unfortunately, however, for the careful presentation of fact for which he is entitled to credit, he has omitted to allocate management expenses between generation and distribution, and appears to have had no regard to the intensity of development as indicated by the most important factor derived from the number of units sold per £ of capital expenditure. This is regrettable and we hope that Table B will help to eliminate the false impression he has unthinkingly given. The conditions under which the Model Scheme operates must also not be forgotten.

TABLE B.

Cost of "Distribution Expenses" and "Management" (*being Items* 2 *and* 3 *on Page* 227) *for the Year* 1929–1930.

(Cost of Electricity, Interest and Depreciation Charges, Rents, Rates and Taxes omitted.)

Name	Capital expenditure on distribution	Units sold for local distribution	Revenue	Revenue per unit sold	Distribution expenses	Management (distribution only)	Total distribution costs	Units sold per £ of distribution capital	Distribution costs per unit sold
	£	kWh	£	d.	£	£	£	kW/£	d.

Gravesend	201 591	16 342	74 882	1·10	2 429	3 007	5 436	81	0·0798
Model Scheme, 3rd year ..	264 440	6 204	52 470	2·03	3 060	4 410	7 770	23	0·300
Model Scheme, 6th year ..	300 500	16 678	95 900	1·38	3 730	4 735	8 465	55	0·122

It will be seen from Table B that in the Model Scheme the expenses per unit taken for the two main items under consideration are ample, and although the figure for the sixth year is somewhat short of the average of the particular undertakings chosen by Mr. Purse, as a result of our investigations we are confident that if every regard is paid to economy of operation as adumbrated on page 192, and with the same intensity of development, results of the order given in the paper will be achieved.

Under the heading "Rents, rates, and taxes," Mr. Perks does not think that the 1½ per cent capital expenditure on which we have based our estimates is adequate. He refers to the item of 1s. 3d. per pole per annum as insufficient and cites the Ministry of Transport compensation figures of 4s. in arable land to 1s. in hedges, but not all pole rentals are determined by the Ministry of Transport and cost this amount. Some cost nothing but the asking, and with care in overhead line lay-out we are still convinced that, apart from the general expenses of obtaining leave to the route tree-lopping

and fence repairs which we have included in our Statement of Capital Expenditure, the annual rentals should not and will not, under careful supervision and the employment of good wayleave officers with local knowledge, be greater than the amount included, of 1s. 3d. per pole on the average. We have seen records of initial costs of £6 per mile and annual pole rentals of very little over 1s. per pole over wide areas.

Mr. Barrett thinks that assessments, presumably in rural areas, will reach nearly 15 per cent of gross receipts, and the rates 13s. 4d. in the £ (of the assessment). Actual costs of operation do not confirm this pessimistic view. A reference to the Ministry of Health's returns shows that a rate of 10s. in the £ is nearer the average rate than 13s. 4d. in rural areas, and on the basis of 7½ per cent on gross income for assessment purposes—which we consider nearer the mark and worth fighting for—the figure for rents, rates, and taxes given as £4 440 (6th year) is fairly sound. It may be slightly on the low side, but not much. Assessments are not, it must be remembered, based solely on gross income, the item of initial cost being also an important factor.

Turning to the question of capital charges, we wish to thank Mr. Bolton for drawing attention to our figure of 3 per cent for depreciation if taken on a 20-year fund bearing interest at 3·5 per cent. The period of repayment would be about 22½ years, and not 20, as given. We can say, however, that 3 per cent is generally accepted as safe for the class of equipment under consideration.

Mr. Bentham and Mr. Siviour ask where in our accounts we have provided the capital and shown the expenses and income connected with the necessary and most important matter of assisted and rental wiring of dwellings and the provision of apparatus. We have not done so as we felt it would greatly complicate the accounts presented, and we were aware that a separate account must be kept under these headings and should and can be made to balance. We admit that we should have referred to this subject. In this connection we would say in answer to Mr. H. S. Ellis that part of the salary of the sales engineer in the 6th year would rightly be debited to this account, and the sum of £520 in the final year for "Publicity" would be a fair apportionment.

Demand and Revenue.

The criticism directed against the revenue to be expected, as shown on the revenue side of the account, may be placed under the headings of:—

(*a*) The rate at which connections have been assumed to be made over the period of 6 years (see Fig. 4).

(*b*) The rate of increase in revenue per consumer taken (see Table 16B).

(*c*) The number of units sold per consumer, and the revenue per unit assumed (see Fig. 9).

In no part of the paper do we feel more sure of our ground than on this point, as it is based on fact and on the experience of those engaged on the actual work of development. To this statement must be added the further remark that very few, if any, undertakings as yet contain at one and the same time all the ingredients for successful results that are referred to as being the *sine qua non* for the Model Scheme, and further referred to on page 192. The reasoning in the paper is, we think, quite logical. Starting with Fig. 4, the rate of connections there shown is the outcome of the considered opinion of engineers with long practical experience in rural work, coupled with some judgment on our part as to the effect of offering assisted or hired wiring and admitting all the essentials referred to. Turning to the revenue to be expected, the number of units sold and the price per unit were based on the 221 returns analysed in Table 7 and Fig. 9. It will be found that the revenues per consumer adopted for the Model Scheme in Table 16B are based on the formula 1 140d./(Units sold) + 0·73d., on which the curve in Fig. 9 is constructed.

Certain members refer to Tables 11 and 12 and ask whether these figures represent returns which may be expected in rural districts. The answer is "No, not on the average." We produced them for the purpose of indicating what large sales may be effected when electricity can be offered at the prices shown.

On the one hand Mr. Bentham thinks we have greatly over-rated the revenue to be expected under the conditions laid down. Mr. Elliott endorses this view by saying that we are too optimistic as regards domestic consumption.

On the other hand Mr. Long says that his experience is that after 3 or 4 years he is getting sufficient income to cover outlay and all expenses from widespread rural areas surrounding Norwich. Mr. Scott gives instances of highly successful development, one with an average revenue of £7 9s. per consumer at a price of 2·445d. per unit sold, the load factor being 25 per cent with 63 per cent of premises connected, and the results being obtained in the 6th year. Mr. Joseph thinks we have based our demand on loads which are much too light, while Mr. H. S. Ellis thinks our revenues, which he recognizes are based on actual results, do not appear to be very different from what he has been accustomed to. It may, therefore, from this brief survey be said that in our estimates of revenue the honours lie with us. In any event, whether the units sold per consumer are slightly greater in quantity and lower in price or are lower in quantity and higher in price, the revenues will remain substantially as given in the Model Scheme. An ounce of fact is worth a ton of estimating, and although we are unable to give full figures, it is hoped that particulars of the actual results obtained to date in the areas of the two Demonstration Schemes will be included in the forthcoming Annual Report of the Electricity Commissioners. Suffice it to say that, after an average period of availability of supply of 24 months to the villages within the area, about 50 per cent of the inhabited dwellings are now connected.

Mr. Perks raises an interesting point when referring to our conclusion (see page 203) "that any drop in the charge per unit to consumers results in an increase of revenue." He assumes that we are referring to net revenue, i.e. the revenue after satisfying interest and depreciation and other charges on capital cost. He then endeavours to show by means of curves that our conclusion is wrong, arguing that increase of load tends to give a worse financial result. In the first place our statement refers to gross revenue and is conclusively supported by Mr. Phillips, where he gives an instance—one among

many—that a reduction in tariff is accompanied not only by an increase in revenue but also nearly always by larger gross profits. When making our statement we had in mind a well-equipped transmission and distribution system of capacity well in advance of existing requirements, and already subject to full interest and depreciation charges. We are fully aware that further connections mean increased capital expenditure, but we fail to understand Mr. Perks's attitude to increase of load. We may not have fully understood him, but he evidently finds it better to refuse load except for lighting and a few minor uses. Every little increment of load placed on his equipment seems to be the last straw that breaks the camel's back. His argument is contrary to all experience of farsighted engineers. Why should any enterprise be expanded if diminishing dividends or return on capital is permanently to be the result?

Sporadic Development.

In several places in the paper we have emphasized the necessity of preparing a complete scheme. Whether it is carried out all at once is not of great moment, but it is essential that the main framework should be prepared from a careful and complete survey. Mr. Phillips says that the Bedford scheme will prove whether one is justified in carrying out the complete scheme as early as possible, irrespective of potential revenue. The opposing view to this is what might be called peaceful penetration, i.e. waiting for each link to pay for itself before proceeding with further work. This, indeed, will be satisfactory, provided the ultimate and complete scheme is always kept in view, but if mains are cut down to suit the immediate load so as to ensure an immediate lucrative return, it will be very doubtful whether these mains will afford a suitable basis on which to expand, and so development will be hindered from the start. As to likely projects, we appreciate and agree to Mr. Perks's suggestion that some factor of wealth of an area would be the greatest value in determining whether or not to attempt development in a hitherto untouched area. We can think of nothing better than to take net rateable value (i.e. the value of property on which rates are levied) per head of population and relate it to some "standard" area and successful scheme. In this connection Mr. Britton submits very useful information when he says that experience teaches him that most country folk are willing to spend on electricity an amount equivalent to half the annual value of the premises they occupy, the exact figure depending upon their wealth and their desire for comfort.

Mr. Bentham and Mr. Phelps refer to the important subject of farm load and our average return of £11 per farm per annum. We are glad to note their optimistic view that in Table 10 this might be taken to yield £50 in place of the £20–£25 there estimated. The actual result given in Table 7 was, for the investigation therein recorded, £11·1 per annum. We can only repeat that we are confident that this actual poor result is due to the custom of loading an isolated consumer with so many initial charges (e.g. for erecting the usually needed spur line and transformer, etc.) that he has no money left to buy electricity and to continue buying it in quantities useful to himself and to our industry. We have referred further to this matter under the heading of "Spur lines."

In answer to Mr. W. T. Taylor, we have, as will be seen in Table 16A, estimated that the units which could be sold in the 6th year in our Model Scheme would be, for domestic and industrial use respectively, 9·5 and 7·2 millions. We consider that the proportion of industrial units taken represents a cautious estimate based on general information contained in the Commissioners' publications. Our omission to include revenue for street lighting is referred to by several speakers. We are glad to learn that electricity is more extensively used in village streets than we had thought. We did not include it as a separate item, chiefly because it would have unduly complicated the Model Scheme. This type of load may prove valuable and should certainly be sought. One of the advantages of overhead line conductors is that the poles may be used for lighting standards. In some of the smaller villages street lighting has been found to increase the rates materially and has therefore been discouraged.

Finally we would reiterate that we feel that the receipts shown on the revenue side of the account for the Model Scheme have not been assailed with success and that they may be accepted with confidence.

Conclusion.

We feel particularly indebted to the very able and concise criticism offered on our paper by members in responsible positions, and intimately engaged in pioneer work in rural areas. Their remarks form a most complete survey of the subject. The careful analysis of the proposals and conclusions at which we arrived has, we think, brought nearer a solution of the problem of rural electrification. The interest evinced, especially on the subject of tariffs, shows how much wider is the issue than that of rural work. We cannot conclude without acknowledging our indebtedness to Dr. Ekstrom and Mr. Ekstrom for their most able electrical analysis of the economies of voltage and conductor selection, and to Capt. Hines for his contribution on the economics of plant provision, the latter a matter not brought into the discussion but of intense interest to us and no doubt to other members engaged in rural development.

DISCUSSION ON "DIELECTRIC PHENOMENA AT HIGH VOLTAGES."*

NORTH MIDLAND CENTRE, AT LEEDS, 8TH DECEMBER, 1931.

Prof. E. L. E. Wheatcroft: I think we shall understand the subject of the breakdown of air better when we know more of the conditions of the ionization which occurs in the air. Although we know little at present about the mechanism of air breakdown, one of the facts which we have regarded as definitely established is illustrated in Fig. 1. This illustration was produced for quite a different purpose from that of explanation, and I have therefore extracted the essential parts of it for that purpose and incorporated them in Fig. E. This shows the characteristics of the breakdown of a sphere-plane gap. The curve OPR gives the breakdown voltage for a sphere of 25 cm radius, and the curve OPQ the voltage at which corona first appears. It is seen that in the range OP the formation of corona is immediately followed by breakdown, whereas in the range PQ–PR corona forms at a lower voltage than that required for breakdown. This has always been explained by assuming that corona tends to enlarge the effective radius of the sphere. If the centre of the sphere be kept fixed, enlarging the radius brings into play two opposite effects. The one is to reduce the length of the gap, and this tends to encourage breakdown; the other is to reduce the concentration of lines at the surface of the sphere, due to the larger effective radius. The region OP of Fig. E is that where the first effect is preponderant and breakdown is encouraged by the formation of corona; in the region PQR the second effect is preponderant and the breakdown voltage is raised by the increase of effective radius. Following Peek's† formula for voltage gradient between two equal spheres, it is possible to calculate the critical spacing for a given radius. The unstable condition is found to occur if the spacing is less than twice the radius of the spheres. On the analogy of this result for two equal spheres, we should expect the critical spacing for sphere and plane to be equal to the radius of the sphere. The critical voltage found by the authors is indicated by the point P (Fig. E) for a 25-cm sphere, and by the point R for a 50-cm sphere. In both cases the critical spacing is 4 times as large as we should expect from Peek's formula. The discrepancy might be due to the fact that the plane was small compared with the infinite plane demanded by theory, but in that case we should have expected a greater discrepancy at larger spacing and larger sphere diameters, whereas the ratio 4 : 1 seems to be fairly constant throughout all the results obtained by the authors. The most interesting part of the paper is the exposition of the theory of thermal breakdown. We have already discussed the difficulties involved in the usual overvoltage test, and we now find it possible on the thermal theory to correlate expected breakdown voltages with the results of inexpensive tests of dielectric losses. It would have been interesting to have had more experimental confirmation of the theory of thermal breakdown. This subject is dealt with in detail by Joffé, and I propose to show as lantern slides three diagrams from his book.‡ The first slide, reproduced from Figs. 48 and 50, gives the circuit to which a crystalline dielectric is equivalent, and the expected variation of dielectric power factors with frequency. According to Joffé, figures for glass and paraffined paper agree well with such a curve. The next slide, reproducing Fig. 53 of the book, shows the variation of breakdown voltage

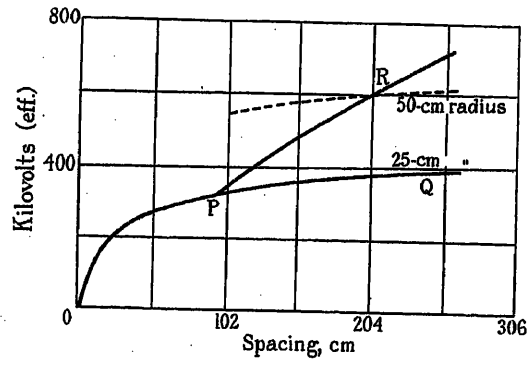

FIG. E.

and resistivity with temperature for two kinds of glass. According to theory, $\log (V)^2$ and $\log \rho$ should both give straight lines when plotted against $1/T$; the slope of the $(\log \rho)$ line should be slightly greater than that of the $\log (V)^2$ line; and the difference $[\log (V)^2 - \log \rho]$ should be the same for two different kinds of glass. All these points are confirmed in the results quoted by Joffé.

Mr. B. D. Youatt: It is interesting to note that Fig. 1 shows a constant ratio of about 3·7 between the critical gap and the radius of the sphere in a sphere-plane gap. The curve for the point-plane gap follows the critical spacings for the sphere-plane gaps, and it is consequently easy to determine the critical gap and voltage for spheres of any size. The radius of the sphere multiplied by 3·7 gives the critical gap, and the breakdown voltage of that gap (obtained from the point-plane curve) gives the critical voltage. The authors raise the question of electric wind and precipitation and couple this with the problem of the contamination of insulator surfaces. Some definite data regarding this question would be of real value. As regards their photograph§ of some insulators after exposure to a polluted atmosphere, a more definite test is to place

* Paper by Messrs. B. L. GOODLET, F. S. EDWARDS, and F. R. PERRY (see vol. 69, p. 695).

§ Not reproduced in the *Journal*.

similar insulators—some at a potential, others uncharged—in a fog chamber, where the conditions are controllable and can be kept reasonably constant. Comparisons of the weight and nature of the deposit indicate definitely the influence of the electrostatic field. The authors refer to the deterioration of the electric strength of air in confined air spaces. A very important instance of this arises in connection with the thin film of air between two dielectrics, e.g. compound and varnish-paper, in a bushing insulator. There is often very poor adhesion and one naturally assumes that such a film of air exists. This thin film is stressed both radially and axially. The dimensions of bushings are usually based on the wet and dry flash-over characteristics of the outside porcelain surfaces. Assuming that the thin film of air has poor dielectric qualities on account of the fact that it is closely confined, the breakdown voltage for the bushing will depend on the electric strength of that air and not of the air outside. Further, the fact that the bushing has associated with it a radial field of high intensity also tends to reduce the electric strength of the confined air. Turning to the question of the breakdown voltage of oil, the authors remark on the fact that the discharge voltage goes up with an increase of temperature, but they offer no explanation of this. Peek noticed a similar effect and suggested that it was due to the decrease in insulation resistance of the oil with increase of temperature, which would result in more even stressing of the oil and thus increase the critical voltage. When investigating surface discharges the authors made an attempt to measure the length of streamers and to correlate the length with other factors; they are to be congratulated on the remarkable way in which they turned an apparent failure into success. Their explanation of the varying length of streamers is interesting from the point of view that the circuit conditions are not dissimilar to those which hold in the case of an overhead line with polluted insulators. We know that the latter are liable to give rise to surges, but there seems to be some doubt as to the true explanation of these. The remark is made on page 712 that 50-cycle and impulsive discharges are very similar. [Mr. Youatt here exhibited two lantern slides.] These slides show a 3-unit post-type insulator flashing-over under 50-cycle and impulse voltages respectively, and it is clear that there is a tendency for the impulse arc to follow the surface of the insulator. Do the authors think that this characteristic is due to the high-frequency ripple which is nearly always present at the peak of an impulse wave? This preference for an impulse flash-over to follow the surface of the insulator was remarkably demonstrated in another case where a surface some 15 inches in length was in parallel with a gap of $2\frac{1}{2}$ inches. The impulse arc showed a decided preference for the longer path. In discussing the breakdown of solid dielectrics the authors seem to disparage the "simple theory" held by many engineers—that insulators have a certain electric strength and that if this is exceeded the dielectric will break down. There is an analogy in connection with the mechanical testing of materials, where another "simple theory" is held by engineers, namely that the test piece will break down if a certain tensile stress is exceeded, in spite of the fact that it is well known that the ultimate stress is altered by temperature conditions; the same should apply in the case of dielectrics. Further, a good deal of work is being done at present on the mechanical fatigue strength of materials, and although the implications are not thoroughly understood, there is no suggestion that we should depart from the original simple theory that stresses above a certain value will cause breakdown. I suggest that the theory at present held regarding dielectrics should be worked to in spite of the fact that we find variations of temperature, and alternating voltages give results which do not entirely confirm it. In the equations which the authors quote in attempting to develop a thermal theory of breakdown, particularly in that due to Dreyfus (No. 6), after substituting for γ_0 one finds that the breakdown voltage varies inversely with the square root of the frequency. If the frequency is made zero, to represent the case of direct current, the critical voltage rises to infinity. One therefore concludes that all high-tension transmission should be by means of direct current in order that insulation may be dispensed with! Fig. 4 illustrates the effect of a sharp-edged electrode in increasing the breakdown voltage of an air-gap. Peek found that the apparent electric strength of air between two parallel wires varies inversely with the square root of the radius of the wires. It is a reasonable assumption that a similar effect occurs in the type of electrode shown; if so, since the radius of the knife edge is infinitesimally small, the apparent electric strength of air in the knife edge—plane gap will be considerably higher than that in the gap in parallel, which consequently flashes over first. The authors' comments on this tentative explanation of the "paradox" would be of interest.

Mr. E. J. Evans: With reference to the question of the strength of materials, mentioned at the beginning of the paper, when approaching the subject of dielectrics it would appear to be helpful to make use of the mechanical analogy which is frequently valuable in obtaining a bird's-eye view of electrical problems. A machine can be considered to be distinct from a mechanism by virtue of the mechanical properties of its elements. A mechanism can be analysed dynamically, but it does not become a machine until the materials of which it is to be constructed are fixed. In other words, the most important factor in machine design is the strength of the materials of construction. Similarly, in applications of electricity one can analyse electrical circuits and pieces of apparatus without reference to the materials of which they are constructed, but one does not arrive at an actual engineering entity until the property which corresponds to mechanical strength, namely electric strength, is taken into consideration. The similarity is found to be even closer when one remembers that the energy in a circuit is transmitted not by the conductors, but via the dielectric. There appears to be a large amount of data available in regard to electrical breakdown of gases at low pressures and electrical phenomena *in vacuo*. Thermionics, to which so much attention is being devoted at present, is only one branch of the subject of electrical breakdown. Are the lessons which have been learnt by physical and

mathematical investigation of electrical breakdown *in vacuo* and in gases at low pressures being extended to air-gap dielectrics, and thence to the breakdown of solid dielectrics? Is the electrical strength of a solid dielectric affected by the presence of any of the several types of mechanical stress? The authors showed a slide of a flash-over occurring in an air-gap of which one electrode consisted of a cylinder with a sharp edge, and they point out that as a result of the presence of the sharp edge the flash-over prefers to take a path which in effect increases the air-gap to approximately twice its actual value. It seems to me that this striking effect should be capable of considerable application in switchgear design. In the section dealing with high-frequency breakdown the authors state that they use a Tesla coil for producing the high-frequency voltages; are other methods used for this purpose, and are they not preferable to the Tesla coil? The question of high-frequency breakdown appears to be bound up with the subject of boundary conditions in electrical phenomena. The study of boundary conditions is becoming increasingly important in both physics and chemistry, and I should like to know whether the authors consider that the study of the mechanism of electrical breakdown would be materially assisted by concentrating on this question of high-frequency breakdown and its general bearing on boundary conditions.

Dr. H. C. Bowker: I was interested to see in the picture* showing the discharges obtained when using the Tesla coil, that the discharge started by coming straight downwards from the sphere for a short distance (about half the radius) and then branched off at right angles, spreading out in all directions and eventually reaching the earthed electrode. It was pointed out to me some time ago that discharges of this shape often occurred, and that the short, straight "stem" was always associated with the negative electrode.† I should like to ask whether the authors have observed any connection between polarity and discharges of this type. Referring to Fig. 1, have the authors had any difficulty in getting those parts of the curves which correspond to the curve for the discharge from a point? When I was obtaining similar curves myself some years ago, I found that my results differed if I used a different transformer or if I put a resistance in series with the gap. The breakdown voltage seemed to vary with the amount of preliminary discharge, which may have heated up the gas or the electrodes. Again referring to Fig. 1, in connection with the first of the peculiar phenomena which the authors mention on page 698, I should like to draw attention to the fact that halving the gap only reduces the breakdown voltage from about 800 to 700 kV for a 75-cm sphere. The paradox remains, however, and I should be glad to know whether the authors have any explanation of it. I am interested in the decrease in the breakdown voltage after successive applications of the voltage, mentioned on page 701. I also have found that when successive spark-overs take place in a gas occupying an enclosed space this will occur. I found that if I raised the voltage very gently when near the spark-over voltage I could reach a higher value than what appeared to be the normal figure. The resulting spark was usually a very fat one, which seemed to heat up the spheres or gas. The next reading was always low. By allowing a little more time and raising the voltage much more slowly, I was able to get fairly consistent readings. I always noticed this irregularity when working at ordinary temperatures. When I was making tests at a high temperature I found that there was no possibility of getting an extra-high reading, nor could I get the extra-low reading. The results were much more consistent, and, of course, they were in agreement with the average readings at ordinary temperatures.

Mr. R. M. Longman: It is fortunate that the electric strength of air, oil, and high-class insulators, is generally greater for impulse or high-frequency tests than for the standard frequency of 50. It means that carrying out tests at a frequency of 50 gives one the comfortable feeling that for higher-frequency or surge conditions there is a much greater margin of safety. Whilst higher breakdown values are obtained both in air and in oil for spheres and planes than for the point-plane gap, there is unfortunately such a tendency to overlook points in the finished article that for safety the point-plane values must be adopted. The presence of a split pin, as I discovered recently, may alter the flash-over value very considerably. I cannot agree with a previous speaker that the insertion of a knife-edge will probably add to the electric strength, for in general practice the reverse is, I think, the case. From Fig. 15 I deduce that an insulator which may be quite satisfactory as a supporting unit without a central conductor passing through it, will have a much lower flash-over value if used with the same clearances but fitted with a central conductor, e.g. as a floor or wall insulator, or as a terminal insulator on a transformer. The effect of a conductor passing through an insulator also occurs in the tube-type current transformer, and it is interesting to apply a voltage to one of these in the dark and watch where the discharge occurs. I should think that under impulse tests it would be even more interesting. I recently came across a porcelain bushing having a central conductor which was used at approximately 20 kV in oil. It was of the ordinary bellied-type construction with centre fixing flange. The latter was filled with air, the slot in the end washer being at the bottom instead of the top, which effectively kept the air in. In my opinion this arrangement was wrong, and I have therefore had it reversed and the air expelled. Regarding the breakdown of solid dielectrics (pages 715 and 716), I am interested in the concept of thermal balance as expressed by Miles Walker. It is very similar to that put forward by Mr. Law many years ago when he spoke of the life of electrical machinery as consisting of so many temperature-hours above a certain critical temperature. The life of an electrical machine depends on its insulation resistance, and if it is overheated either by dielectric stressing or by purely thermal stress, its life is seriously affected. The authors refer (page 721) to the mechanism of real electrical breakdown of solids, but I think they are quite correct in dwelling so much upon thermal instability; after

* Not reproduced in the *Journal*.

† T. TERADA, U. NAKAYA, and R. YAMAMOTO: "Experimental Studies on Form and Structure of Sparks," *Scientific Papers of the Institute of Physical and Chemical Research, Tokyo*, 1930, vol. 13, p. 207.

all, have we in practice any perfect solid dielectrics? Glass and porcelain are the ones which most nearly approach the ideal. We have to make the best of, and know the worst of, the solid insulating materials with which we have to work, and we are always hoping and striving for something better. As regards Tables 13 and 14, may not the greater electric strength in oil be partly due to better heat conduction as well as to elimination of air? The authors deal at some length with the electric strength of fibrous materials, pressboard, and bakelite. My own experience of the breakdowns of bakelite is that they are due without exception to faults in manufacture—either through the laying-on of the paper or the bakelized powder. In one case the bushing was built up on a slightly smaller-diameter rod, and this allowed small air spaces to be formed, resulting in the failure of all the bushings made in that manner. In another case, after a breakdown a slight separation was found between layers after about one-eighth of the bakelite had been removed. The authors emphasize that it is of no use increasing the length of bushings without regard to their thickness. Designers and those who specify terminals should bear this in mind. A long thin procelain bushing is not satisfactory.

Mr. R. D. Ball: I should like to ask whether the authors have investigated the effect of a directed air-blast on the spark-over voltage between electrodes in air. By this means it may be possible to replace the ionized air by neutral air, and if the breakdown action is slow there is a chance of raising the breakdown voltage for a given gap setting. If the breakdown action takes place at the velocity of light, however, there is of course little chance of the breakdown voltage being raised. Experiments in this direction might yield useful information regarding the question of the rate of ionization and formation of corona.

Mr. W. R. T. Skinner: The figures given in Table 3 do not agree in all cases with the points plotted in Fig. 12. Which is correct, the table or the figure?

Messrs. B. L. Goodlet, F. S. Edwards, and **F. R. Perry** (*in reply*): The points raised by the various speakers will be dealt with according to the subject matter of their remarks.

(1) *Phenomena With Alternating Voltages of Normal Frequency.*

(*a*) *Air Breakdown at Large Spacings.* The explanation of the apparent discrepancy between the calculated gap setting at which the discharge-voltage and breakdown-voltage/distance curves begin to diverge, to which Prof. Wheatcroft refers, is that, although according to Peek* the divergence starts for a gap of $2r$ between spheres, the difference is not noticeable to an observer until the gap is considerably increased. According to Peek again, corona is not actually visible between two spheres until the spacing is equal to $8r$. The curves in Fig. 1 are seen to diverge at gap settings varying from about 6 to 7 times the sphere radius, though this is for the sphere-plane gap. We do not consider it safe to assume that from considerations of symmetry the field between two spheres is unaffected by the insertion of a plate at a potential midway between those of the spheres, in the region where brushing occurs before spark-over. Klemm* gives tables showing the starting point of discharges for sphere-sphere and sphere-plane gaps, for spheres up to 8 cm in diameter. In all cases the starting voltage for a sphere-plane gap is more than 50 per cent of the starting voltage for a sphere-sphere gap set at twice the spacing. The smallness of the scale of the illustration also prevents the beginning of the deviation from being shown clearly. Incidentally, the dimensions given in Fig. 1 are those of the sphere diameters, not the sphere radii. They affect Prof. Wheatcroft's figures, increasing, however, the discrepancy to which he refers.

Mr. Youatt has similarly assumed the dimensions to be radii, so that his value should be 7·4 instead of 3·7. His statement that the curve for the point-plane gap follows the critical spacing/voltage curve for the sphere-plane gap is not quite accurate, but we agree that the difference is not very marked.

The theory, so commonly applied to concentric conductors, that corona enlarges the diameter of the smaller electrode and so reduces the stress if the ratio R/r is above a certain critical value, while true to some extent is not an accurate representation of the conditions in a discharging sphere-gap, as the boundary of the discharge is highly irregular in shape, with numerous pointed projections.

In reply to Dr. Bowker, no difficulty was experienced in obtaining the breakdown curves at the larger spacings, but we can well understand that he obtained different results with different transformers or different series resistances. The most reliable results, which correspond with service conditions, are those where a transformer of large output and low reactance is used.

Mr. Youatt's suggestion regarding the fouling of insulators has been anticipated.†

We agree with him that air pockets may occasionally be found in outdoor bushings between the compound filling and the paper, or between layers of paper, but the danger does not lie in the confined space. This may be an advantage, as the supply of oxygen is thereby strictly limited. Also, thin films of air have a considerably higher electric strength than is obtained with thicker films. The risk of axial breakdown is greatly increased by the presence of air pockets, but the designed normal axial stress at the test pressure is usually less than the stress required for air breakdown. During a dry spark-over test, however, there would be some risk of internal spark-over on a badly manufactured outdoor-type bushing. We agree with Mr. Longman that air spaces between the paper layers are a prolific source of trouble.

Regarding Fig. 4, Mr. Youatt quotes Peek with approximate accuracy as saying that the apparent electric strength of air between parallel wires varies inversely as the square root of the radius of the wire, and proceeds to the limit for $r = 0$, whence the apparent electric strength is infinite. It must not be overlooked, however, that although as the radius decreases, the electric strength increases, so does the stress, and the breakdown

voltage may therefore decrease with decreased radius of wire.

Dr. Bowker's remarks on breakdown in confined air spaces are very interesting.

In reply to Mr. Ball, we have not investigated the effect of a directed air-blast on the spark-over voltage between electrodes in air. Nishi and Ishiguro* found that an appreciable increase in spark-over occurred due to air flow, the effect being more pronounced at low than at high frequencies.

(*b*) *Oil Breakdown at Large Spacings.* In reply to Mr. Skinner's query, Table 3 is correct. We regret that one of the points in Fig. 12 was mis-plotted.

(*c*) *Surface Discharges in Air and Oil.* Mr. Longman's remarks on the proportioning of bushings and the futility of increasing one dimension, say the length, without regard to the laws governing the behaviour of bushings, emphasize the need for a sound knowledge of the laws of surface discharge.

(2) *Phenomena with Impulsive, High-Frequency, and Continuous Voltages.*

We agree with Mr. Youatt that there is sometimes a tendency for an impulse spark to follow the surface of the insulator more closely than a 50-cycle spark, and that this may be due to high-frequency ripples at the peak of the impulse wave. Other causes, however, contribute to the appearance of the spark. The polarity of the impulse has an effect; a positive impulsive discharge takes the direct air path, while a negative impulse causes a discharge which clings more closely to the insulator, even when no high-frequency ripple is present in the wave.

In reply to Mr. Evans, the Tesla coil is the most satisfactory method of producing damped high-frequency voltages. Equipment producing undamped oscillations is perhaps easier to work with, but does not correspond to service conditions.†

The question of polarity does not, of course, arise in high-frequency damped oscillatory discharges.

As Mr. Longman remarks, it is very fortunate that the electric strength of air, oil, and solid insulation is generally greater for impulsive and high-frequency voltages than for 50-cycle voltages, because the voltages impressed as a result of lightning and switching disturbances are also higher, so that the true factor of safety is not increased as much as the test figures indicate.

(3) *The Breakdown of Solid Dielectrics.*

In reply to Prof. Wheatcroft, on account of limitations of space we were unable to include as many experimental results as we should have wished, but Fig. 31 may be taken as typical of the correlation which exists between the power factor and breakdown voltage of varnish-paper tubes.

We cannot agree with Mr. Youatt that there is any real analogy between mechanical and electrical breakdown (see Appendix II). As stated in the paper (page 715), there is some evidence that at low temperatures the form of the electric field plays a predominant part in determining the breakdown voltage, to the almost complete exclusion of effects such as time of stressing and temperature; but this ceases to be the case at higher temperatures. If we have understood Mr. Youatt aright, he suggests that we ought to obtain the same breakdown stress on a thick sample as on a thin one, i.e. the breakdown-voltage/thickness curve should be a straight line through the origin of co-ordinates. This is rarely even approximately true for cold materials, however, and it ceases entirely to have any validity for hot materials. In fact, as equations (7) and (8) lead one to expect and experience proves, the breakdown-voltage/thickness curve departs very widely from a straight line through the origin.

Mr. Youatt's statement that there is no suggestion that we should depart from the original simple theory of breakdown due to the stress exceeding a certain figure, is therefore hardly correct. Why, if the maximum-stress theory is correct, are d.c. breakdown figures sometimes two or three times as high as the peak values of the corresponding 50-cycle a.c. breakdown figures? The same speaker's deduction from equation (6) is invalid as he assumes that p_0 is proportional to the frequency, which is not necessarily the case, particularly at very low frequencies. p_0 is not zero, even with continuous voltages. Other factors also begin to operate with d.c. voltages which can be neglected in comparison with the much larger effects associated with alternating voltages.*

Mr. Evans inquires regarding the effect of mechanical stress on electric breakdown. The breakdown strength of insulating material always decreases with increasing mechanical tension, the change being quite small until the material is damaged by the mechanical tension, when the decrease becomes more rapid. The tests specified in B.S.S. 419—1931 ("Varnished Cloth, Sheet Strip or Tape for Electrical Purposes") and B.S.S. 137—1930 ("Porcelain Insulators for Overhead Power Lines") recognize this fact.

In quoting Mr. Law's statement that the life of electrical machinery consists of so many temperature-hours above a certain critical temperature, Mr. Longman seems to be confusing thermal stability and deterioration. This point has already been dealt with in our reply to Dr. Miller.† Nor do we agree that the life of an electrical machine depends on its insulation resistance, unless this term is being used in a much more general sense than its strict technical meaning warrants. Regarding Tables 13 and 14, the greatly improved breakdown voltage of paper and pressboard after oil-impregnation is attributed to the displacement of air, though no doubt the better heat conduction and heat capacity of oil have an effect on the tests at 50 cycles per sec. Under impulsive voltages, however, this explanation ceases to be tenable.

THE SELECTIVITY OF BROADCAST RECEIVERS.

By PROF. C. L. FORTESCUE, O.B.E., M.A., Member.

(*Introductory remarks to a Discussion before the* WIRELESS SECTION, *24th February*, 1932.)

(1) *Introduction.*—The electromotive forces in the aerial of a broadcast receiver are of infinite variety. Even those arising from the transmitting station to which it is tuned have a considerable range of frequency, within which range there are also undesired components arising from other transmissions and from natural causes. The different elements of the receiver have different functions, but, considered as a whole, its duty is to convert the incoming signal into audible sound, the intensity and frequency of which is related in some manner to the variations of the electromagnetic waves radiated from the transmitter. The selectivity of the receiver may be described as the extent to which the output of sound is independent of the waves emitted from all sources other than the transmitter from which the desired programme is being received.

(2) *What range of audible frequency is desirable?*—The first question arising in connection with the selectivity is the extent to which the sound output should be a replica of the modulation of the waves radiated from the transmitter. If the output is not an exact replica, what deviation is permissible or desirable, and under what conditions?

Many analyses of sound have been attempted and, as the apparatus becomes more and more sensitive, components of higher and higher frequencies are found. The female voice is known to have components with a frequency of 10 000;* and footfalls, hand-clapping, and the operation of typewriters are observed to have components of frequencies approaching 16 000. Provision is not usually made in broadcast transmitters for so great a range, and the vast majority of receivers have a much more limited range. A lower frequency limit of 50 and an upper limit of 5 000 are considered to give good results. But where audio-frequency output is subjected to the most careful scrutiny, i.e. in the production of talking films, it is noticeable that the tendency is to exceed this limit and to provide a full response up to 10 000 cycles per second.

It is, however, not only the limiting frequency that is involved; there is the even more difficult question of the uniformity of response essential for good results. A highly trained observer—not necessarily "musical"—may detect at particular frequencies accentuations, or the reverse, which the ordinary person would not notice. "Musical" people are sometimes even the least critical of all in this respect, owing to their peculiar power of imagining all the missing parts; just as in an ordinary telephone conversation the listener himself provides anything up to 50 per cent of the intelligibility.

No answer to these questions can be satisfactory unless it is given in terms of quantities capable of reasonably exact measurement. What shall be the quantities, how shall they be measured, and what shall be the specified limits in each case? In my opinion some arbitrary maximum frequency-range of, say, from 50 to 10 000 should be taken, and at least two figures of merit should be used to characterize the receiver, viz.—(*a*) a figure giving the area of its response curve as compared with the ideal; and (*b*) a figure representative of the uniformity of response over the active range of frequency. In each case the response must of course be measured in actual sound intensity from the loud-speaker for a given high-frequency input.

(3) *Why do these considerations determine the selectivity of the receiver?*—The rigid logic of the mathematician confirming the experience of the most careful observers shows that the modulated incoming signal may be analysed into an infinite series of harmonic components.* The frequency of these components is distributed above and below the frequency of the unmodulated transmitted wave over a range which is equal to the range of the audible frequency sound that is being transmitted. The unmodulated wave is the familiar "carrier wave," and the harmonic components are the "side-bands." This analysis applies not only to wireless telephone transmission but also to "spark" signals and to atmospherics. In the receiver itself the high-frequency characteristics, the behaviour of the rectifying device, and the "tone correction" in the audio-frequency amplification stages, may be made to combine with the properties of the loud-speaker in any desired way. The properties of all the constituent parts are well known or can be determined experimentally,† and generally there are means for the adjustment of these characteristics when the receiver is in use. For the given receiver with a given adjustment, however, each side-band component gives rise to a sound output, the fundamental frequency of which is equal to the difference between the frequency of a side-band component and that of the carrier wave. This is true whether both side-bands are transmitted or only one; it is also true for any form of detector and whether or not the tuning of the receiver corresponds exactly to the carrier wave. These factors only influence the amplitudes of the fundamental and harmonic components of the sound output. It follows, therefore, that if when receiving the carrier wave of the desired transmission a component of the same frequency as that of a side-band, but from some other transmission, impinges upon the receiving aerial, the results must be the same as if this wave had been a side-band of the desired transmission. In other words, of the infinite number of waves striking the receiving aerial at the same time as the signals from its own transmitter, all must contribute to the sound output in the same way as the

H. FLETCHER: *Bell System Technical Journal*, 1931, vol. 10, p. 349.

* "Encyclopædia Britannica," 14th edn.; H. LAMB: "Dynamical Theory of Sound," 2nd edn., p. 89; C. R. BURCH and J. BLOEMA: *Philosophical Magazine*, 1925, vol. 49, p. 480; and L. J. PETERS: *Transactions of the American I.E.E.*, 1926, vol. 45, p. 581.

† C. L. FORTESCUE and F. RALPH: *Journal I.E.E.*, 1930, vol. 68, p. 883.

corresponding side-bands contribute. Since only the side-bands of a limited range produce audible results, it follows that only the interfering waves within this range will become audible (unless these waves include both carrier waves *and* side-bands of an undesired programme). The greater the range of side-bands for which provision is made, therefore, the greater will be the range of interfering components also included. Is it not thus beyond question that the limit of selectivity of a broadcast receiver is solely determined by the range of audible-frequency notes for which it is designed? And is not any denial of this tantamount to endowing the receiver with some imaginary quality enabling it to examine incoming waves of a given frequency and to say " This one is mine, that is not "?

(4) *Are receivers as selective as possible?*—There is a good deal of evidence that many receivers accept high-frequency energy over a far wider range of frequency than is necessary, with the result that they suffer from serious interference, both the side-bands and the carrier waves of transmissions on neighbouring frequencies being received and their programmes heard. Such receivers are unbalanced in the sense that high-frequency components are received over a far wider range of frequency than is reproducible in the audio-frequency stages or in the loud-speaker. For instance, a receiver tuned to a high frequency of 10^6 ($\lambda = 300$ m) may respond to the extent of perhaps 30 per cent to frequencies which are 50 000 above and below this central value, and yet the loud-speaker may be limited to a frequency only just above 2 000. It would obviously be more satisfactory to limit the high-frequency range to 30 per cent at a departure of, say, 5 000 cycles per second from the central frequency. The needs of the loud-speaker could still be met and the energy received from other transmissions would then be negligible.

(5) *What is the best circuit arrangement for obtaining the necessary selectivity?*—The ideal high-frequency response curve would, no doubt, be a rectangle covering a range of 10 000 or 12 000 cycles per second on either side of the frequency of the carrier wave. But this can only be realized to within a few per cent by means of a complicated filter, which is both expensive and difficult to adjust if provision is to be made for more than one wavelength. A two-coupled circuit with its double-humped response curve can be made to give a fair approximation, but it involves tuning two circuits and adjusting the coupling to give the best results. Some reaction may also be necessary. A single circuit of high decrement can easily be made to give practically a uniform response over the required frequency range, but, as already mentioned, is subject to unnecessary interference. There seems, therefore, to be no way of obtaining the ideal characteristic on the high-frequency side alone that is not open to objection. The simplest arrangement is undoubtedly the single resonant circuit, but when the decrement is sufficiently low to avoid interference by transmissions on adjacent wavelengths, the higher-frequency side-bands of its own programme are themselves seriously reduced. Audio-frequency correction in the same sense thus becomes necessary on account both of the high-frequency effects and of the characteristics of the loud-speaker. It may be reasonably easy to accomplish one of these corrections without undue complication, but is it possible to compensate satisfactorily for both of them? Alternatively, since the loud-speaker causes the most serious errors, is it not possible so to reduce the decrement of the high-frequency circuit that interference is relatively slight, and, in doing so, to reduce the high-frequency side-bands only to such an extent as will result in the errors being small compared with those of the loud-speaker? This aspect of the selectivity problem thus seems to depend mainly on the loud-speaker. When its errors are reduced, the correction for the shape of the resonance curve will be more important.

(6) *Can the average purchaser of a broadcast receiver be entrusted with a sharply-tuned high-frequency circuit?*—This is a matter admitting of no mathematical treatment, and it is wholly outside the realms of any logical argument known to me. The results of experience in this direction, not only of the users of expensive receivers but also of the much larger number of people who have the simpler and cheaper instruments, would be very valuable.

(7) *Would the general use of selective receivers enable the difference of wavelength between transmissions to be reduced?*—In view of the facts set out above, it must be concluded that there are neither theoretical nor experimental grounds for any hopes in this direction. For morse signalling at hand speed, yes! for the range of side-bands for which provision is necessary is quite small. For broadcasting, however, the problem is different. Even the possibility of using only one side-band is not promising—it complicates the correction, and the insertion of the carrier wave at the receiver is quite impracticable. In fact, any tendency that may be observable is in the direction of a wider spacing in the frequency spectrum rather than the reverse.

Discussion before the Wireless Section, 24th February, 1932.

Mr. N. Ashbridge: Since the selectivity of receivers is closely associated with the performance of broadcast transmitters, the subject of selectivity is of great importance to the British Broadcasting Corporation. The first question I wish to discuss is the demand for selective receivers on the part of the public. We may divide the public into two classes: in the first class there are those who live in an area of strong field strength of upwards of 20 millivolts per metre, where selectivity is not particularly necessary because very little interference from other sources is noticeable. In the second class there are those who live in an area where the signal strength is about 5 millivolts per metre, and who might reasonably expect good reception were it not for interference due to peaks of signal strength from a distant station at night. At times the two stations may be of equal field strength and only 9 kilocycles per sec. apart in frequency. It is often suggested that the B.B.C. ought to cut off the higher frequencies at the transmitter. Apart from the effect that the adoption of this suggestion

would have on what we call "side-band heterodyning," if we were to cut off at, say, 5 000 cycles per sec. the masses of people living in areas of strong field strength would have reason to complain of the inferior quality of the transmissions. In this connection one has to consider what frequencies from the interfering station cause the "grasshopper" kind of noise which we call side-band heterodyning. I think this noise is due not to the extremely high frequencies but to those where the energy is the greatest, i.e. frequencies of 1 000 to 2 000 cycles per sec. It is therefore questionable whether, if the higher frequencies were deliberately cut off in the transmitter, there would be much reduction of these noises. With regard to highly selective receivers, one of the first essentials is stability of tuning. Unless care is taken in the design of a mains receiver the tuning will vary with every change in the mains voltage. Even in the case of transmitters a greater degree of stability is desirable if we are to use the extreme degree of selectivity which has been discussed lately. Prof. Fortescue has stated that the range of musical frequencies which ought to be included is 50 to 5 000 cycles per sec., and although I am in agreement with him here I consider that sooner or later higher frequencies will have to be considered. Recording by the "hill and dale" method in America deals with frequencies up to about 9 000, and this may tend to accentuate the demand for higher frequencies. On the other hand, a large number of our programmes are transmitted over Post Office circuits, some of which cut off at just over 6 000 cycles per sec., and of course this prevents the transmission of the higher frequencies in some cases. With regard to the judging of quality by musical people, we notice that a musician, no matter how good he may be, is not particularly sensitive to the width of the frequency band included in the transmission. He is, however, very sensitive to changes in amplitude, i.e. bad modulation control. On the other hand, people who are not musicians but who are interested in musical reproduction will at once notice if one cuts off frequencies above 5 000 cycles per sec. I believe this class of listener is very numerous nowadays. The public in general do notice the difference between the frequency cut-off of 5XX and that of the new transmitters. Even at 5 000 cycles per sec. the response of 5XX is reduced by at least 8 or 10 decibels. In addition, many receivers cut off seriously on the long wavelength employed by 5XX. As regards the upper limit for loud-speakers, I think 2 000 cycles per sec. is rather pessimistic for the average receiver in use to-day. Many modern loud-speakers register well above 5 000 cycles per sec., and although the response may be hopelessly non-linear at this frequency the fact that some sound is produced is more important than the maintenance of an exact mathematical relation to the response at other frequencies. Turning to the question of the spacing which should be allowed between the frequency channels of broadcasting stations, I should like to draw attention to the fact that the London Regional transmitter works at a frequency which differs by 11 kilocycles per sec. from that of its troublesome neighbour, and the frequency of the North Regional transmitter is roughly 11 kilocycles per sec. different from those of the Langenberg and Prague stations. Because these are free from interference, however, it is not necessarily correct to say that the present standard spacing of 9 kilocycles per sec. is quite adequate. We are very interested in single side-band working, i.e. transmitting one side-band with the carrier but not the other. To derive any considerable advantage from this system one would presumably have to cut off one side-band in the receiver. If the whole of Europe decided to change over to single-side-band working (and one day they may do so), each of the 12 million licensed receivers in Europe would have to be provided with a filter which would cut off one side-band completely. Such a filter could certainly not be produced for less than £1, and therefore, apart from the technical difficulties, the change-over to the new system would be exceedingly costly. Finally, I want to say something about the position abroad with regard to the frequency separation between stations. Many broadcast engineers abroad are not very concerned about frequencies over 4 000, and the type of receiver which they consider suitable for working in a country district is designed to cut off almost completely at 4 000 to 4 500 cycles per sec. in order to give interference-free reception. Foreign radio engineers do not complain of side-band heterodyning from our stations, whereas in England we get numerous complaints of side-band heterodyning even when there is an 11-kilocycle separation. There are two reasons for this state of affairs. In the first place, ultra-selective receivers are used abroad, and secondly (this is much more important) other countries employ a much higher mean modulation than we do. Modulation records which we have taken recently on certain Continental stations show that their mean modulation may be double ours. I consider that in the future there will be a demand for higher modulation frequencies: we should be able to receive on a loud-speaker much higher frequencies than 4 500 or 5 000, and I therefore feel that we must seriously consider the question of a wider frequency separation between stations. In this connection it is interesting to note that the United States consider that the broadcast cables now being put down should have a linear response up to 8 000 cycles per sec.

Mr. P. K. Turner: Prof. Fortescue makes the implication that the talking film sets a higher standard than broadcast reception in the matter of the upper frequency limit, whereas my experience of both gramophone recording and talking-film making, and, from the receiving end, of broadcast transmission, proves to me that the reverse is the case. My experience is that a clear cut-off at 5 000 cycles per sec. is regarded as a luxury in gramophone or talking-film recording, whereas we know that broadcast transmission contains at least another octave above that frequency. Prof. Fortescue is of opinion, and in strict logic I think he is perfectly correct, that in any attempt to estimate the performance of radio receivers one must include the performance of the loud-speaker. Unfortunately the practicability of this is very doubtful, because even if one includes in the performance curve of the receiver the mean spherical radiation of the loud-speaker, one cannot make any allowance for the acoustic circumstances in which it is being used. It is not only that the set must include one particular loud-speaker and no other, but it must be used in one particular type of room and no other; otherwise the

curve cannot be guaranteed. A sounder procedure is to base all our considerations on getting the best possible receiver, and to leave as a separate problem the selection of the best loud-speaker by suitable impedance matching. Again, according to Prof. Fortescue, strict mathematical logic implies that if a stray side-band from an unwanted transmission cuts into the band we are trying to receive, the results must be the same as if this wave had been a side-band of the desired transmission. I am not entirely convinced about this, because there is the difference that what we wish to receive consists of two side-bands, on each side of the carrier and having a definite phase-relation with it, whereas the unwanted radiation consists of one side-band only, its carrier and other side-band being possibly cut out by the receiver. Therefore we cannot say that the stray side-band must necessarily be identical in behaviour with the wanted pair of side-bands. An interesting point in this connection is the "demodulation" effect, i.e. the fact that the modulation of the unwanted carrier tends to disappear when the signal strength of the latter has been reduced to not more than 1/100 of that of the wanted carrier. I have found by experiment that when a carrier 10 kilocycles per sec. from the desired transmission is reduced to 1/300 or 1/400 of the signal strength of the wanted carrier, and the audio-frequencies are then reconstituted by means of a differentiating circuit, the "grasshopper effect" is reduced to very small dimensions. In a circuit of that kind the actual carrier, the heterodyne 10-kilocycle whistle, is reconstituted at full strength and has to be dealt with specially; but this presents little difficulty. I should like to press very strongly for the retention of frequencies above 5 000 cycles per sec. There is no doubt that anyone who has a keen (but not necessarily musically trained) ear and who is not deaf to those frequencies, soon learns to appreciate the difference between a transmission with them and one without. I find that even musical people are at first satisfied with transmissions which do not contain either these frequencies or those below 100 cycles per sec., and which suffer from all sorts of defects. They sub-consciously supply what is missing and they also dispense with what ought not to be there. However, if such people hear in quick succession a good and a comparatively poor transmission, they soon learn to notice the difference and become dissatisfied. In my opinion 8 000 cycles per sec. is the lowest cut-off possible if first-class quality is to be obtained. Lastly, I should like to state that there may be difficulties as to the handling of extremely selective sets by unskilled people. First, the mechanical difficulty of adjusting to exact tuning is merely a matter of gearing. Secondly, there is the difficulty of knowing when the set is correctly adjusted—a much more difficult problem. Receivers of the kind which I have been discussing, in which a super-selective circuit is followed by tone correction, give extraordinary results if there is any error in tuning. If the set is 200 cycles per sec. off tune, strong resonance is obtained at 200 cycles per sec. and nothing at all at lower frequencies. It is therefore essential to provide some indicating device, so that the listener may tune in by adjusting until the needle on the indicator goes up and comes back again, instead of relying on his own ear.

Mr. F. S. Barton: With regard to the remarks which have been made as to the necessary frequency range, I should like to refer to some work carried out in the Bell Telephone Laboratories which has recently been published* in America. In these tests, while several experienced listeners were listening to an orchestra the low and high frequencies were cut off by varying amounts with filters. It was found that when a frequency range extending from 80 to 8 000 cycles per sec. was employed the listeners considered the reproduction to be 95 per cent perfect. The problem before the designer of a commercial radio-telephony channel is simpler than the broadcast problem, because the designer knows definitely what band he has to deal with and he has not to arrange the apparatus so that it may be operated by a layman. Further, he is not hampered by financial considerations, because increasing the cost of a commercial receiver by £50 only adds a trifle to the capital outlay on the whole channel, and if the more expensive receiver gives an improved performance it will soon show an economic return. The increasing congestion in the short-wave channel makes it necessary to use that channel as efficiently as possible, and this can best be done by means of stable transmitters and very selective receivers. At the Royal Aircraft Establishment at Farnborough we are faced with the problem of obtaining short-wave communication for the Royal Air Force despite the inroads of commerce, and in order to solve this problem we are trying to design more selective receivers. Our ultimate object is to produce receivers suitable for aircraft work, but we usually approach an aircraft problem by first considering the same problem as applied to ground communications. Inspired by the work of the Post Office Research Station at Dollis Hill, we decided to investigate the possibilities of a super-heterodyne receiver with a band-pass filter in the intermediate-frequency amplifier. By a band-pass filter in the intermediate-frequency amplifier I mean a filter designed on the Campbell and Zobel theory and working between definite impedances, and not the arrangement of two coupled circuits arranged to maintain their coupling substantially constant over the tuning range, to which the term "band-pass filter" has been wrongly applied by the broadcast receiver manufacturer. While the latter arrangement is an improvement on a single circuit, and also on a coupled circuit with adjustable coupling, it is not a band-pass filter in the strict sense of the term. I cannot understand why band-pass filters have not been more used for radio frequencies, and I should be glad of information regarding the operating characteristics of this type of filter.

Mr. M. G. Scroggie: It may clarify our ideas on the subject of the relationship between selectivity and the desirable band of audio frequencies, to refer to three practical cases. In the first case the two transmissions are completely separated and the side-bands do not overlap at all. It is universally agreed that, at any rate in theory, it is possible to separate these transmissions completely in the receiver by using a perfect band-pass filter. In the second case the side-bands overlap, and there seems still to be some controversy over the question

* W. B. Snow: *Journal of the Acoustical Society of America*, 1931, vol. 3, p. 155.

whether it is possible to obtain the whole band of frequencies due to one of the stations, at the full modulation without any heterodyne interference. In the third case the side-bands overlap the carrier waves; it is now, I think, generally agreed that it is impossible to receive one of these transmissions without interference except by losing some of the modulation. The orthodox position is that complete separation is possible only in the first case, and, as Prof. Fortescue points out, it is generally considered desirable to cover an audio-frequency band of 10 kilocycles per sec., or preferably even more. What I have great difficulty in understanding is how it is possible to reconcile these aims with the unpleasant fact that the frequencies of stations are at present, on the average, separated by 9 kilocycles per sec. It seems to me not very much use discussing, at length, principles which can have no actual application to things as they are, but which can only be applied in things as we should like them to be. Assuming the principles stated by Prof. Fortescue, even with a theoretically perfect receiver one can cover an audible range up to only 4 500 cycles per sec. In the second case to which I referred, if one tried to include an audio-acceptance up to 10 kilocycles per sec. one would include not only the wanted station but also the carrier waves of two other stations and side-band frequencies of four other stations. To obtain complete freedom from interference the highest audio frequency put out by broadcast stations and received must not exceed 4 500 cycles per sec. with theoretically perfect apparatus; which means in practice that a good receiver can be allowed to reproduce up to perhaps 3 500 cycles per sec. Only those who claim to be able to discriminate between two waves of the same frequency can indulge in any higher hopes than these. If the unwanted station puts out modulation up to 9 kilocycles per sec. it seems theoretically impossible to receive anything at all of the wanted transmission without interference. I think it would be useful if the broadcasting authorities stated exactly what the limits of audio-frequency modulation are. Even if it is possible to discriminate between wanted and unwanted side-bands it is quite idealistic to think of accepting audio frequencies up to 10 kilocycles per sec., for this value includes the neighbouring carrier wave. It would therefore be helpful to know whether it is considered better to cut off at 3 000 or 4 000 cycles per sec. in receivers of practical design, or to tolerate the interference. I would add that there are districts in this country where the field strength from the nearest British station is considerably lower than that from Continental stations, and therefore one cannot assume, even for "local-station" reception, that the field strength of the wanted station is very much greater than that of the unwanted station.

Mr. I. J. Cohen: I should like to give a rough picture of the existing conditions in commercial radio-telephony. Consider, in the first place, the long-wave transatlantic telephone service, which operates on the single-side-band suppressed carrier system. As the circuits are required for telephone use, only the frequencies corresponding to the audio-frequency band of from 250 to 2 750 cycles per sec. are considered. Over this range the response characteristic of the receiving system has to be flat to within ±1 decibel. At present there are not many long-wave telephone circuits, so that there is no necessity to guard against interference from this source. The ether is full of long-wave telegraph transmissions, however; at 250 cycles per sec. from the carrier frequency on one side of the allotted telephony band and at 500 cycles per sec. from it on the other, there exist strong telegraph carrier frequencies. These spread slightly, the degree of spreading being dependent on the nature and speed of keying, and therefore the cut-off of the telephony receiver must be extremely sharp. As to the relative strengths of the wanted and unwanted frequencies, the field strength of the American signals may be as low as 1 microvolt per metre (the usual figure being about 25 microvolts per metre), and that of the telegraph stations about 100 microvolts per metre. An attenuation of 40 decibels is, therefore, required to bring the signals to equal strength, and then to make the telegraphy nearly inaudible another 40 decibels or more have to be added. Thus at least 80 decibels cut-off is required at 500 cycles per sec. from the edges of the received band. In this case, therefore, the ideal rectangular overall frequency characteristic mentioned by Prof. Fortescue is almost a necessity, and I maintain that such a characteristic can be obtained only with properly designed band-pass filters or their equivalent high- and low-pass sections. Referring to the multiple-detection type of receiver, provided that the early stages are properly protected against the image side-band, the intermediate-frequency band, and overloading, there can be little doubt that the overall curve of the super-heterodyne type of receiver can be made to approach the ideal characteristic more closely than the curves of other types of receivers. On the wavelengths from 14 to 40 metres conditions are now nearly as bad as on the broadcasting band. It is necessary to limit the receiving band widths of the short-wave telephony sets to between 8 000 and 9 000 cycles per sec., and to have a large degree of attenuation outside this range. The Post Office receivers used on these services contain some two dozen valves, five high-frequency tuned circuits, intermediate-frequency band-pass filters containing many sections, audio-frequency filters, and equalizers. To obtain sufficient selectivity it will perhaps be necessary to build the broadcasting receiver of the future on these lines.

Mr. P. W. Willans: One of the principal difficulties associated with a scientific treatment of selectivity problems is, as Mr. Turner has pointed out, our ignorance of the performance of loud-speakers. The acoustic problem involved in the complete circuit of transmitter and receiver comprises the polar characteristics of both the microphone and the loud-speaker, and the acoustic characteristics of both the transmitting and the receiving rooms. These considerations prevent us from taking a strictly scientific view of the subject; broadcasting is an art, not a science. We have to envisage the performer not as playing in the studio and being reproduced as faithfully as possible, but as playing in the home of the listener through the transmitting and receiving systems, which are in effect a part of his instrument. While scientific considerations are invaluable for indicating what is going on, the ultimate criterion must be one of æsthetic value. In any event it seems clear that no

precise quantitative definition of acoustic response is possible and that, in consequence, there is no satisfactory answer to Prof. Fortescue's first question. My second point is more particularly concerned with transmission. I believe that, in view of the nature of present-day broadcast transmissions, Prof. Fortescue's rectangle is not the most desirable response characteristic for a receiver. Most microphones, including the condenser and carbon types used by the B.B.C., give a rising characteristic in the neighbourhood of 3 000 cycles per sec. In the case of condenser microphones this rise in response may amount to 12 decibels at 3 000 cycles per sec. as compared with the response at low frequencies, if the sound is normally incident on the diaphragm. For random incidence this "top" accentuation will not be so heavy, the corresponding rise in response for a condenser microphone being about 7 decibels. As a result of some experience obtained in adjusting the response characteristic of a sensitive receiver, I am fairly certain that the present transmissions are in general too "toppy," and that a receiver designed to have a flat band-pass characteristic will be incorrectly adjusted for best results. I believe it is possible to cut out the higher frequencies without detriment to quality, and this is the only way in which the problem of lessening carrier-wave interference can be tackled. My only fear is that the B.B.C., realizing the situation, may suddenly decide to transmit on a flat response characteristic, in which case listeners would probably find their reproduction lacking in "top." I hope that the B.B.C. will pursue their investigations into the subject of microphones, with a view to eliminating sound-field effect and producing an exact translating device, and that they will consider accentuating the upper frequencies so as to aid in the solution of the selectivity problem at the receiver. Turning to the question of the desirable frequency range in receivers, I regard an upper limit of 5 000 cycles per sec. as more practical than one of 10 000 cycles per sec. Whatever is ideally desirable, we must face the realities of the situation; these are the present state of the ether and of public demand. If the public demands to listen to foreign stations—and a strengthening of this demand is a natural consequence of the increase in the field strength from these stations—the manufacturer is obliged to face the problem of removing the present conditions of severe interference. In actual fact the frequency separation between stations is not as great as 9 kilocycles per sec., since heterodyne notes of 3 000 cycles per sec. or less are often encountered. The only hope of solving the problem of heterodyne interference lies in increasing the strength of our own side-bands; the degree of selectivity necessary to give correct response at the receiver will then at the same time reduce the level of interfering signals. With reference to "grasshopper noises," the idea, mentioned by Mr. Turner, of reducing the effective interference from the side-bands of a neighbouring station by cutting down the amplitude of the interfering signals at the detector stage and restoring the attenuated side-bands of the wanted signals by audio-frequency distortion, is very important. One must, however, bear in mind that if the higher frequencies are removed before the detector stage, when they are restored the ground noise at the detector will be accentuated. I should be interested to hear of any practical experience of this effect. If development is to proceed along the lines of this idea we shall have to consider all possible means of accentuating the upper frequencies after the detector stage, and this may prove to be an important consideration in loud-speaker design. It was interesting to hear Mr. Turner state that in comparing two systems with different cut-off frequencies it was necessary to present the two alternatives in quick succession, in order that the difference might be appreciated. This would indicate that the gain in quality of reproduction was but a slight compensation for the resultant loss of selectivity, and on this account manufacturers would be reluctant to increase the frequency range of their receivers. In my opinion we are not yet using to the best advantage the limited frequency range imposed by the present state of the ether.

Dr. W. F. Rawlinson: Problems connected with the selectivity of broadcast receivers become ever more important as the number of high-power broadcasting stations increases. Comparisons of receivers and discussion of their characteristics would be greatly facilitated if some definition of selectivity could be agreed upon. Prof. Fortescue's two figures of merit do not appear, however, to cover the whole of the problem; in fact his figure (*a*) giving the area of the response curve as compared with the ideal appears to have no definite meaning. Assuming the receiver under consideration to give a somewhat peaked curve; at what point does he propose to make the height of the ideal curve equal to that of the actual curve? This point, which will obviously decide the relative areas, can be varied at will. A better way of aiming at such a figure of merit would be to construct an ideal curve of rectangular form having as base a frequency range of 50 to 10 000 cycles per sec., and an area equal to that of the actual curve of the receiver between the limits of zero and 20 000 cycles per sec. (Anything above the latter frequency would be inaudible.) Counting the actual area of the receiver curve which lies within the ideal curve as positive, all areas of the receiver curve which lie outside as negative, and any area of the ideal curve not filled by the actual curve as negative; the ratio of the algebraic sum of these areas to the area of the ideal curve would be the figure of merit for the response curve as a whole. Prof. Fortescue's proposals will only give the low-frequency response curve of the receiver, and this has little to do with the selectivity. For instance, a receiver with no high-frequency circuit at all, but having a simple detector resistance coupled to the aerial and a band-pass low-frequency filter with a sharp cut-off at 50 and 10 000 cycles per sec., would give perfect results according to Prof. Fortescue's two figures of merit; yet it would be hopelessly unselective. The measurement of the sound-intensity output for a given high-frequency input may give a figure of merit applicable to the case of ordinary-type receivers used in or near London, but it is not of so much value for receivers to be used at a distance from a high-power local station. From aural observation on the South Coast it appears that the signals from Mühlacker are often 10 to 100 times as strong as those from London Regional, and at such times it is the shape

of the high-frequency resonance curve outside the ideal band which is all-important. Unless the attenuation at 9 kilocycles per sec. from the carrier frequency is greater than 100 we shall receive the carrier and one side-band of the unwanted station, and these will be received at greater strength than the programme of the wanted station, and no audio-frequency correction will get rid of the interference. The figures of merit proposed by Prof. Fortescue would not show up this defect, even with the modifications suggested. A receiver which cut down to 30 per cent at 5 000 cycles per sec. would apparently be considered satisfactory on the basis of the proposed figures of merit, yet it might prove very unselective under the conditions of reception suggested above. True selectivity must be associated with the high-frequency part of the receiver, to which any figures of merit must apply. The following is a possible way of defining two figures of merit. Plot the high-frequency resonance curve of the receiver for a continuous-wave input of constant amplitude at various frequencies. Measure the actual area within a band of $\pm$ 4 500 cycles per sec. of the frequency to which the receiver is tuned. Construct a rectangle of the same area on the base of $\pm$ 4 500 cycles per sec. about the mean frequency. The first figure of merit (*a*) depends on the maximum departure of the actual curve from the mean height, i.e. the height of the rectangle. If this is not greater than 50 per cent it will not be noticeable in the audio-frequency output. The second figure of merit (*b*) expresses the ratio of the height of the rectangle to the height of the actual resonance curve at 9 000 cycles per sec. from the mean frequency. For receivers used near London a figure (*b*) of about 10 might be good enough, but for receivers used on the South Coast this figure should be of the order of 1 000. Experience shows that moderate quality free from interference is preferable to ideal quality and another station breaking through. Since in practice the carrier waves of stations are only 9 kilocycles per sec. apart, one cannot hope to avoid interference and cross modulation if one retains frequencies much above 5 000 cycles per sec. in the transmitter output. Whilst I do not think that the loud-speaker really affects the selectivity, I cannot support the suggestion that modern types of loud-speakers have a cut-off at 2 000 cycles per sec. Modern loud-speakers are much better than Prof. Fortescue would have us believe. The questions of shock and interference due to atmospherics and tramway systems, etc., must clearly be considered in connection with selectivity problems. In obtaining high-frequency selectivity we must guard against circuits capable of maintaining free oscillations for a considerable period of time.

Mr. D. N. Corfield: The discussion of the problem of frequency range seems to centre round the question of whether in order to eliminate interference it is desirable to have a range of only 4 to 5 000 cycles per sec. and put up with poor speech. Such a frequency range will give exceedingly good "commercial" speech, but it will not give lifelike speech; a frequency range of about 8 000 cycles per sec. is necessary if the sibilants are to be reproduced properly. Such a range renders necessary some form of band-pass tuning, but this introduces difficulties because the side-bands of the interfering station will come into the band width at their full strength. On the other hand, we may use instead some form of circuit giving high selectivity, and then correct for the side-band cutting in the audio-frequency stages. Such an arrangement produces a different effect, because with a selective circuit very little interference is produced by a station whose side-band frequency is receivable but whose carrier frequency is not. The accepted explanation of this is that if there is a carrier spacing of 10 kilocycles per sec. and the receiver cuts off at 8 000 cycles per sec., a 6-kilocycle interfering signal is demodulated as 4 000 cycles per sec.; in other words, the interfering side-band becomes inverted. It is well known that the highest frequencies contain the least power, and the result is that when these become demodulated they are automatically reduced in strength, since they are inverted. If we are going to get a sufficient number of stations into the allotted wavelength range, the single-side-band system will have to be adopted, either at the transmitter or at the receiver. If it is adopted at the transmitter, all the receiving sets in use at present will have to be replaced by new ones. Alternatively, we could arrange to receive only one side-band of a double-side-band transmission by employing a quartz-crystal resonance circuit, which gives a very sharp response characteristic and can be arranged to cut off either side-band at will. This system would enable one to receive a transmission even when there was an interfering transmission working on a frequency only a few hundred cycles per sec. above or below that of the wanted station. Unfortunately this applies only to one side: if there are two interfering stations, one of slightly higher and the other of slightly lower frequency than that of the wanted station, single-side-band reception will not eliminate interference. A further difficulty which presents itself in connection with the commercial use of a band-pass tuning circuit is that variation of the wavelength tuning causes a variation in band width, and nothing short of a very complicated filter will remove this defect. If a very selective circuit is employed it is found that the shape of the resonance curve remains almost identical over the whole wavelength range, and one would therefore require about the same degree of low-frequency correction throughout. It seems to me that a low-frequency correction circuit is much more likely to remain stable when installed in a private house than is a high-frequency band-pass circuit.

Mr. F. Murphy: Prof. Fortescue emphasized the necessity for a definition of selectivity: in my opinion such a definition must depend upon the conditions to be met, as clearly if there were only one broadcasting station in the world there would be no selectivity problem. In the area where I live the field strength from Brookman's Park is about 300 mV per metre, and that from Mühlacker is 1·5 mV per metre, so that if I desire to receive signals from the latter station my receiver must have a selectivity sufficient to discriminate against the adjacent channel of a station 200 times as strong. There are three forms of interference, namely ordinary heterodyne interference, intelligible modulation interference, and side-band interference. It occurred to me to investigate whether any one form of resonance circuit would give greater freedom from interference

than any other, assuming that a certain audio-frequency response had to be obtained. Assume that one station is transmitting with a modulation depth M_1; the strength of the side-band is $\frac{1}{2}M_1$, and the response in the receiving circuit is $\frac{1}{2}M_1\theta$. Assume that the second station has a carrier strength of x units and modulation depth M_2, so that the strength of its side-band is $\frac{1}{2}M_2x$ and the response in the receiving circuit is $\frac{1}{2}M_2x\theta$. If we divide one response by the other, θ cancels out, and the ratio of the interfering side-band to the wanted side-band is M_2x/M_1. In other words, it is quite independent of the shape of the resonance curve if the same audio-frequency response is obtained. The only way of getting rid of the side-band interference is to make $\theta = 0$. I recently had occasion to investigate a system which uses a very low-decrement circuit, and I was told that in this particular system the important feature was the free vibrations set up by the applied signal. If a modulated sine wave of e.m.f. is applied to a simple resonant circuit, the resultant can be expressed by two sets of terms. One term represents the free vibration of the circuit and the others the forced vibrations. The coefficient of the free vibration term depends only on the accidental value of the applied e.m.f. at zero time of application to the circuit. This free-vibration term cannot, therefore, be a measure of the modulation. We are dependent on the other terms in exactly the same way as we are in the case of the more normally damped circuits in common use. Returning to the question of the definition of selectivity, I think this should involve three terms. The first term should define the selectivity in terms of the field strength which it would discriminate against in the adjacent channel. The second term should be a statement of the percentage audio-frequency response at, say, 4 kilocycles per sec. off tune. The third term should define the volume-level at which the tests are conducted.

Mr. H. A. Brooke: I should like to refer to the necessity for discriminating between definitions of selectivity which apply to one side of the detector stage, and those which apply to the other. The difficulty with regard to neighbouring transmissions which are capable of giving interference cannot be overcome merely by limiting the audio-frequency response, owing to the fact that cross modulation will occur in the detector itself. Selectivity must therefore be defined on the high-frequency rather than on the audio-frequency side. If interference is to be eliminated under the present conditions of a total separation of about 9 kilocycles per sec., the highest audio frequency that it is permissible to transmit and receive must necessarily be limited to about 4 500; otherwise there is always trouble due to the neighbouring side-bands.

Mr. H. L. Kirke: I recently investigated the problem of stray side-bands and the cut-off at 5 000 cycles per sec. by carrying out a test on two transmitters of frequencies separated by 9 kilocycles per sec. One was supposed to be giving the transmission which was required, and the other the interfering transmission. In the interfering-transmitter circuits I inserted an arrangement enabling me to switch in and out a filter circuit cutting off at 5 000 cycles per sec. The receiving circuits were so arranged that no programme interference was audible, but there was strong side-band interference. I found that frequencies above 5 000 in the neighbouring transmission created no interference in the receiver. Mr. Harvey Fletcher has recently published* in America curves giving the average energy to be expected in speech and music over the frequency range, and these curves show that although the human ear appreciates frequencies above 5 000 the intensities at which these frequencies are normally transmitted by musical instruments or the human voice are very low indeed. There is therefore no argument in favour of cutting off in the transmitter at 5 000 cycles per sec.; it is better to leave the higher frequencies for those people who are fortunate enough to be able to appreciate them. As regards Mr. Willans's reference to the frequency characteristics of microphones, I should like to state that the microphone we normally use has a rising frequency characteristic both above and below 1 000 cycles per sec., rising up to about 6 decibels at 4 000 to 6 000 cycles per sec. and cutting off fairly sharply above 6 000 cycles per sec. All our amplifiers have straight-line characteristics to within a decibel or so, and we are therefore sending out an excess of the audio frequencies of the order 4 000–5 000 cycles per sec. The response of an untreated condenser microphone is liable to be 15 decibels higher at 4 000 or 5 000 than it is at 1 000 cycles per sec., when one is speaking in a direct line with the microphone; in other directions the response will be lower. We have recently been experimenting in two of our studios with a new type of condenser microphone which we believe will respond to frequencies well above 10 000 cycles per sec. It has a sensibly flat frequency characteristic. Tests in our studios show that everybody can distinguish the presence of the higher audible frequencies in the output from loud-speakers of modern design. The majority of people prefer to have these frequencies present and they like the flat response given by the microphones, whatever may be the frequency characteristic of the loud-speaker. When listening with a receiver which has a cut-off before the detector of 6 decibels at 5 000 cycles per sec. and 14 at 8 000 I can tell at once whether the new type of condenser microphone is being employed. With regard to the question of stray side-bands, we have made many tests on the question of the difference between general interference and side-band interference, all of which tend to show that the shape of the frequency characteristic is the important factor. In an arrangement whereby total demodulation could be made to take place either by complete removal of the interfering carrier or by demodulation in the detector, provided our receiver had otherwise flat frequency characteristics we should expect to experience considerable side-band interference. Our tests show that this interference actually occurs. By using a circuit with a radio-frequency characteristic which can remove all frequencies above 5 000 cycles per sec. on each side of the wanted carrier, we can eliminate side-band interference. If, instead, we place immediately after the first detector a low-pass filter which cuts off at 5 000 cycles per sec., the same result will be produced. Consider the case where we obtain complete demodulation due to the use of a linear detector, the field-strength ratio of the two carriers being 10 or 12 to 1. If the difference between the carrier frequencies is 9 kilocycles

* *Bell System Technical Journal*, 1931, vol. 10, p. 849.

per sec., we have in the anode circuit of the detector a 9-kilocycle note which has the same modulation as the interfering station. The system is like the intermediate-frequency circuits of a super-heterodyne receiver. If we remove all the frequencies associated with the interference we shall experience no interference at all. If, on the other hand, we do not remove all these frequencies the interference will be audible as side-band and not as programme interference. If these currents or voltages encounter any subsequent non-linear device in the apparatus, such as a valve or a transformer, they will again be rectified as in the second detector of a super-heterodyne circuit, and whole-programme interference will be experienced. Thus one can get rid of side-band interference by cutting off after the detector. With regard to cut-off at high audio frequencies, several years ago we carried out tests with what were then considered to be the best types of loud-speakers, and we found that most people were agreed that an overall cut-off at 5 000 cycles per sec. was tolerable. They liked the higher frequencies to be included if possible, however. Very few people could notice when frequencies above 7 000 were cut off. Turning to the question of the use of highly-selective simple tuned circuits and tone compensation, I am impressed by the importance of amplitude distortion in and before the detector valve. If we use a non-linear detector we shall certainly produce distortion, resulting in the appearance of harmonics which were absent originally. The process of amplifying the higher frequencies to a greater extent than the low, exaggerates all these distortion terms. If any of the side-bands are wrongly phased or have the wrong amplitude in relation to one another, we shall also experience distortion. As an example of this, we recently tested a set made up on the principle of a super-heterodyne circuit with very sharply tuned intermediate-frequency circuits and compensation for the frequency characteristic in the low-frequency circuits. When observing frequency characteristics we noticed that an applied modulating frequency of 200 cycles per sec. produced in the loud-speaker a note whose frequency was estimated to be about 800 cycles per sec. The analysis of the output was as follows:—Fundamental frequency 1·6 per cent; 2nd harmonic 30 per cent; 3rd harmonic 9 per cent; 4th harmonic 37 per cent; etc., up to the 10th harmonic. We then proceeded to observe the high-frequency characteristics by injecting a variable-frequency carrier into the receiver and measuring the resultant rectified current. The high-frequency characteristics were found to be very asymmetrical, due to various so-called band-pass filters which had been incorporated to reduce the signal strength of the second channel, and presumably also to errors in the tuning of the intermediate-frequency circuits. The shape of the overall characteristic is important. I prefer a tail-off to a cut-off at 5 000 cycles per sec. In the design of receivers manufacturers are up against the problem of endeavouring to make a receiver which is acceptable to all sections of the public. In the first place, as Mr. Murphy suggested, some people want to receive a signal strength of $1\frac{1}{2}$ millivolts per metre when the interfering signal of an adjacent channel has a strength of 300 millivolts per metre. To do this, one must be prepared to accept a cut-off at 4 000 or 5 000 cycles per sec. in the overall characteristic. Secondly, there are those who are receiving 25, 50, and 100 millivolts per metre, and who are quite content to go on listening to their local programme. For them the problem is easy. Thirdly, there is the question of designing a type of set suitable for the people who live in areas where the signal strength is 5 or 10 millivolts per metre, and it is here that the problem of knowing where to cut off is most difficult.

Mr. H. Dewhurst: I have been asked to show a few slides of a filter (referred to by Mr. Barton) which was

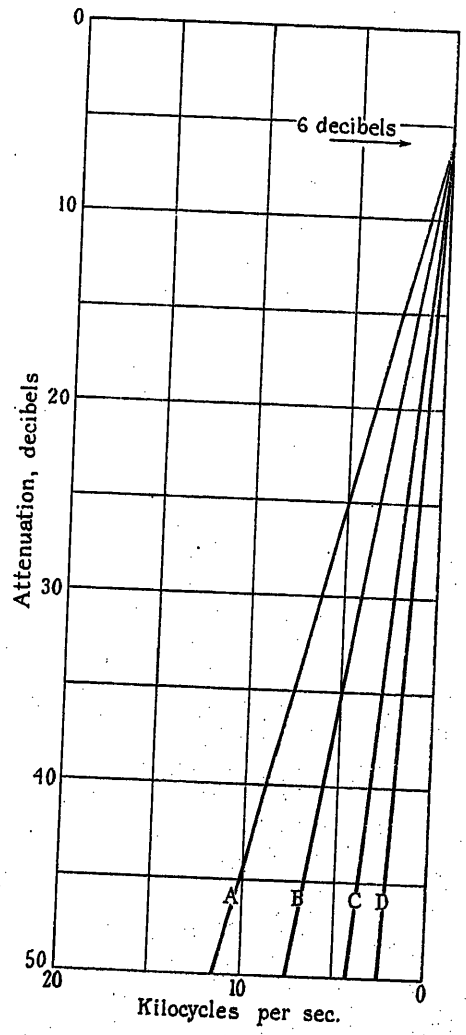

FIG. A.—Average filter slopes, reduced to 300 kilocycles per sec.

A.—180 kilocycles per sec.; slope 2·7 decibels per kilocycle.
B.—300 " " " ; slope 4·5 " " "
C.—500 " " " (R.A.E.) } slope 8·0 " " "
C.—300 " " " (R.A.E.) } slope 8·0 " " "
D.—300 " " " ; slope 13·5 decibels per kilocycle.

A, B, C, are commercial 3-element intermediate-frequency filters. D is a 4-element intermediate-frequency filter designed by the Royal Aircraft Establishment.

constructed at the Royal Aircraft Establishment, Farnborough, for use in a super-heterodyne receiver. The filter design was based on the telephone practice

developed by Zobel and Campbell in America. The first consideration in designing a filter is that of the impedance out of, or into, which it is to work. If the filter is worked at an impedance level for which it is not intended, reflection losses occur. For example, if a band-pass filter with a flat-top characteristic were used under wrong impedance conditions the flat top would degenerate into two peaks and the sides of the filter characteristic would become less steep. The only existing high-frequency filters which we knew about were of the 3-element type incorporating a tuned circuit in either the series or the shunt arm, and a condenser in the other; the usual arrangement being a coupling condenser in the series arm. Filters of this type are being used on commercial short-wave telephony and telegraphy. They are cheap to construct and are fairly easily tuned and handled. Fig. A shows the characteristic curves of various 3-element filters. Our first attempt (Filter C), also a 3-element filter, was an improvement on the existing types. A drawback of the 3-element filter, however, is that the losses in the coils modify the performance; instead of a flat top, a rounded top is obtained to the characteristic. A first essential, therefore, is to have very good coils. A further drawback is that this type gives an attenuation of a high

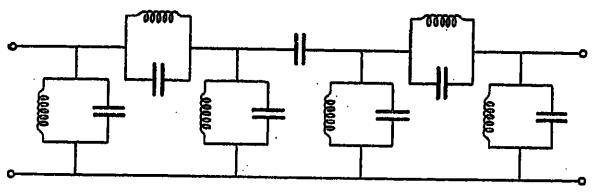

FIG. B.—Circuit of Royal Aircraft Establishment intermediate-frequency filter (D), composed of two complementary 4-element, double-M derived, π sections, and one 3-element π section.

order where it is not required. We therefore tried what is known as the " infinity cut-off " type of filter. This gives a cusp which pulls down the slope to a higher degree than would an increase in the magnification of the constituent coils. Our second design (Filter D) gives an attenuation of 34 decibels $2\frac{1}{2}$ kilocycles per sec. away from the point where the flat top starts. Thus, D would attenuate by 34 decibels an interfering signal $2\frac{1}{2}$ kilocycles per sec. away, whereas C would attenuate it by only 20 decibels. Filter D is of the 4-element type with a 2-element (see Fig. B) circuit tuned in both series and parallel arms. The series members provide the infinity cut-offs. The coils used in this filter are placed in copper cans to maintain their frequency characteristics constant and prevent interaction. Used in this way they still have a magnification of 200. The amplifier is provided with a semi-aperiodic tuned-anode coupling coil; and there are three contacts which automatically connect up the filter as soon as this is dropped into position.

Mr. C. E. G. Bailey: Experiments with a highly selective receiver incorporating audio-frequency correction show that this arrangement has certain advantages. If in order to correct the high-frequency cut-off we put in a resonance circuit to obtain the last iota of correction, the audio- and radio-frequency responses alike will drop after the selected upper frequency limit, and the consequent overall cut-off will be very steep. Accordingly, these circuits can eliminate that type of interference where the side-bands of the two transmissions do not overlap. Interference of the type where the side-bands do overlap can only be eliminated with the help of the demodulation effect. As has been pointed out, 2 carriers, each with a pair of side-bands, produce in the detector 27 components, some assisting and others tending to neutralize each other. The demodulation effect consists in the counteracting of certain components present in the output of the detector. It is clear that if a receiver with a sharp response curve is capable of receiving single-side-band telephony, it is also capable of responding to the note produced by the carrier or one of the side-bands of an interfering wave. How does such a receiver discriminate between these two? As Mr. Turner pointed out, in the first case there is only one side-band, whereas in the second there are two. It is easy to see that if we injected single side-band telephony signals into such a receiver we should get some sort of response: but the solution is to be found, I think, in the fact that we still get the carrier and, to a certain extent, the remoter side-band of the unwanted station, and demodulation balances out certain audio-frequency components produced by the two unwanted side-bands. This can be confirmed experimentally by the fact that if to a selective circuit one adds additional circuits, thus making a band-pass system which cuts off very rapidly, interference may increase. This may account for the selectivity of receivers of the quartz-crystal type, which, apart from the tremendous increase in response near the resonant frequency, behave as rather poor single-circuit receivers. I know of no way of eliminating that type of interference where both sets of side-bands overlap both carrier waves. Mr. Willans mentioned the effects of noise in connection with corrected receivers. One of the startling characteristics of this system is the decrease in the noise background. I account for this effect in the following way. If we imagine the noise spectrum to consist of a number of components spaced at unit intervals, the noise-level is produced partly by the interference of the carrier with each component and partly by the interference of the components among themselves. A perfectly level amplifier would give a noise response due to the latter cause proportional to $N!$, but in the case of a sharply-tuned amplifier there is little cross-heterodyning between the noise components, so that this source of noise disappears. Selective receivers employing resonant audio-frequency circuits for correction suffer from phase distortion at the upper frequencies, and, in the limit, resonance of long duration may occur round about the 4 000-cycle region. This type of distortion condemns resonated audio-frequency correctors as a method of obtaining quality with selectivity. Finally, we need a definition of selectivity. Since demonstration effects are complicated it is advisable to base this on the simplest considerations, and I suggest that selectivity should be defined in terms of the degree of mistuning in kilocycles per sec. which is required to reduce the signal level of a wave by 40 decibels. In order to avoid the logical confusion of using a term which is greater when the number describing it is less, I propose to name this

quantity the " connivance " of the receiver and not the "selectivity."

Mr. G. Builder: A question relating to receiver design which has been very little discussed is the distortion of transient modulation in tuned circuits of low decrement. In this connection some interesting effects may occur in band-pass filters having a double-peak resonance characteristic. The effect of the double peak is to superimpose a damped low-frequency oscillation on the original transient modulation; this oscillation may be regarded as a surging of energy between the coupled circuits of the band-pass filter. The dependence of the superimposed frequency on the separation of the resonance peaks may be readily confirmed by experiment. The effect may also be considered to be due to the combination of two transients set up at the resonant frequencies, and it may equally well be interpreted in terms of side-bands. I should like to point out that in the case of sinusoidal modulation, if one employs a band-pass circuit in which the ratio between the gain at the side-band frequencies to that at the carrier, multiplied by the modulation ratio, is greater than unity, serious distortion (chiefly second-harmonic) is introduced into the modulation. I have given these particular examples, not because they are directly relevant to the subject of selectivity, but in order to show that we must consider the possibilities of distortion of the transient modulation when designing circuits of low decrement.

Mr. T. Wadsworth: While there is little doubt that a certain degree of selectivity must be allowed, the real criterion of a receiver from the user's point of view should be the quality of the output which it delivers. From what has been said by the previous speakers it seems to me that there are two schools of thought regarding this question of selectivity and quality. The first school regards the quality of the receiver as its essential characteristic, and Mr. Ashbridge's remarks have shown that the B.B.C. belongs to this school. The second school regards the receiver as an extremely selective device, and considers that the quality which can be achieved at present is good enough for broadcast reception. We are of opinion that the first school is right. It follows as a corollary that we must regard the present frequency separation, 9 kilocycles per sec., as inadequate, because with this separation one can only get 4 500 cycles per sec. of audio-frequency range. The second school favours ultra-selective circuits and the use of tone control. It is questionable whether this method is fundamentally correct, because there is no evidence that by the use of tone control one can reinstate something which has already been taken away in order to provide increased selectivity. In connection with the B.B.C. transmissions, it would be an advantage to know the frequency characteristics of all the stations. Contrary to Mr. Turner's opinion, we have recently recorded on a film frequencies up to 7 000 or 8 000, and have found these films, both on speech and on music, to be of better quality than the average broadcast reception. We have also made a loud-speaker which has a response at 9 000 cycles per sec. and have found by experiment that the presence of this high frequency in the reproduction is beneficial, particularly in connection with speech.

Mr. W. J. Brown (*communicated*): It has been adequately demonstrated that the upper limit of the audio-frequency response of a sensitive receiver is approximately half the kilocycle spacing of adjacent broadcasting stations. With the present 9-kilocycle separation of stations the highest audio-frequency permissible is therefore 4 500 cycles per sec. It is not to be expected that any real improvement will be obtained by merely extending the station spacing to 11 or 12 kilocycles per sec. (with a corresponding maximum audio frequency of 5 500 or 6 000 cycles per sec.), since the increase in range would be much less than an octave in the musical scale. To produce any real effect at least a full octave should be added, which involves one of two alternatives, either (*a*) increasing the broadcast station spacing to 18 kilocycles per sec., which involves halving the number of stations; or (*b*) enforcing the suppression of one side-band from every broadcasting station, leaving the carrier and a single side-band to be transmitted. Transmission of a single side-band only has been rightly condemned, as it necessitates a special homodyne receiver; but a carrier and single side-band can, of course, be received on any normal receiving apparatus. Such a transmission would have the additional advantage of reducing the harmonic distortion in reception. When two side-bands and a carrier are received, even the best of detectors cannot avoid the introduction of a double-frequency component due to the beating of the two side-bands with each other. The elimination of one side-band from the transmission would eliminate this double-frequency component.

Prof. C. L. Fortescue (*in reply*): The outstanding feature of this discussion is the unanimity of opinion in favour of an extension of the audio-frequency range amongst those speakers who have had the opportunity of carrying out careful comparisons. Mr. Ashbridge and Mr. Kirke, Mr. Turner and Mr. Wadsworth, Mr. Corfield and others, all advocate extension up to 8 000 or even 10 000 cycles per sec. One or two speakers advocate a limitation to 5 000 cycles per sec., but apparently only on the grounds of unavoidable compromise. The feasibility of this extension of range with the present separation of carrier waves by 9 000 cycles per sec. has not been fully debated. Mr. Turner, Mr. Barton, Mr. Cohen and others envisage very complicated receivers; Mr. Corfield and Mr. Brown advocate single-side-band working in spite of the difficulties mentioned by Mr. Ashbridge and in my opening remarks. Mr. Bailey appears to favour very highly selective circuits combined with tone correction, but other speakers express doubts with respect to this system. Several speakers, and particularly Mr. Scroggie, point out the remarkable results already obtained with the small separation of carrier waves now used, the explanation being, no doubt, that given by Mr. Kirke and others, viz. that the energy in the high-frequency audio components is small. The advantage to be gained by linear detectors has been mentioned by Mr. Turner, Mr. Kirke and Mr. Bailey, but without making the matter very clear. That a strong carrier on an adjacent wavelength but not giving audible beats will almost blot out an incoming programme is certain; but when this carrier is modulated and when side-bands of both transmissions beat audibly with both

carriers the situation is quite different and far more complicated. The analysis is laborious but favours the view that in this case there is no immunity from interference to be obtained by a straight-line rectifier. The final conclusion appears to be that the greater perfection of rendering resulting from an extension of the audio-frequency range can only be obtained by increasing the separation of carriers. Actual experience must, of course, be the final arbiter, and it is unfortunate that so few people have actually heard the results obtainable by extension up to a frequency of 8 000.

An important question of design has been raised by Dr. Rawlinson in claiming that true selectivity must reside in the high-frequency stages of the receiver. It is obvious, of course, that if both the carrier and a side-band of an interfering programme are received on the high-frequency side, no selectivity on the audio-frequency side can have any effect. Provided, however, that the carrier of the interfering programme is eliminated in the high-frequency stages, it certainly becomes possible to eliminate very high beat notes either in the audio-frequency stage or even in the acoustical conversion in the loud-speaker. The essential point is that the beating of interfering side-bands shall not produce an audible note within the desired range of audibility.

One of the most important points raised in my opening remarks is the ability of the non-technical general public to handle a very selective receiver. Mr. Turner has alluded to the difficulties experienced, but several other speakers advocating complicated receivers seem to have omitted this aspect entirely. The situation has changed enormously in this respect during the last few years on account of the introduction of "ganging" of the controls. Provided that this ganging is sufficiently accurate, the public can probably be trusted to make a delicate adjustment with the accuracy necessary to give a good result. It is only necessary to watch an entirely non-technical person adjusting a receiver having ganged tuning and reaction control to realize the skill that is acquired in the course of a very brief experience. But in spite of this it seems very doubtful whether a receiver having more than two delicate adjustments would meet with public approval.

Finally there is the point raised by Mr. Willans of the non-linearity of the B.B.C. transmissions and the effects which this must have on the shape to be given to response curve of the ideal receiver. The present over-accentuation of the frequencies between 4 000 and 6 000 is almost certainly valuable with most of the more commonly used receivers, owing to the falling-off of their curves in this range. If this falling-off were not common there would probably be a great outcry against the action of the B.B.C. and an urgent demand for linear transmission characteristics!

DEVELOPMENTS IN THE TESTING OF RADIO RECEIVERS.

By H. A. THOMAS, M.Sc., Associate Member.

[From the National Physical Laboratory.]

(*Paper first received 5th January, and in final form 8th February, and read before the* WIRELESS SECTION *2nd March*, 1932.)

SUMMARY.

The paper describes the improvements in the technique of radio-receiver testing that have been made at the National Physical Laboratory. The arrangements now used for this purpose having been described in detail in Part 1, a proposed specification of methods of testing broadcast receivers is given in Part 2, together with experimental results obtained on such receivers. This specification is examined as to its applicability to the relative comparison of widely different types of receivers, and a classification is suggested so as to diminish the number of tests which it is necessary to make in order to assign a figure of merit to a particular receiver.

Part 1. DEVELOPMENTS IN TECHNIQUE.

(1) INTRODUCTION.

The apparatus installed at the National Physical Laboratory for testing the performance of radio receivers has been modernized and partially rebuilt, and while it still conforms to the general arrangement described in a previous paper,* considerable modifications have been made. This part of the paper gives an account of these modifications and a general description of the apparatus.

The original apparatus involved difficulties in the method of obtaining and measuring the modulated signal e.m.f. for application to the receiver under test. These difficulties have now been eliminated. Originally no accurate means were provided for giving very small radio-frequency variations on either side of a particular known value, such as are required to obtain selectivity characteristics. Provision has now been made for this, together with an improvement in the frequency stability of the system.

In any routine tests on receivers, rapidity in making the tests is important, and consequently ease of operation has throughout been regarded as a primary requirement. The attenuating system has been improved and made suitable for tests at very high frequencies. The range of input voltage which can be obtained has been greatly increased, also the screening, both of the feed system to the attenuating apparatus and of the attenuator itself.

The present arrangement is schematically illustrated in Fig. 1. Cabin B, which was described in the previous paper,* consists essentially of a completely shielded

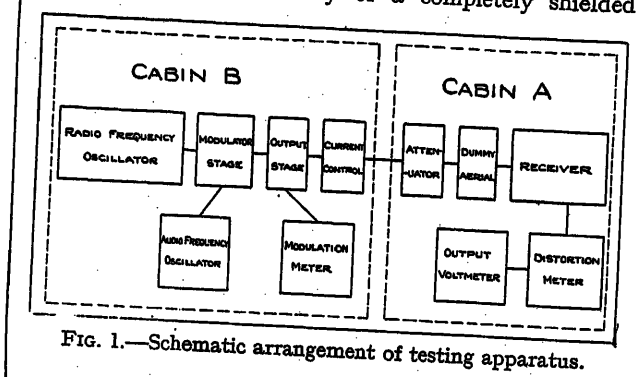

FIG. 1.—Schematic arrangement of testing apparatus.

room with a mercury trap-door seal. The generating apparatus which is enclosed by this screened room has been reconstructed, and consists of the master radio-frequency oscillator, a modulator stage supplied by a beat-tone audio-frequency oscillator, an output stage, a modulation meter, and a special device called a "current control." The radio-frequency oscillator has a range of from 10 to 50 000 kilocycles per second, and gives a good sine wave-form in the output stage. The audio-frequency beat-tone oscillator has a frequency range of from 20 to 10 000 cycles per second, the output containing less than 1 per cent of harmonics, and the modulator stage is capable of giving a correct modulation envelope up to a depth of modulation of 100 per cent.

The value of the current in the attenuator is controlled by the operator in cabin A by means of the current control device, which varies the output current but preserves a constant resistance load on the output stage of the generating system. Cabin A, which was also de-

* H. A. THOMAS: "A Method of Measuring the Overall Performance of Radio Receivers," *Journal I.E.E.*, 1930, vol. 68, p. 475.

* *Loc. cit.*

scribed in the previous paper, has remained substantially the same, except that improved screening has been constructed to minimize stray fields set up by the attenuator. The attenuator itself has been considerably altered to give greater range, and it is now more completely screened. A series of dummy aerials has been constructed for use with different classes of receivers, and these dummies represent the constants of the various types of aerials that would be used with receivers of different frequency ranges.

The audio-frequency output power is measured electrostatically in terms of the voltage across known resistances in the output stage of the receiver. The purity of the output is also examined by a harmonic distortion meter, which expresses the R.M.S. value of the whole of the harmonics as a percentage of the R.M.S. value of the distorted wave.

(2) Design of Modulated Radio-Frequency Generator.

The production of a modulated radio-frequency current in the attenuator system by means which do not involve several separately-tuned circuits is difficult. The simplest method of obtaining a modulated output is to insert an audio-frequency voltage in series with the anode voltage supply of a simple oscillator. This method, however, gives rise to a pure audio-frequency component superimposed upon the modulated radio-frequency component of current due to the inter-electrode capacitance between the anode and grid of the oscillator valve. Such a component, even if it were only of the order of 1 per cent of the R.M.S. value of the modulated wave, would give rise to serious errors not only in the measurement of the current fed to the attenuator but also in the determination of the modulation percentage by the use of a double rectifier system (as explained later). Although this difficulty can be eliminated by loosely coupling a tuned circuit to the main oscillation circuit, this involves two separate tuned circuits—a slight operational drawback.

The most serious objection to this simple method of modulation is that it introduces frequency modulation as well as amplitude modulation, due to the fact that the generated frequency of a triode oscillator is dependent upon the anode voltage supply. Admittedly this is only a second-order effect, but the frequency change so introduced may be many kilocycles per second, which is a serious matter when testing a very selective receiver. Consequently, to eliminate these difficulties a simple master radio-frequency oscillator, very lightly loaded and giving a small output, is used, the output from this oscillator being taken to the modulator stage. This modulator consists of a radio-frequency amplifier stage with tuned-anode circuit, and it is so biased that the characteristic working point lies on the non-linear part of the I_a/V_g characteristic It is possible, by suitable adjustment of the magnitude of the radio-frequency input e.m.f. and the value of the bias voltage, to obtain a linear relationship between the radio-frequency current in the tuned-anode circuit and the voltage supply to the anode. Once this condition has been arrived at by experiment, it is found to hold at all frequencies. When this condition obtains, a modulating e.m.f. inserted at an audio frequency into the anode circuit of the modulator gives rise to a modulated output in the anode circuit free from frequency distortion, since the amplitude of oscillation of the radio-frequency master oscillator remains sensibly unchanged, except for very minute changes introduced into the input impedance of the modulator stage by the varying anode potential. The two tuned circuits are ganged, and a fine adjustment or "trimming condenser" is provided to establish resonance. The output from this modulator stage is taken to a large-power output stage with an aperiodic load circuit, which delivers about 150 milliwatts to the current control circuit.

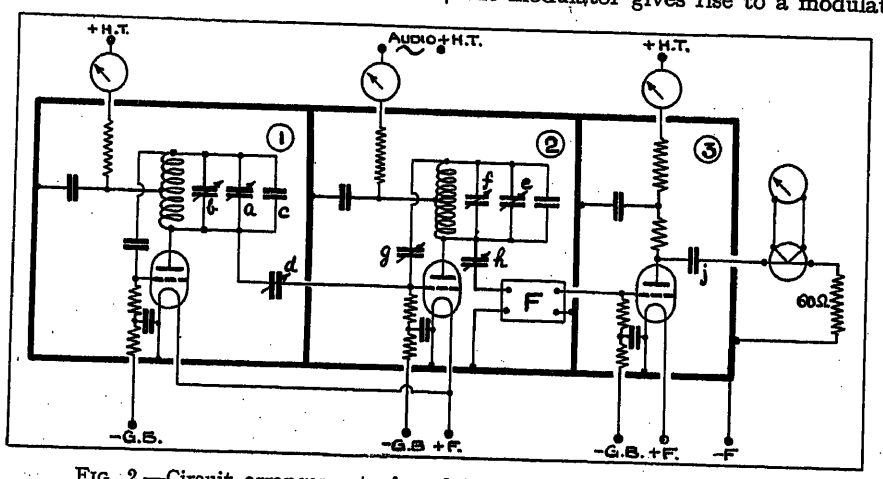

Fig. 2.—Circuit arrangement of modulated radio-frequency generator.

The general circuit arrangement of the modulated radio-frequency generator is shown in Fig. 2. The small-power master oscillator (1) is provided with a small variable condenser "a" of 15 $\mu\mu$F for giving small changes in frequency (a few kilocycles per second) for selectivity determinations. The main tuning condenser "b" is shunted by a fixed condenser "c," which ensures that the value of the capacitance is always large, this condition giving a good wave-form. The output from this oscillator is passed to the modulator

stage (2) by means of the coupling condenser "d," the value of which is definitely fixed after the condition for a linear relation between output and anode voltage of the modulator has been established by trial.

The main tuning condenser "e" of this stage is ganged to the main tuning condenser of the radio-frequency oscillator, and a trimming condenser "f" is provided. The audio-frequency voltage derived from the beat-tone oscillator is inserted in series with the anode voltage supply to this stage. Neutrodyning is found to be necessary, since without it the unbalanced inter-electrode capacitance between the anode and grid gives a radio-frequency output to the modulator when there is no anode voltage. This neutrodyne condenser is shown at "g."

The modulated radio-frequency energy is taken to the output stage (3) by means of the coupling condenser "h," which acts as a volume control. The audio-frequency component in the anode circuit is filtered out by means of the high-pass filter F.

The output valve supplies the line to the current control and attenuating system, and the d.c. component of the anode voltage is eliminated by the condenser "j." The impedance of the output line (60 ohms) is constant for all arrangements of the attenuator. The current output is measured by means of the thermo-junction shown. This junction serves only to give an approximate idea of the output to the operator in cabin B; the actual measurement of the current to the attenuator is made in cabin A.

The three stages of the modulated radio-frequency generator are carefully screened from each other, and the whole unit is enclosed in a heavily-screened metal box. A number of coils are plugged into the oscillator and modulator stages to cover the large frequency band required, and no difficulty is experienced in obtaining satisfactory operation over the range required.

(3) Measurement of Modulation Percentage.

Owing to the selective properties of the tuned-anode circuit in the modulator stage, the value for the modulation depth of the output radio-frequency current supplied to the attenuating system is not the same as that calculated in the modulator by means of a measurement of the peak audio-frequency voltage and the known linear law relating the output to the anode voltage of the modulator. At very low audio frequencies, the simple law holds, and it can be used as a means of checking any meter used for the purpose of measuring the modulation percentage of the current in the output circuit. This is due to the fact that the side-band cut-off is negligible at very low audio frequencies. It is safest, therefore, to measure the modulation percentage of the current in the output circuit; a separate modulation meter, the input to which is taken from the outgoing line circuit, has been constructed for this purpose.

The direct observation of modulation percentage is a rectification problem. The rectification of a modulated wave gives rise to a current having a direct and an alternating component, these being related to each other in a manner depending on the characteristic of the rectifier and the modulation percentage. The design of a modulation meter therefore resolves itself into the design of a rectifier of calculable behaviour, with means of measuring separately the direct and the alternating components of the output. The simplest calculable rectifiers are those operating by square-law or linear rectification. K. W. Jarvis* has described a modulation meter based on square-law rectification and consisting essentially of two anode rectification valve-voltmeters, one recording the direct and the other the alternating component of the rectified current. The instrument used in the present investigation has been developed on similar lines, and the theory on which it is based is given in full in the Appendix.

The calibration so obtained was compared with an experimental calibration obtained at a low audio frequency by using the simple modulation law which holds in the modulator stage and assuming no side-band cut-off in the anode circuit of this stage. Satisfactory agreement was obtained between the two calibrations. The calibration of the second rectifier is independent of frequency up to 5 kilocycles per second, and from 5 to 10 kilocycles per second the error is only of the order of 1 per cent. The values of the components used in the filter circuit connecting the two rectifiers are so chosen as to prevent any radio-frequency energy from giving a readable deflection on the second rectifier.

(4) Complete Generating Equipment.

The complete assemblage of the generating apparatus is shown in Fig. 3. The various components already described are mounted in panel form on a rigid metal frame. The modulated radio-frequency oscillator (1) occupies the top portion of the panel, and the three condenser controls operate the tuning, trimming, and volume-control condensers. Milliammeters are inserted in the anode supply to the master oscillator and the power output stage, the former to indicate the oscillating condition and the latter to show the presence of overloading.

The modulation meter (5) is situated below the oscillator, and the two microammeters (10) used with this instrument are placed on the shelf in front of the panel. The beat-tone audio-frequency oscillator (2) supplies a variable-ratio transformer (3) which in turn supplies the modulator through screened leads. The control of the output from this oscillator is at (4), and by means of the switches (6) the audio-frequency oscillator can be connected either directly to the attenuator system for calibrating audio-frequency amplifiers or to the terminals (11), which can be connected to telephones for checking frequency or for testing loud-speakers. The output current is indicated by the thermo-junction (7) and its associated microammeter (9). A small coil (8) may be inserted in series with the output line for coupling to a wavemeter for calibration purposes. The milliammeter (12) in series with the anode supply to the modulator is used to adjust the trimming condenser to the resonance condition. A voltmeter panel and switch (13) is provided to measure all battery voltages: this is necessary in order that faults may be rapidly located.

*K. W. Jarvis: "Radio Receiver Testing Equipment," *Proceedings of the Institute of Radio Engineers*, 1929, vol. 17, p. 664.

(5) Attenuating System.

The general arrangement of the means provided for obtaining known radio-frequency voltages for application to the dummy aerial system is shown schematically in Fig. 4. The leads from the generating equipment in cabin B are taken to the current divider, which consists of the series and shunt resistances R_1 and R_2 respectively. These resistances are arranged in the form of two parallel circles of studs, and the two contact arms are connected together mechanically. The values of the resistance steps per stud on R_1 and R_2 are so arranged that the division ratio I_2/I_1 is proportional to the number of studs (100 in all). At the same time the resistance load of the whole system—including the screened resistance in cabin A—is constant at a value of 60 ohms. By this means, control of the current divider from cabin A gives a 1 per cent change of current per stud and at the same time maintains a constant load on the output stage of the oscillator, thereby preventing any second-order frequency variations due to the alteration of the input impedance of this stage on the modulator. The divided current I_2 is passed through a special screened resistance R of the type described in a previous paper.* The voltage across this resistance may be used to supply the dummy aerial.

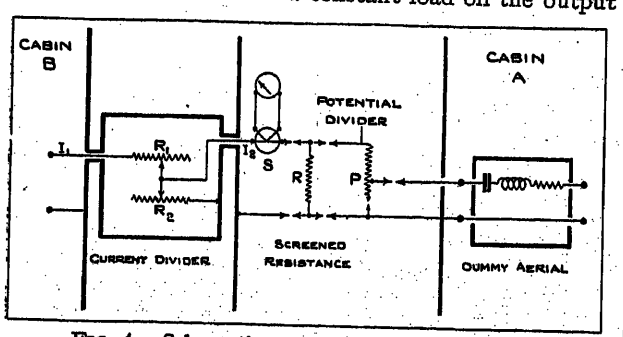

Fig. 4.—Schematic arrangement of attenuator.

* *Loc. cit.*

Since the possible current range as measured at S is about 10 : 1 and the range of resistances is about 40 : 1, the total voltage range is about 400 : 1 and the minimum measurable voltage is about 1 millivolt. To increase this range, a series of resistance potential dividers P are connected across the screened resistance R, and these can reduce the voltage to 1/1 000 of the value across the screened resistance. The use of this divider, which has an output resistance of about 1 ohm, enables a radio-frequency voltage range of from 1 microvolt to 1 volt to be applied to the dummy aerial system. Great care has been taken in the construction of these potential dividers to ensure that there is no frequency error up to 30 000 kilocycles per second, and at frequencies above this the error due to the inductance of the wires used in the divider is calculable.

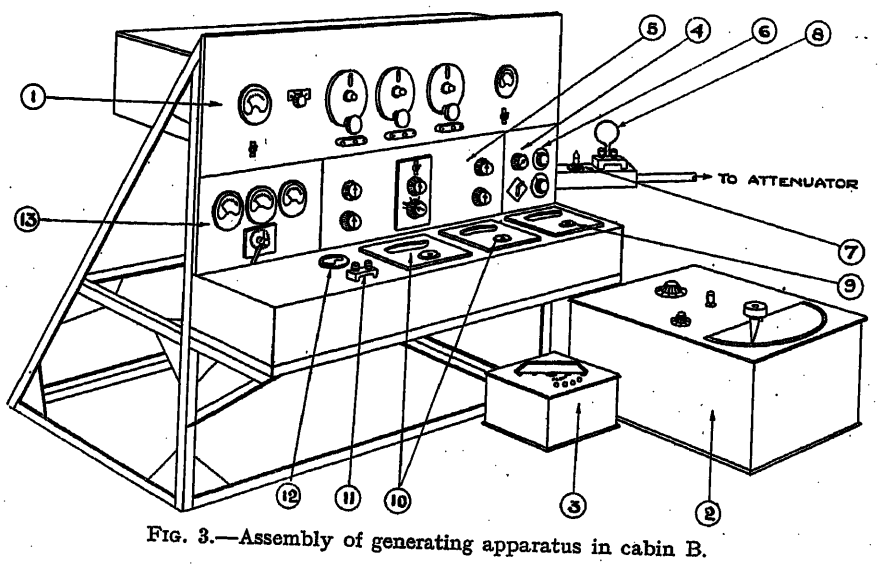

Fig. 3.—Assembly of generating apparatus in cabin B.

The arrangement of the attenuator is shown in detail in Fig. 5. The concentric lead from the current divider is taken to the screened box containing the thermo-junction for current measurement, and thence to a bayonet socket B into which one of the screened resistances is plugged. The potential leads from this resistance terminate in contacts C which engage with two insulated pins connected to two of the three contacts D. The series of potential dividers are mounted on the periphery of a disc, rotation of which brings any one of

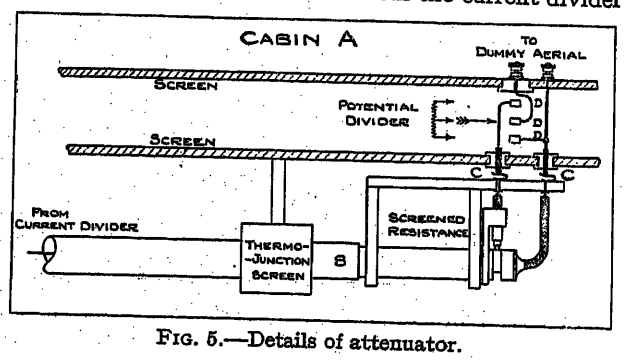

Fig. 5.—Details of attenuator.

them into engagement with the contacts D. The tapping contact and the earthed side of the screened resistance are taken to the terminals connected to the dummy aerial. Metal screens isolate the divider from both the screened resistance and the dummy aerial, and by the use of this screening system all direct induction effects are eliminated. The values of the effective resistance of the attenuator for its various combinations have been measured by a d.c. potentiometer, contact effects being eliminated by taking the mean value of the resistance so obtained with reversal of current.

The known e.m.f. is applied to a dummy aerial having constants equal to those of an aerial suitable for use with the receiver under test. The dummy aerial is made up as a small screened unit, and for broadcast receivers the following values recommended by the Institute of Radio Engineers* have been selected: capacitance 200 $\mu\mu$F; inductance 20 μH; resistance 25 ohms. These values are considered to be typical of an aerial having an effective height of 4 m. The equivalent e.m.f. to be applied to the dummy aerial by the attenuator to reproduce the condition required for the use of this standard aerial is 4 times that of the field strength in volts per metre. The potential applied to the receiver is calculated from the known resistance of the attenuator and the R.M.S. value of the current supplied, measured by the thermo-junction.

The R.M.S. value of a modulated wave having the form

$$E_{max.}(1 + m \sin nt) \sin \omega t$$

is

$$(E_{max.}/\sqrt{2})\sqrt{(1 + \tfrac{1}{2}m^2)}$$

where m is the modulation depth.

TABLE 1.

Modulation percentage	Ratio $\frac{\text{R.M.S. value of modulated wave}}{\text{R.M.S. value of carrier only}}$
0	1
10	1·0025
20	1·010
30	1·022
40	1·040
50	1·061
60	1·087
70	1·116
80	1·148
90	1·185
100	1·225

In actual broadcasting the carrier wave of R.M.S. value $E_{max.}/\sqrt{2}$ remains constant, and hence with varying modulation depths the R.M.S. value of the modulated wave will vary if the carrier wave is to remain the same throughout. A correcting term must therefore be adopted for different modulation depths, and the input must be expressed in terms of the R.M.S. value of the carrier wave only. The value of the function $\sqrt{(1 + \frac{1}{2}m^2)}$ for various values of m is given in Table 1.

Hence, if the modulation percentage is increased from zero to 100 per cent, the R.M.S. value of the modulated wave will increase by 22·5 per cent and the input to the receiver must be increased by this amount to maintain the same carrier-wave amplitude. This correction is negligible for the standard conditions of 30 per cent modulation when we are applying a signal e.m.f. to obtain a specified output in a sensitivity test, but it becomes important when a test of amplitude distortion is being made, i.e. when we are examining the proportionality of the output with respect to the modulation percentage at a constant input e.m.f.

(6) Measurement of Output.

The output load used throughout a test on a receiver may be the actual loud-speaker or telephones with which the receiver is normally used, but since receivers are supplied for use with any type of loud-speaker it is more usual to use as an output load a specified non-inductive resistance. This method is not ideal, for, as the author has shown,* the electrical characteristics of the loud-speaker affect the amplification of the receiver, owing to the fact that the input impedance of the power-valve stage depends upon the nature of the load in the anode circuit. Fortunately, however, the effect is small, and since it would be impossible to adhere to a particular loud-speaker for each receiver, the method of using a non-inductive load is permissible as a means of obtaining a general performance test of the electrical properties of the receiver itself. The value of the optimum resistance load to be used with any particular output valve is specified by the manufacturers, who use this value in giving the maximum undistorted power output. Since tests have shown that the magnitude of this resistance is not critical, the value suggested by the manufacturers has been adopted.

The output is measured in terms of the voltage across this resistance, which readily gives the power output; this is usually adjusted until it equals the maximum undistorted value the valve is rated to give. A double-range electrostatic voltmeter is used for the measurement of the output voltage, this method having been found to be more reliable than valve-voltmeter methods and quicker and more sensitive than a current measurement. The output is given in terms of R.M.S. values.

The output is also passed through a distortion meter, which gives the percentage of harmonics present in the output circuit. The meter is essentially an audio-frequency bridge which can be balanced at the fundamental frequency, leaving the harmonic remainder unbalanced and capable of measurement. The bridge, which has been developed by F. M. Colebrook on the lines suggested by I. Wolff,† is arranged as shown in Fig. 6. The meter is inserted in series with the output current circuit, i.e. the terminals X,Y, are connected in series with the output load. An e.m.f. equal to IR_1 or IR_2 is thus applied to the points A, B, of the bridge according as the switches are placed in position 1 or position 2. With both switches on 1 (the switches in

* "Proposed Standard Tests on Broadcast Radio Receivers," *Proceedings of the Institute of Radio Engineers*, 1930, vol. 18, p. 1282.

* H. A. Thomas: "Effect of Output Load upon Frequency Distortion in Resistance Amplifiers," *Experimental Wireless*, 1931, vol. 8, p. 11.

† I. Wolff: "The Alternating Current Bridge as a Harmonic Analyser," *Journal of the Optical Society of America*, 1927, vol. 15, p. 163.

practice being interlocked), the bridge is closed and an e.m.f. IR_1 is applied to it, I being the R.M.S. value of the current in the output circuit. The resonant arm CB is now tuned to the standard modulation frequency of 400 cycles per second used for these tests, and the resistance R_3 is adjusted to give balance for the fundamental. The system now becomes a simple resistance bridge. This balance is detected by means of the amplifier and telephones connected to the transformer T. The harmonics are now left unbalanced. Since the impedance of the resonant arm CB is large compared with that of the remaining three arms at all harmonic frequencies, and since the impedance of the transformer T is also large at all frequencies, the voltage across T due to the harmonics is to a close degree of approximation given by

$$IR_1 \frac{R_4}{R_4 + R_5}$$

The amplifier has an adjustable control for varying its amplification, and this control is now set to give a measurable output as read on the thermo-junction and galvanometer J. The switches are thrown over to

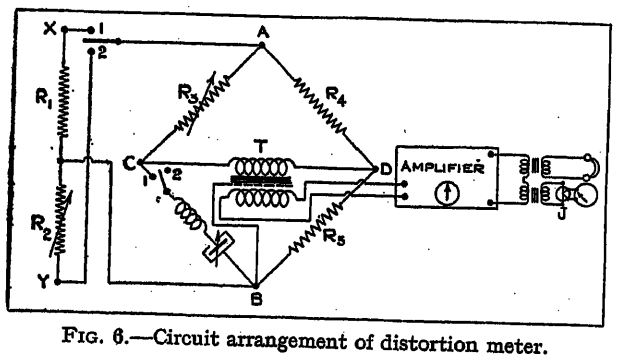

FIG. 6.—Circuit arrangement of distortion meter.

position 2, and the e.m.f. now applied to the points A, B, is IR_2. The bridge is now open, consequently the voltage applied to the transformer is

$$IR_2 \frac{R_4}{R_4 + R_5}$$

Leaving the amplifier adjustment unchanged, the value of R_2 is adjusted to give the same output in J.

The ratio of the R.M.S. value of all the harmonics taken together to the R.M.S. value of the distorted wave (including the harmonics and fundamental) is therefore given by R_2/R_1, and the measurement becomes dependent on the ratio of these two resistances only.

The variable resistance R_2 consists of two ribbons of constantan resistance wire about $\frac{1}{8}$ in. wide wrapped in grooves on the edge of a circular disc of keramot, forming a non-inductive bifilar circuit. The disc rotates, and contact with it is made by two stationary flat brushes composed of constantan wires. This type of brush has been found to give very satisfactory behaviour from the point of view of constancy of calibration. A second calibration made after an interval of several months was found to be identical with the first within the degree of accuracy with which the setting could be determined. The value of this variable resistance (R_2) is about 1·5 ohms, and the values of the fixed resistance R_1 may be 2·9, 6·6, or 12·16 ohms, depending on the range of harmonic content required to be measured. The meter is capable of measuring harmonic contents from just under 1 per cent to 50 per cent. The resistances R_4 and R_5 have values of 50 and 100 ohms respectively; an electric screen is inserted between the two windings of the transformer to eliminate capacity-current effects, and the whole bridge is screened by being enclosed in an earthed metal box.

From the above description it will be seen that the apparatus is capable of measuring a modulated radio-frequency voltage of from 1 microvolt to 1 volt at any frequency within the range 10 to 50 000 kilocycles per second. The accuracy of the voltage measurement is chiefly dependent upon that of the current measurement, and in the absence of any simple alternative method a non-contact thermo-junction is used at present. Within the limits imposed by the use of this instrument the accuracy is of the order of 1 per cent, which is quite adequate for radio-receiver testing.

The modulation frequency may have any value from 20 to 10 000 cycles per second, the exact figure being set by beating with a standard tuning-fork, while the accuracy of the measurement of modulation depth is within 2 per cent over the whole range from 0 to 100 per cent.

Part 2.—Proposed Method of Specifying Performance of Broadcast Receivers.

(1) Introduction.

In this part of the paper an attempt will be made to draw up a schedule of tests by means of which the relative performance of different broadcast receivers may be assessed. No apology is needed for making such an attempt, and although certain details of the proposals put forward may be subject to criticism on technical grounds, it is believed that there is a definite need for such a specification in order that the public may have information as to the quality of the apparatus which they use.

The difficulties of drawing up a satisfactory series of tests are many, due first of all to the several properties of the receiver which have to be considered and to the varying importance of different qualities depending on the purpose and method of use, and secondly to the fact that receivers have several controls, any one of which may produce large changes in the performance of the apparatus. It is owing to this fact that the testing of broadcast receivers is much more difficult than the testing of the majority of other electrical appliances where the conditions of operation are narrowly limited.

Hitherto, it has been the practice of manufacturers and testing laboratories to express the performance of a receiver by a number of graphical results. It is found to be extremely difficult to use such results for any direct comparison of the relative merits of different receivers, however, owing to the varying nature of the experimental conditions and to the impossibility of determining the performance under a set of conditions differing from those used in the particular test.

These facts point to the need for some standard of test methods and performance, so that both manufac-

turers and purchasers of receiving apparatus may have a simple means of assessing the merits of particular receivers. The essential properties of a receiver may be classified as (*a*) sensitivity, (*b*) selectivity, and (*c*) audio-frequency response and purity factor. To group these three together and give an overall performance figure may appear to be a dangerous procedure, but an attempt has been made to do so, and whatever may be the disadvantages of such a course it cannot be denied that an overall figure of merit is of great value in so far as it introduces a comparative method of assessing performance. The difficulty of so doing arises from the fact that the test specification must be such as to assess fairly the properties of the whole receiver and also give due weight to each individual property. In making this attempt, therefore, the author is fully aware that any proposed specification is open to detailed criticism; but if the result of such criticism leads to a standard specification he will consider himself amply rewarded.

(2) Sensitivity and Classification of Receivers.

Measurements on radio receivers have hitherto included sensitivity tests, in which the output was plotted against the input over the working range of radio-frequencies for different settings of the volume and retroaction controls. Since it is possible with modern receivers to obtain a very large sensitivity range by adjustments of this kind, such tests do not reveal any vital characteristics of the receiver, except in the case of super-sensitive receivers used for telegraphy where other considerations are made subservient to sensitivity. In these cases, however, the background noise has to be measured, and the ratio of wanted to unwanted signal determines the operational limit to the sensitivity.

It will usually be found that when the sensitivity is high the other properties of the receiver—particularly the audio-frequency characteristics—are adversely affected. Hence it is preferable to fix the sensitivity at some rated value and obtain the other properties of the receiver when operating under these standard input conditions.

Most broadcast receivers are required to operate under certain known local conditions; for example, the field strength is known if the receiver is to work in a broadcast service area, and the amount of interference due to other radio stations, mains hum, tramways, etc., is approximately known from experience and the topographical conditions. Hence a receiver should be tested to examine the extent to which it will give true reproduction of telephony under the known conditions of working.

In a general scheme of specifying the performance of the many different types of receivers, it is felt that it would be better to substitute for the sensitivity test a type classification, and to determine the properties of the receiver within the limits so imposed. This method possesses the advantage of eliminating a mass of irrelevant tests.

P. P. Eckersley* has suggested the following field strengths as suitable for the various service areas from a broadcasting station:—

(1) "A" service area, in which the field strength is greater than 10 millivolts per metre.
(2) "B" service area, in which the field strength is greater than 5 millivolts per metre and less than 10 millivolts per metre.
(3) "C" service area, in which the field strength is greater than 2·5 millivolts per metre and less than 5 millivolts per metre.

It is suggested that a fourth "D" class area should be recognized for field strengths below 2·5 millivolts per metre.

Any receiver submitted for test should be classified as suitable for one or more of the service areas defined above, and the test signal applied to it would correspond to the minimum field strength of that area. In the case of a "D" class receiver, it is suggested that the signal applied should correspond to a field strength of 1 millivolt per metre. It is probable that a receiver may be suitable for more than one service area, in which case separate tests should be made at the inputs corresponding to the various field strengths. The input would in all cases be applied to the receiver through the standard dummy aerial system described on page 118.

The output from the receiver presents another difficulty, in so far as the possible outputs from different receivers vary so widely. It is suggested, therefore, that the output power should be classified in a similar manner according to the type of output circuit adopted. The following scheme for broadcast receivers is proposed:—

(1) Very small output—below 250 milliwatts.
(2) Small output—250 to 500 mW.
(3) Medium output—500 to 1 000 mW.
(4) Large output—1 000 to 5 000 mW.
(5) Very large output—above 5 000 mW.

The output of the receiver would be measured in the optimum anode-circuit load resistance specified by the valve manufacturer as suitable for the valve used. The output resistance would in all cases be adjusted to this optimum value and the receiver would be tested with the maximum rated output.

The normal output level would in practice be very much less than this maximum, but since the receiver must be capable of handling the maximum output on transient high modulation percentages, it is better to test it at the maximum rated output.

According to this proposed specification, therefore, a "B 3" receiver is one that will give a medium output of 500 to 1 000 milliwatts when a field strength of 5 millivolts per metre is applied to the standard aerial. In such a case, a fixed input of 20 millivolts would be applied to the dummy aerial, since its effective height is taken as 4 m, and the receiver would be adjusted to give the maximum rated output with a modulation frequency and percentage of 400 and 30 respectively. This receiver adjustment would remain constant for all further tests at that particular radio frequency. The procedure would be repeated for any other test frequency. The number of frequencies at which tests are

* P. P. Eckersley: "The Design and Distribution of Wireless Broadcasting Stations for a National Service," *Journal I.E.E.*, 1928, vol. 66, p. 501.

made should be sufficient to establish by interpolation the general performance at intermediate frequencies. For the high-sensitivity receivers of class "D," the appropriate field strength adopted for the test would be stated.

(3) Selectivity.

The method of test proposed by the Committee on Standardization of the Institute of Radio Engineers* consists in plotting the input required over a band of frequencies covering resonance to give a constant output in the power stage with a constant modulation frequency and percentage of 400 and 30 respectively. This test is not altogether satisfactory, since it does not simulate the actual conditions of operation. It is better to maintain a constant radio-frequency input e.m.f. and to plot the output power when the input frequency is varied over a narrow band on either side of resonance. Such a test, however, gives the result in graphical form and the necessary deductions must be made from the graphs so obtained.

In seeking some test procedure which will give a figure for selectivity by which different receivers may

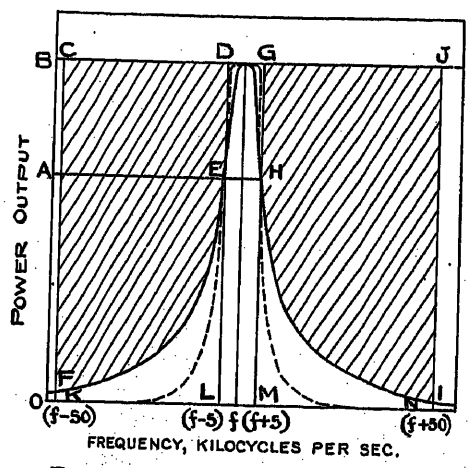

Fig. 7.—Definition of selectivity.

be compared, it is soon realized that simple ratios of the output at resonance to the output at frequencies differing from that of resonance by known small amounts do not give sufficient information and, in fact, may lead to quite misleading results. For example, suppose the resonance curve of a receiver is found experimentally to be as shown in Fig. 7 by the heavy-line curve, in which the power output is plotted against the radio frequency using linear scales for constant input e.m.f. One suggested method of expressing selectivity is to give the ratio of the response at a frequency displaced a known amount from resonance, to the response at the resonance frequency. In view of the crowded nature of the frequency allocations of broadcasting stations, it is considered that the upper audio-frequency limit which should be catered for is 5 kilocycles per second, and hence a receiver giving no side-band cut-off should have a uniform response over a total band width of 10 kilocycles (i.e. 5 kilocycles on either side of resonance). Referring to Fig. 7, it can be seen that the ratio OA/OB is the same for the simple tuned circuit as for the band-pass filter-circuit characteristic given by the dotted-line curve, yet the two circuits are obviously quite different so far as selectivity is concerned.

It is clear that from the point of view of radio-frequency selectivity the form of the response characteristic within the limiting frequencies $(f - 5)$ and $(f + 5)$, where f is the resonant frequency in kilocycles per second, is not what we wish to measure, since the form of this portion of the curve will determine the audio-frequency response and will make itself manifest in the later tests on this characteristic. The selectivity may be defined as a function of that portion of the response characteristic which lies outside the 10-kilocycle band, and it is suggested that the selectivity be expressed by the effective area of this curve between the 5-kilocycle line and another line separated from resonance by some arbitrary frequency. If 50 kilocycles per second be taken as this arbitrary frequency limit, we can express the selectivity as

$$\frac{1}{90P_f}\left\{90P_f - \left[\int_{f-50}^{f-5} Pdf + \int_{f+5}^{f+50} Pdf\right]\right\}$$

where f = resonant frequency in kilocycles per second,
P = power at any frequency,
and P_f = power at the resonant frequency.

This is represented graphically in Fig. 7 by the sum of the shaded areas CDEF and GHIJ divided by the sum of the rectangles CKLD and GMNJ. For a receiver having a perfect filter system which passed only those frequencies lying between $(f - 5)$ and $(f + 5)$ kilocycles per second, the value of this expression would obviously be unity; for any other characteristic the selectivity would be less than unity. This simple definition gives a figure which, although not so instructive as the plotted characteristic, forms a useful criterion of selectivity in most practical cases. It is suggested that this figure—expressed as a percentage—should be obtained at certain selected values of the resonant frequency, and that by its use different receivers could be compared at those frequencies. It is admitted that such a numerical statement of the selectivity does not give all the information contained in the actual response characteristic, but it must be remembered that the object of the specification is to obtain some simple figure which will act as a useful guide in comparing different receivers. With this object in view the suggested method of expressing the selectivity appears to be satisfactory.

Selectivity tests should be made at a very low modulation frequency of about 50 cycles per sec., so that the characteristic is virtually that which would be obtained with no modulation.

(4) Audio-Frequency Response and Purity Factor.

There are two important audio-frequency properties of a receiver:—

(*a*) The audio-frequency output power plotted against

* "Proposed Standard Tests on Broadcast Radio Receivers," *Proceedings of the Institute of Radio Engineers*, 1930, vol. 18, p. 1282.

the modulation frequency for constant radio-frequency input e.m.f. and constant modulation percentage,

(*b*) The harmonic distortion produced at various values of the output power up to the maximum rated output of the power stage.

(*a*) is important since it reveals the general response obtainable over the audio-frequency range.

Let us assume that the response characteristic is plotted on a logarithmic audio-frequency scale from 50 to 5 000 cycles per second and a linear power-output scale, as shown in Fig. 8. Here again, we seek some means of assigning a numerical value to this characteristic which will express its relative merit with respect to the desired uniform response over the stated range. The simplest method, that of giving the ratio of the maximum to the minimum power output, is unsatisfactory, since it permits widely different divergent characteristics to have the same value of this ratio. To express the characteristic as the area of the curve

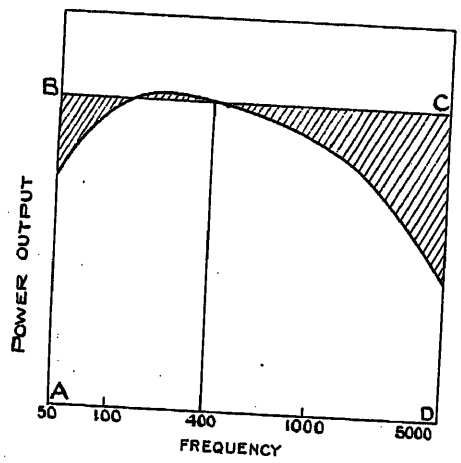

FIG. 8.—Definition of audio-frequency response.

between the frequency limits of 50 and 5 000 cycles per second divided by the rectangle having the same base and a height equal to the maximum ordinate, is also unsatisfactory and for the same reason.

A better method is to express the characteristic as the ratio of the sum of the shaded areas (see Fig. 8) to the area of the rectangle ABCD, where AB is the value of the power output at the standard frequency of 400 cycles per second. This method gives a figure which is more nearly a function of the departure from the mean value. Since we desire a perfect characteristic to have a numerical value of unity, we must define this audio-frequency response figure as

$$1 - K\left(\frac{\text{Sum of shaded areas}}{\text{Area of rectangle ABCD}}\right)$$

where K is some arbitrary constant which we must choose so as to grade various characteristics in proportion to their degree of excellence. Since, according to this definition, a characteristic which decreased according to a linear law from some value at 50 cycles per second to zero at 5 000 cycles per second would have a value of about 0·44 if K were equal to unity, and since we can say that such a characteristic would represent an exceedingly bad form of audio-frequency distortion, it is suggested that K be given the value 2, in which case such a bad characteristic would yield a numerical figure of 0·12, or 12 per cent. Hence the audio-frequency response can be defined as

$$1 - 2\left(\frac{\text{Sum of shaded areas}}{\text{Area of rectangle ABCD}}\right)$$

It will be found that this method gives a comparatively satisfactory method of discriminating between a good and a bad audio-frequency characteristic.

The usual form of the harmonic-content characteristic is as shown in Fig. 9, and a numerical value can be assigned to this characteristic by defining the purity factor as

$$1 - K\left(\frac{\text{Shaded area AEFD}}{\text{Rectangle ABCD}}\right)$$

where K is again some arbitrary constant.

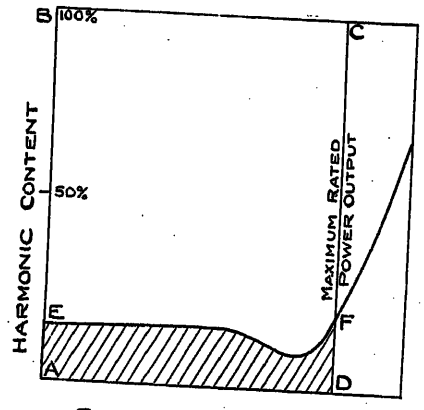

FIG. 9.—Definition of purity factor.

It is more difficult to assign a value to K, but since harmonic distortion probably plays a very important part in contributing to poor-quality reception, we desire to choose K in such a way that the effect of strong harmonics is to give a large reduction in this numerical figure. Tests have shown that a typical harmonic content for a fairly good receiver is 10 per cent. It is claimed that in first-quality receivers employing straight-line rectification and push-pull output circuits the harmonic percentage has been reduced to values below 2 per cent, and that a 5 per cent harmonic content is readily noticeable. In view of this, it is suggested that K be assigned the value 4, in which case we can define the purity factor as

$$1 - 4\left(\frac{\text{Shaded area AEFD}}{\text{Rectangle ABCD}}\right)$$

For an output containing no harmonics, the purity factor is 100 per cent.

(5) OVERALL PERFORMANCE.

In order to see what values the previous definitions will give when applied to a typical receiver, two cases

from actual tests are given. In the first case, a typical 3-valve receiver employing retroaction and using a grid-circuit rectifier, an audio-frequency amplifier stage,

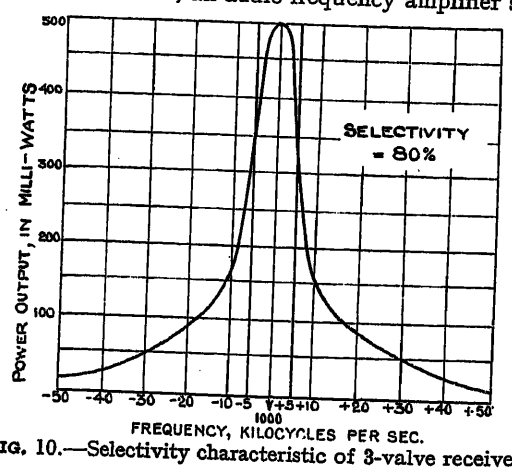

FIG. 10.—Selectivity characteristic of 3-valve receiver.

and an output stage, was tested. It was found to be suitable for a "B" service area, and consequently the input to the dummy aerial was adjusted to correspond

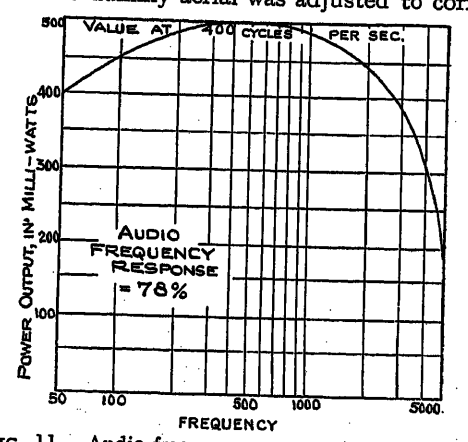

FIG. 11.—Audio-frequency response characteristic of 3-valve receiver.

to a field strength of 5 millivolts per metre. The radio frequency used for the tests was 1 000 kilocycles per second. The output stage was found to correspond to

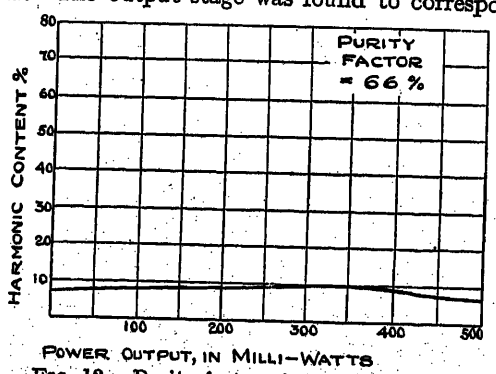

FIG. 12.—Purity factor of 3-valve receiver.

Class 2 (250–500 milliwatts), its maximum rated output being 500 milliwatts. This output was adopted throughout the tests.

The selectivity characteristic is shown in Fig. 10, from which it will be seen that there is an appreciable cut-off at 5 kilocycles per second departure from the resonant frequency. This is a very general type of selectivity curve for a receiver with a simple tuned circuit and retroaction, without band-pass tuning. Adopting the definition already given, the selectivity figure for this curve is 80 per cent.

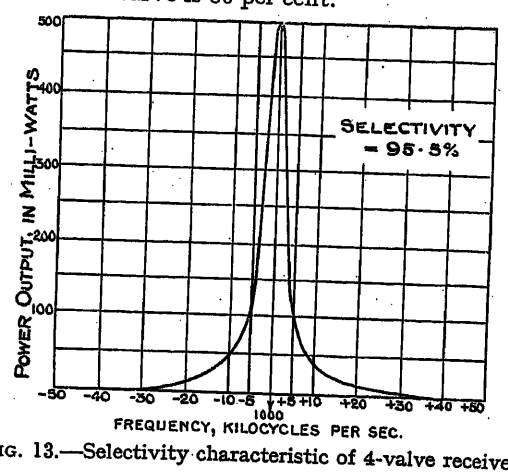

FIG. 13.—Selectivity characteristic of 4-valve receiver.

The audio-frequency response characteristic is shown in Fig. 11. The rapid drop in sensitivity at frequencies above 2 000 cycles per second is due to the shape of the response characteristic shown in Fig. 10, and the audio-frequency response for this curve is found to be 78 per cent.

Lastly, the purity factor (see Fig. 12) is found to be 66 per cent.

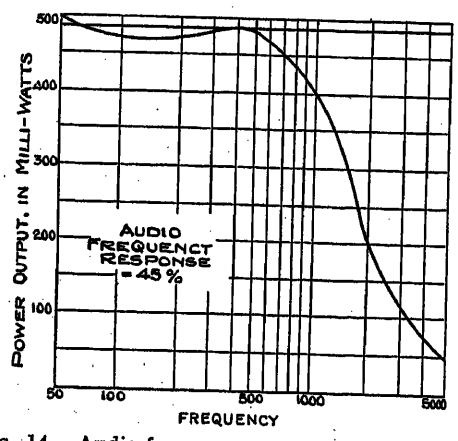

FIG. 14.—Audio-frequency response characteristic of 4-valve receiver.

A 4-valve receiver was examined in a similar manner. This receiver had a screen-grid stage, a grid-circuit rectifier, an audio-frequency amplifier, and a power-output stage similar to that of the previous 3-valve receiver. It was found to be suitable for a "C" service area, and is therefore a "C 2" receiver. The input was adjusted to correspond to a field strength of 2·5 millivolts per metre, and the selectivity characteristic was obtained. This characteristic, which is shown in Fig. 13, exhibits a greater side-band cut-off than that of the

previous receiver, and without retroaction it was found impossible to improve it. The selectivity of this receiver (95·5 per cent) is greater than that of the previous one, but the audio-frequency response characteristic (Fig. 14) shows how serious the side-band cut-off has become. The audio-frequency response figure obtained from this latter characteristic is 45 per cent, while the

TABLE 2.

Receiver	Class	Test frequency	Selectivity	Audio-frequency response	Purity factor	Overall performance figure
		kilocycles per sec.	per cent	per cent	per cent	per cent
3-valve	"B 2"	1 000	80	78	66	41·2
4-valve	"C 2"	1 000	95·5	45	58	24·9

purity factor—given in Fig. 15 as 58 per cent—is much the same as for the previous receiver. The results obtained on these two receivers are collected in Table 2.

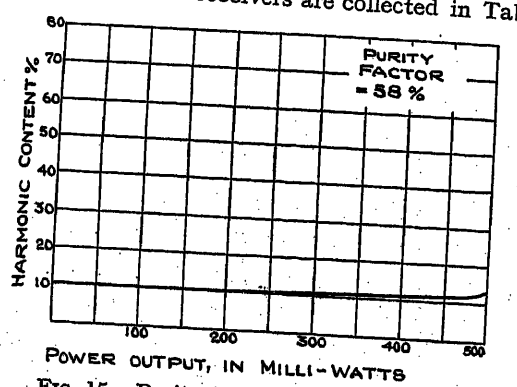

FIG. 15.—Purity factor of 4-valve receiver.

The overall performance figure is the product of the three separate characteristics expressed as a percentage.

If retroaction had been used in the 3-valve receiver so as to convert it to a "C 2" receiver, the side-band cut-off would have been far greater and the audio-frequency response figure correspondingly lower. It is clear, therefore, that this method of classification prevents high figures from being obtained by the excessive use of retroaction, and at the same time ensures that a poorly-selective receiver is not awarded a high figure of performance. The overall figure acts as a useful general guide to the performance, but it should only be given in conjunction with the three separate figures from which it is built up.

It may be argued that the test curves shown in Figs. 10 to 15 do not represent modern practice. While it is true that they do not represent a modern band-pass receiver with linear rectification, they are typical of many commercial receivers without band-pass tuning. As an example, Fig. 16 shows the audio-frequency response characteristic of a well-known modern commercial 3-valve "all-mains" receiver, and this demonstrates that the characteristics given are in keeping with general practice.

One advantage of the proposed method of specification is that it does not fix a definite minimum performance for each of the three properties. To obtain such a minimum figure it is necessary to make a large number of tests on various classes of receivers, and it is exceedingly difficult to say what minimum requirements are essential for satisfactory operation. The author feels that it would be better to adopt some such classification as the above, and then, as information was obtained for different receivers, certain values would be found by experience to be applicable to the limiting performance. As the general standard of design improved, these values would rise automatically and act as a strong stimulus to further improvement. Ultimately, a minimum value for each separate test, together with a minimum value for the overall figure, could be adopted as a satisfactory criterion of the efficient behaviour of a receiver.

In conclusion, the author wishes to express his indebtedness to Dr. R. L. Smith-Rose for his constant

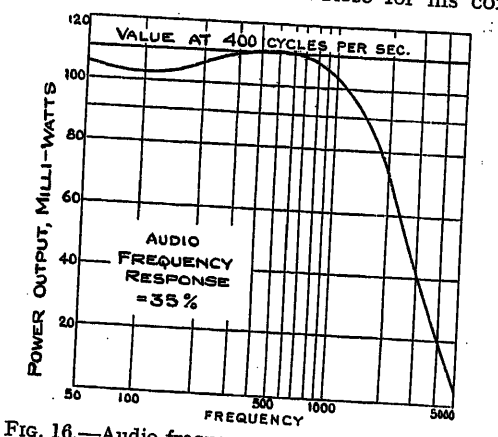

FIG. 16.—Audio-frequency response characteristic of a typical modern receiver.

interest and helpful suggestions, to Mr. F. M. Colebrook for designing the modulation meter and harmonic distortion meter, and to Mr. C. W. Spencer, who helped in the constructional and test work.

APPENDIX.

THEORY OF MODULATION METER.

$$I = aV + bV^2$$

where I = anode-current change in first rectifier,
V = grid-voltage change,

a and b are constants of the circuit.

Now, for a modulated wave,

$$V = E_{max.}(1 + m \sin nt) \sin \omega t$$

where $E_{max.}$ = maximum value of carrier-wave e.m.f.,
m = modulation depth,
$n = 2\pi \times$ (modulation frequency),
$\omega = 2\pi \times$ (radio frequency).

The d.c. component of the rectified current is given by

$$I_1 = \tfrac{1}{2}bE^2_{max.}(1 + \tfrac{1}{2}m)^2$$

since

$$v^2 = E^2_{max.}(1+2m\sin nt+\tfrac{1}{2}m^2-\tfrac{1}{2}m^2\cos 2nt)(\tfrac{1}{2}-\tfrac{1}{2}\cos 2\omega t)$$

The a.c. component of the rectified current is given by

$$I_2 = \tfrac{1}{2}bE^2_{max.}(2m\sin nt - \tfrac{1}{2}m^2\cos 2nt)$$

Therefore, the R.M.S. value of I_2 is given by

$$I_3 = \frac{bE^2_{max.}}{2\sqrt{2}}m\sqrt{\left(4+\frac{m^2}{4}\right)}$$

If the signal input is adjusted by means of the potentiometer of the modulation meter to give a definite known change (k) in anode current,

Then $$\tfrac{1}{2}bE^2_{max.}(1+\tfrac{1}{2}m^2) = k$$

and $$I_3 = \frac{k}{\sqrt{2}}\cdot\frac{2m}{1+\tfrac{1}{2}m^2}\sqrt{\left(1+\frac{m^2}{16}\right)}$$

The audio-frequency voltage supplied to the second rectifier is $V = R_1I_3$, where R_1 is the anode-circuit resistance in the first rectifier.

Thus $$V = \sqrt{2}(kR_1)\frac{m}{1+\tfrac{1}{2}m^2}\left(1+\frac{m^2}{32}\right)$$

The second rectifier is calibrated experimentally by supplying an audio-frequency potential to its grid circuit. It should obey a square law, so that $\theta = KV^2$, where θ is the deflection in microamperes, K is the experimentally-determined constant, and V is the R.M.S. value of the audio-frequency potential supplied. By measuring R_1 and assigning a value to K within the square-law operational range of the first rectifier, we can calculate values of V for various values of m, and then convert these calculated values of V into values of θ from the calibration of the second rectifier. In this way the deflection in microamperes can be plotted against the modulation percentage for any assigned value of the anode-current change in the first rectifier.

Discussion before the Wireless Section, 2nd March, 1932.

Mr. P. K. Turner: I shall deal first of all with Part 2 of the paper. The author's proposal (page 120) of awarding an overall figure of performance to broadcast receivers seems to me to be an impossible one. For example, although his overall performance figures show the 3-valve to be better than the 4-valve set, we have to face the fact that the question which of those sets is better for a particular user depends on what that user wants. In other words, it is impossible in principle to give any such overall figure. The class "D" receiver referred to on page 120 is designed for distant reception, i.e. field strengths below 2·5 millivolts per metre, and I suggest that the signal strength of 1 millivolt per metre which is applied is much too high. A receiver of that type should give its full output at 25 microvolts per metre. I do not agree with the statement (page 121): "In view of the crowded nature of the frequency allocations of broadcasting stations, it is considered that the upper audio-frequency limit which should be catered for is 5 kilocycles per second." A good deal of propaganda work is being carried out at present with a view to convincing the ordinary listener that he does not require a higher frequency limit than 5 000 cycles per sec., the maximum which can conveniently and cheaply be provided for sound films and gramophone records. In my opinion, however, a good frequency response characteristic up to 8 000 or 9 000 cycles per sec. is necessary and can be obtained, in spite of the state of the ether. While I support the author's idea of judging selectivity by the amount that one can cut out over a wide frequency band, as illustrated in Fig. 7, I think that the scales of this diagram should be modified in the way described below. I would also press for a wider frequency band in Fig. 8, as it is not fair to base the figure for the audio-frequency response of a first-class receiver on a range of 50 to 5 000 cycles per sec. Further, any local irregularity in the response curve of a loud-speaker in the neighbourhood of 400 cycles per sec. would have an altogether disproportionate effect on the result as obtained from the author's calculation. If a loud-speaker were tested in the way suggested, a 100 per cent resonance at 400 cycles per sec. would result in the reactangle ABCD being doubled and its efficiency figure halved. I therefore suggest that the output used for purposes of comparison should not be that at 400 cycles per sec. but should be that corresponding to the mean height of the curve: this would be independent of local irregularities. My second point in connection with Fig. 8 is that I think the units of the vertical scale should be decibels. For example, the audio-frequency response of the 4-valve receiver of Fig. 14 is reduced to one-tenth of the full value at 5 000 cycles per sec. If, however, between 2 000 and 5 000 cycles per sec. the response had dropped to one-hundredth of the full value, although the additional area would not have been greatly different from that shown the actual change in performance would have been very large. The use of a decibel scale would really make the area of the rectangle ABCD disappear from the problem altogether. It is a pity that all three of the receivers the results of which are shown should be so bad. With regard to Part 1 of the paper, I should be glad of further details of the valves used in the radio-frequency amplifier, and of the adjustments which are necessary in order to obtain a linear relationship. Instead of the small variable condenser to give small changes in frequency for selectivity determinations, it would perhaps be preferable to have part of the inductance in the form of a small variometer, because this would enable one to make a definite percentage change no matter what the main frequency setting happened to be. A modulation meter based on approximately linear rectification is much easier to handle than one based on approximately square-law rectification. I should be glad of further details of both the current divider and the potential divider, as I have found such instruments very difficult to make with any pretence to accuracy. They have to be extremely well screened, and usually screening upsets the calibration on account of

capacitance effects. Table 1 shows the corrections to be applied to the modulation percentage owing to the fact that the input was measured with an R.M.S. meter (thermo-junction), but I am surprised that this difficulty was not evaded by making the essential measurement with a valve-voltmeter, which reads mean volts and needs no correction if its calibration curve is linear. My own experience in less accurate work is that the convenience of the radio-frequency voltmeter outweighs in most cases the theoretical accuracy of the thermo-junction. With regard to the measurement of harmonics, it seems to me that a weak point in the author's method is that what is actually obtained is the sum of the R.M.S. values of all harmonics. Thus a receiver with an output of 10 per cent of second harmonic and nothing else would give exactly the same rating as another receiver with outputs of 5 per cent each of the second and third harmonics: yet it is curious that the one with the 10 per cent of second harmonic seems much more offensive to listen to. As far as I can judge, the effect of harmonics on the ear is more a function of the amplitude or percentage of the largest harmonic present —if it is of a low order (second or third)—than of the sum of all the harmonics. We therefore need an instrument which will measure the amplitude of the maximum harmonic rather than the sum of all the harmonics present.

Mr. F. S. Barton: I should like to know the size of cabin A, as it occurs to me that manufacturers and others may sometimes wish to submit other than broadcast receivers for testing. The author's dummy aerials—of which more details would be appreciated, especially for those not within the ordinary broadcast range—seem to me to be arranged specifically for the type of receiver that has aerial and earth connections. How would he test portable broadcast receivers with frame aerials, and the commercial type designed for a balanced array in which both sides are at high-frequency potential with respect to earth? Has the author had any experience with standard-signal generators, in which the whole of the generating, measuring, and attenuating equipment is in a screened box, and the receiver remains unscreened? If so, what are the faults of that type of arrangement? Passing now to Part 2, with regard to the author's definition of selectivity there are two features of a selectivity curve in which we are interested. One is the width of the flat top, and the other is the width of the resonance curve near the skirts. The width of the flat top, which governs quality of reproduction, could be given as the total width 6 decibels down from the maximum. To specify the bottom of the curve, I suggest that the lower width should be given at something like 50 decibels down from the maximum. If the curve were only some 17 to 19 kilocycles wide there, one would expect fair freedom from interference. A recent article* by W. B. Snow, of the Bell Telephone Laboratories, describes a series of tests on the range of frequencies necessary for satisfactory musical reproduction, which embodies the opinion of some 20 or 30 trained observers. Briefly, the results are that whereas audible frequencies as low as 40 cycles per sec. are produced by musical instruments, reproduction down to 60 cycles per sec. is considered to be almost perfect. The transmission of the highest audible frequencies is necessary for the perfect reproduction of sounds produced by musical instruments, mainly because of the noises accompanying the musical tones. An upper cut-off at 10 000 cycles per sec. had a slight effect on the quality of most instruments, but a cut-off at 5 000 cycles per sec. had an appreciable effect on all but the large drums. The quality of reproduction of orchestral music continued to improve materially when the lower cut-off was extended to 80 and the upper to 8 000 cycles per sec. Reproduction of the full range, which in these experiments extended from 30 to 13 000 cycles per sec., was preferred to any limitation of band width. For the reproduction of noises the highest audible frequencies were required; even a cut-off at 10 000 cycles per sec. caused appreciable reduction in the naturalness of common noises. The results seemed to necessitate no radical revision of the qualitative ideas which have been accepted by accoustical engineers for some years; their value lay rather in the quantitative corroboration which they supplied. I wish, then, to register a strong plea for a frequency range of at least 80 to 8 000 cycles per sec.

(*Communicated*): No provision seems to have been made by the author for testing receivers having an automatic volume control, nor does he specify any performance factor to cover this feature. I think automatic controls will become increasingly common on broadcast receivers in the near future. In regard to the tests and specification proposed for selectivity, these do not seem to me to cover the case of a receiver depending partly for its selectivity on the demodulation effect at the detector. This case could perhaps be dealt with by tuning the receiver to a fixed carrier and determining its selectivity by means of a second variable carrier modulated at 50 cycles per sec. as in the author's method. The audio-frequency power output resulting from this variable carrier could then be measured, and the selectivity curve plotted as is suggested in the paper.

Mr. M. G. Scroggie: Is there any particular object in selecting such a low value as 60 ohms for the output resistor shown in Fig. 2? This appears to be a rather inefficient arrangement, without a step-down transformer or other device for adapting it to the valve, and in my opinion it would be likely to encourage overloading. I should like to ask the author whether his arrangement is capable of covering, say, the medium wave-band at one sweep of the condenser. The total wave-band covered by the apparatus is very large and requires a number of coils, but whatever disadvantage this may constitute in manipulation is largely removed by ability to cover the most usual bands without coil-changing. The general practice now is to do away with screened cabins, and I should like to know whether they are really necessary in the author's equipment. In commenting on his previous paper* I remarked that in American practice only one cabin was used. American radio engineers now dispense with cabins entirely, even for signals of 1 or 2 microvolts. With regard to the method of measuring distortion, has the author tried the method of using a filter to cut out the fundamental, leaving only the harmonics? One measures first the harmonics

* *Journal of the Acoustical Society of America*, 1931, vol. 3, p. 155.

* *Journal I.E.E.*, 1930, vol. 68, p. 475.

alone, and then the fundamental plus harmonics, but with an attenuator in circuit to bring the total output to the same level in each case. The attenuator can then be calibrated in percentage harmonics. In my opinion the service areas defined (" A," " B," etc.), however suitable when first proposed, are not now representative delimitations. Only a small part of the whole gamut of field strengths existing in practice is split up into these classes, and the proposed additional area " D," which includes the aim of most modern receivers, does not quite restore the balance. A logarithmic classification is surely more in accord with modern practice. I notice that the author tests receivers without their associated loud-speakers, and in this connection I would point out that 90 per cent of present-day designs incorporate the loud-speaker in the receiver, and in many cases the characteristics of receiver and loud-speaker are complementary. I should like to know what precautions it is considered possible to adopt in order to avoid treating such receivers unfairly. I am glad to note that the author recognizes the conditions that actually exist, and fixes his upper frequency limit at 5 kilocycles per sec. Idealistic aspirations after 10 kilocycles per sec. acceptance should be reserved until international commissions have succeeded in reducing the present overcrowding of frequency channels. Turning to the method of defining selectivity, though the author rightly rejects the method which considers the ratio of response at resonance to that 5 kilocycles per sec. off tune, his objections do not apply if the frequency difference is increased to 9 kilocycles per sec.—the spacing between adjacent channels—and this ratio is much less tedious to derive than the one he advocates. In view of present tendencies in receiver design, demodulation effects should certainly be taken into consideration in assigning a figure of merit for selectivity. The author's preference for a linear power-output scale is surely contrary to all accepted practice in communication engineering. The advantages of a decibel scale are too well known to need emphasis. The definition of audio-frequency response (Fig. 8) is unsatisfactory, for this reason: a fairly level characteristic, marred by one bad resonance, would actually be much the same whether the resonance were at 400 or 450 cycles per sec.; yet widely different figures of merit would be assigned according to the plan suggested, owing to the arbitrary fixing of the datum level at 400 cycles per sec. I agree with Mr. Turner that it is almost impossible to place a useful interpretation on overall figures of merit for broadcast receivers. For my own part, I prefer the "24·9"-receiver (Table 2) to the "41·2"-receiver. Although the selectivity of the former is awarded the encouraging figure of 95·5 per cent, its selectivity is not nearly adequate for present-day conditions; while the audio-frequency response, for which the low figure of 45 per cent is awarded, is tolerably good according to commercial standards. The difficulties of rating broadcast receivers seem almost insuperable, and the author is to be congratulated on tackling the problem so boldly.

Mr. W. D. Oliphant: The subject of the paper is of vital importance to the radio industry, and I look forward to the day when a standardization committee will be formed to review the whole matter and lay down specific definitions and methods of test. American engineers have already realized the existence of this need, and their deliberations are to be found in the 1931 report of the Standardization Committee of the Institute of Radio Engineers. The compilation of a set of standards will present many difficulties, but an equally difficult task will be the setting of limits within which the tested apparatus must fall. In view of the complexity and expense of the possible tests, it will be impossible for individual manufacturers to install the necessary apparatus, and I have in mind the establishment of a central proving station whose duty it will be to carry out the necessary tests on the submitted apparatus; then, when the tests yield data satisfactory to the manufacturer concerned, they can be published and thereafter production can be checked against the standard-tested article by simple comparison tests. This proving station, which would be supported by the

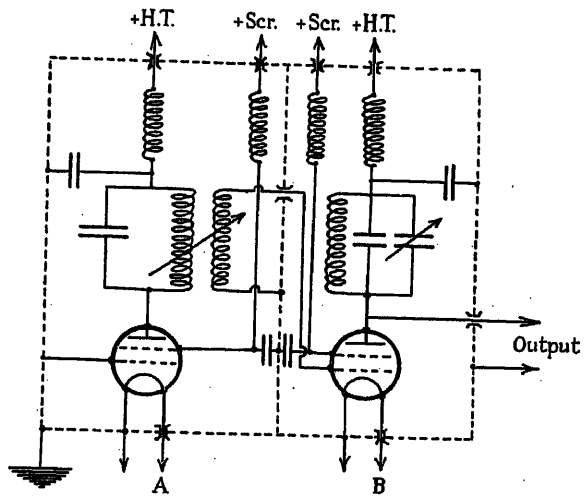

FIG. A.

industry, would also carry out research on subjects of interest to the industry as a whole. Passing on now to the paper, the author's primary object was to localize between the input terminals of a receiver a known minute modulated radio-frequency voltage. We must consider not only circuit details but also the mechanical arrangement of the entire system, as on this factor depends the elimination of a number of stray voltages whose presence would defeat the object in view. A comprehensive analysis of this question has been given by J. R. Bird.* I should like to ask the author whether he has used the dynatron oscillator as either a modulated radio-frequency or a beat-frequency oscillator. The results which I obtained some time ago on the simple dynatron oscillator confirm those recently published by F. M. Colebrook.† I further found that this type of oscillator could very easily be modulated by applying the modulation voltage to the control grid. These experiments led me to suggest the design for a beat-frequency oscillator shown in Fig. A. It consists of two dynatron oscillators A and B; A oscillates at a

* "The Design of Radio-Frequency Signal Generators," *Proceedings of the Institute of Radio Engineers*, 1931, vol. 19, p. 488.
† *Experimental Wireless*, 1931, vol. 8, p. 581.

fixed frequency, while the natural frequency of B can be varied within 10 kilocycles per sec. of that of A. Further, B is modulated at the frequency of A, so that the output from B is of the desired beat frequency: this is rectified, filtered, and amplified in the usual way. Has the author investigated any experimental methods of checking attenuator output voltages? The best method appears to be to connect two dissimilar attenuators in cascade; on increasing the attenuation of one and decreasing that of the other by the same amount, any change of output could easily be detected on a calibrated receiver. The validity of the method rests upon the fact that the two attenuators would not have compensating errors. I am very sceptical about calculated outputs, as we do not know what stray effects are present. In the case of mains receivers we are faced with another possible input, namely via the mains leads and high capacitance between the mains transformer and the rest of the wiring. Some test will have to be devised to investigate this effect, and I should be glad of the author's views on the matter. In conclusion, I would point out that the modulation percentage used by the Americans is 30, and not 40 as stated in the paper.

Dr. R. L. Smith-Rose: The first part of the paper describes the improvements and modifications in the apparatus which is in use at the National Physical Laboratory for calibrating receivers, and outlines the alterations which have been made in order to cope with modern demands. While from the description the screening may seem to be rather elaborate, it does not add in any way to the difficulties of carrying out the measurements. We have a screened cabin (a 6-ft. cube) into which an observer can get with all his apparatus, and the receiver under test is taken into a screened room of considerable dimensions; there is no difficulty in operating the whole installation. A number of problems which probably do not occur to the ordinary technical man at the works when catering for the testing of his own receivers, are introduced by the enormous range in both wavelength and sensitivity which has to be dealt with by the apparatus. Naturally its use for broadcasting wavelengths is very important, but it has also been used for testing short-wave receivers down to 7 metres, at which wavelength the apparatus behaved quite well. Turning to Part 2 of the paper, the circumstances which have led up to the development of the proposed method of specifying performance are as follows. Manufacturers and others have been in the habit of sending receivers to the National Physical Laboratory with a letter asking that these should be "tested," but without stating the nature of the test required. In replying, to put the matter on a concrete basis, we had roughly to outline the tests we proposed to make, viz. sensitivity test, selectivity test, and audio-frequency test. We never carried out one of these tests apart from the others, since the results of such a test might easily have been used to misrepresent the real performance of the receiver. We therefore had to cater for the whole series of tests, and the scheme set out in the paper was devised by the author with a view to simplifying the procedure. We hope that the proposals may perhaps serve to inaugurate a committee of this Institution or of the British Standards Institution which may in due course produce a practical specification for the testing of receivers. With regard to Mr. Turner's query as to why the author selected the 400-cycle ordinate in Fig. 8 for the definition of audio-frequency response, 400 cycles per sec. was tentatively adopted as the standard audio-frequency. In most of the audio-frequency characteristics we have come across there has been no substantial peak or dip at that frequency, so that the possible error envisaged by Mr. Turner does not seem likely to occur with the types of receivers at present available. The great advantage of standardizing the ordinate, of course, is that it does away with the necessity for calculating the mean value of every curve measured. One of the criticisms which might reasonably be levelled against the use of a band of more than 5 000 cycles per sec. is that modern receivers do not appear to take much account of frequencies above 5 000. As regards the criticism of the choice of the response curves given in the paper, I would state that Fig. 16 is the actual curve obtained from a modern commercial receiver. Taking the published response curves of three commercial receivers at present on the market, and working on the basis of the paper, I find that the audio-frequency responses of these three lie between 46 and 63 per cent. I should like to refer in conclusion to the question of selectivity characteristics. As has been pointed out, our method of recording selectivity characteristics is just the inverse of that adopted by the Institute of Radio Engineers. I do not like the inverted resonance characteristic, in the first place because it is not the type we have been used to, and secondly because it does not seem to represent the conditions as we want to know them. In talking of the selectivity of the receiver we do not necessarily want to know how strong an interfering signal must be to produce the same output as was obtained from the wanted station. The problem is rather that of determining how much output an interfering signal produces in relation to that of the wanted signal when the two incoming sets of waves are both of the same field strength.

Mr. W. J. Brown: Has the author made any direct measurements of low radio-frequency voltages as a check on the potentiometer calculations which he employs in his signal-measuring device? I have in mind that in the design of radio-frequency attenuators or potentiometers very serious errors may be introduced on account of stray capacitance currents flowing from the oscillator through the attenuator to the receiver. These stray capacitance currents produce quite an appreciable voltage-drop in the inductance and the earth-return leads, and the error may amount in some cases to 10, 50, or 100 per cent. I feel that any figure of merit for a broadcast receiver should include the acoustic performance of the loud-speaker and cabinet. It is useless to aim at an ideal audio-frequency response curve for the receiver alone, when this is liable to be entirely spoilt by the usual irregularities in response of the average commercial loud-speaker. In particular, when testing receivers employing pentode output valves it is very misleading to use a resistive load, as this takes no account of the variation in amplification of the pentode when working into a loud-speaker whose impedance varies widely with the frequency. Turning to the various

factors which contribute to the figure of merit, it seems to me that the sensitivity of the receiver is dismissed rather summarily by merely placing it in one of a number of classes. The sensitivity of a receiver often varies considerably over the wave band, particularly in the case of gang-tuned circuits. In such cases a great deal of development is often required to establish correct ganging, so as to obtain uniform sensitivity over the wave band. I think the performance of the receiver in this respect should be acknowledged in the figure of merit. As an example, a badly ganged superheterodyne receiver may have a sensitivity of 20 microvolts at 300 metres, and of 2 000 or 3 000 microvolts at 220 metres or 500 metres. On the other hand, a similar set of good design would have a sensitivity varying between 20 and 50 microvolts over the entire range. The author's suggestion that receivers should be tested at their maximum rated output seems to be subject to the drawback that when the output is approaching saturation the audio-frequency response curve will appear flatter—and therefore actually better—than it really is. I suggest a figure of one-half the rated output as being a rather more satisfactory compromise. With regard to the selectivity, the author suggests that this should be measured at constant input instead of constant output, but I do not feel that this gives the kind of comparison we need. The purpose of a selective receiver is to receive signals of the order of 0·1 mV per metre from a distant station the frequency of which is spaced only 10 or 20 kilocycles per sec. away from that of a local station giving a signal strength of 100 mV per metre. The input thus varies in the ratio 1 000 : 1. The output, on the other hand, is naturally adjusted by the user to a more or less constant value, sufficient to give a comfortable volume of sound in his room. Thus we can only simulate the actual conditions of listening if we test with constant output and vary the input accordingly. A further point is that if we have a curve of output at constant input we get the sort of thing the author depicts in Fig. 13. If we wish to find how many kilocycles per sec. we have to detune in order to decrease the response 1 000 times, so as to get the conditions of receiving a distant station from a point close to the local transmitter, the scale of Fig. 13 becomes so small as to be unreadable; in fact, the lowest output we can estimate from Fig. 13 is 10 milliwatts, which corresponds to only $\frac{1}{50}$ the peak output or $\frac{1}{7}$ the peak output voltage. A sevenfold reduction in voltage is very small compared with the 1 000 : 1 ratio which actually exists between the signal strengths of the local and the distant station, and it is impossible to say from Fig. 13 how far it would be necessary to detune the receiver from the local station before a distant station could be received (it looks as though it would be of the order of 100 kilocycles per sec.). I should like to refer to the high figure of 95·5 per cent which the author gives for the selectivity of the arrangement shown in Fig. 13. This is obviously not a very selective receiver, as nearly 100 kilocycles per sec. detuning is necessary for a 1 000 : 1 ratio, and in a modern receiver of the superheterodyne type it is only necessary to detune 10 kilocycles per sec. to allow for the same ratio. In other words, modern receivers can be produced having 10 times the selectivity of the arrangement shown in Fig. 13, and the figure of merit of 95·5 which has been allotted to this receiver does not give sufficient scope for improvement.

Mr. L. B. Turner: Many of the previous speakers have referred to the undesirability of an omnibus figure of performance for a broadcast receiver, and I thoroughly agree with their objections to such a figure. Also, one of the three terms upon which the figure of performance is based is selectivity, and I should like to criticize the manner of defining this which is explained in Fig. 7. The method adopted by the author leads to the selectivity being expressed as x/y, where x and y are respectively the areas CDEF and CKLD. These areas approach equality as the selectivity approaches perfection. I think it would be preferable to measure the small difference of these two nearly equal large quantities, and perhaps define the selectivity as $y/(y-x)$. The unrejected residuum has to be dealt with, and there is a practical 2 : 1 relation between two receivers whose selectivities the author would express as 99 and 98 per cent.

Mr. A. H. Cooper (*communicated*): To what does the author attribute the presence of 10 per cent of harmonics in the output of his 3- and 4-valve sets even near zero output? Is it due to impurity in the low-frequency oscillator, or in the modulator, or does it originate in the detector of the receiver? I cannot understand why his method of measuring selectivity is more representative than that adopted by the Institute of Radio Engineers. The author's method gives the product of the ordinate of the resonance curve and the detector efficiency at the correspondingly decreased input. Thus, in two similar receivers, one with a square-law and the other with a linear detector, his method will give a better selectivity figure for the square-law detector, whereas it is common knowledge that, owing to demodulation, the linear detector is the better. This is quite in addition to the difficulty already mentioned by another speaker of measuring the output to a sufficient attenuation to be of any use. It is idle to suggest that this curve represents actual fact: in practice the set is used to receive a wanted signal in the presence of a neighbouring unwanted one. The wanted signal will load the detector so that its efficiency is that of the centre of the scale, and its changes at other inputs do not concern us directly. I can see no way of stating the selectivity of two widely different receivers except in terms of two inputs, representing the wanted and unwanted signals. A trivial point in the proposed standardization scheme is the division between the medium-output class (3) and the large-output class (4) at 1 watt. The output of many typical 3-valve mains sets ranges from 0·8 watt to 1·2 watts: some of these sets will fall in one class and some in the other, whereas in point of fact they are all very similar. I suggest that the point of division should be raised to 1·5 watts. Finally, I should like to utter a word of warning against the apparent safety of elaborate screening. A radio-frequency generator of large dimensions (and the author's is of a very large size) is difficult to check; its output is often only partly controlled by the attenuator. The voltage-drop in the various earth paths is considerable and cannot be checked completely by varying the

attenuator ratio and current in opposition. The laboratory where I work has in the past 2 years abandoned the use of large screens in favour of rational screening of small size, in which earth paths can be isolated and allowed for. By this means a generator can be made to work in a week instead of 6 months. A large generator in a screened room often gives less accurate results than a small portable generator, which is so easy to use and cheap to make or buy that it will be used throughout the design of a receiver, and the product will be better in consequence.

Mr. R. H. Nisbet (*communicated*): If, for a measure of audio-frequency response, a quantity is required which will be unity for perfect response, why does the author not choose the ratio of the unshaded area *under* the response curve of Fig. 8 to the area ABCD? Is the reason that the figure so obtained would be too near to unity for all receivers, so that the worst receivers would appear to differ by too little from the best? If this be the case the construction of the author's formula, with its arbitrary constant K, may well be justified. Why not extend the principle to the definition of selectivity, where the author's plan gives high figures of merit even for very unselective receivers? I should like to propose that the level of the line BC of Fig. 8 should be that of the highest peak. This would have the undoubted merit of penalizing receivers with the narrow and very peaked type of resonance curve, which is often associated with the combination of receiver and loud-speaker. In view of the possibility of demodulation of one received signal by another, a subject on which the last word has not yet been said, is it legitimate to define selectivity in terms of unmodulated waves? The definition of selectivity must be based upon the nature of the audio-frequency output when the receiver is tuned to a modulated transmission while subjected to interference from other carriers—modulated and unmodulated. At what level of retroaction would the author test a receiver for selectivity and audio-frequency response? There is still scope for considerable variation inside one of the type classifications, especially in type "D." Who would classify the receiver—the manufacturer or the tester? How would a receiver be tested which was claimed to be suitable for all four service areas? As regards the numbering of the classes, I think a system should be avoided in which a 3-valve mains set might be classified as "C3," while a simple crystal set might be described as "A1."

Dr. E. H. Rayner (*communicated*): The paper deals with a subject of considerable public as well as technical interest. There are many cases in which receiving sets of the more powerful and expensive types are installed in churches, schools, and village institutes. The people responsible for choosing such apparatus have very little to guide them, except perhaps the advice of friends or a certain amount of experience of one or two receivers which will generally be obsolescent owing to rapid progress in methods of operation, new design of circuits, valves, and loud-speakers. From a manufacturer's point of view the amount of advertising is in such circumstances probably as important as quality as an aid to selling apparatus. It would obviously be much easier to spend money wisely if a graded standard of performance were instituted. The question as to what type of receiver should be installed in any given instance depends upon the distance of the particular locality from the wanted station. In this country there are some 10 000 schools which are potential users of good-quality receiving sets. At present probably less than one-quarter of these are provided with receiving equipment, and much of the apparatus now in use is not up to the present-day standard. A recognized scheme of type-testing such receiving sets would not only be helpful to those who are entrusted with expenditure of money of a public character, but it would also be a valuable educational influence for both manufacturers and users of equipment. Several speakers have mentioned the desirability of including tests up to a frequency of 8 000, and it seems that even the most experienced radio engineers have little definite knowledge of the frequency characteristics of commercial receiving sets. I agree with the author that there is little object in testing at 8 000 cycles per sec. if practically nothing of such a frequency is included in the output. The results of a type test, even if as is desirable to begin with—the standard of performance required is a low one, cannot fail to be of valuable assistance to both the user and the manufacturer. Type tests would help to create a demand for good-class equipment. One such test would probably cost less than a page of advertisement space, of which several are taken in the weekly and monthly Press by many firms.

Mr. P. G. A. H. Voigt (*communicated*): The paper suggests standards which may be difficult to change once they have been generally adopted, and it is therefore desirable to examine any possible alternatives to them. I think that a wider frequency scale should be adopted. "Grasshopper" noises are greatly reduced by eliminating frequencies in the immediate neighbourhood of 9 000, so that a system cutting off sharply at 8 000 will exhibit but little of this class of interference, while retaining a clarity which cannot be obtained with a system cutting off at 5 000 cycles per sec. With regard to classification, I suggest that the number should be placed first and the letter last, for according to the author's system a "C3" set is better than one classed as "A1." I am glad to see that he includes the "purity factor," which becomes increasingly important as the frequency scale is improved. I suggest that this should also be measured at a lower frequency than 400, say at 100, as a measurement at 400 cycles per sec. may not disclose whether the output choke or transformer is capable of handling a strong, low note without introducing serious hysteresis or saturation distortion. In my opinion the percentage fault should be stated rather than the percentage perfection. An unscrupulous salesman could easily persuade the gullible public that the difference between his set, which is 95 per cent selective, and a rival set with a selectivity of 99 per cent, is too small to make any difference. If these two sets were described respectively as 5 per cent and 1 per cent non-selective, this would not be so easy. I consider that the selectivity and response curves should not be drawn on a power scale, but on either a voltage or a decibel scale, using suitably modified values for K. I agree with Mr. Turner that it is undesirable to make use of a fixed frequency in order to obtain the height of the rectangle ABCD (Fig. 8) for the low-frequency

response figure; the mean of two octaves, say from 250 to 1 000 cycles per sec. or from 500 to 2 000 cycles per sec., would be easier to estimate (and more appropriate) than the mean over the whole scale. The question of including the loud-speaker in the calibrations has been raised, and I think that this should be done when the set is intended to be used with a particular loud-speaker, but the figures should be stated separately. The total forward sound radiation can be obtained with sufficient accuracy by taking three response curves, one on the centre line, one 30°, and one 60° off the centre line, and "weighting" the results according to the area which each belt represents. With suitable gear, a response curve covering the whole scale can be drawn automatically in less than 3 minutes; thus the three curves can be drawn and the total result estimated in less than ½ hour. Whether the purity factor of the loud-speaker should also be measured is a matter for debate. The author's apparatus for purity-factor measurement, together with the microphone and amplifier used for the response measurement, should be satisfactory for this purpose. If this latter test is to be of any value it should be made at several different frequencies.

Mr. H. A. Thomas (*in reply*): Mr. P. K. Turner points out that the specification may give a better overall figure for a receiver having a poor sensitivity than for a receiver having a much higher sensitivity, and he says that he personally would prefer the more sensitive receiver. He also states that the question of which is the better of two receivers is determined by the needs of the particular user. That is precisely what the suggested classification does, in so far as it permits of comparative analysis being made between two different receivers. Doubts may arise as to the feasibility of an overall figure of merit, but I cannot see where the suggested specification fails to bring to light the relative properties of receivers. The field-strength classification is essential if tests are to be made with any rapidity, and it appears to me to be the only method of obtaining comparative results. Results of selectivity, audio-frequency response and purity factor, given for all sensitivity settings of a receiver, would be so cumbrous as to be worthless for quick-comparison purposes. The field-strength figures are adopted as a result of measurements on broadcast transmission-service areas, and they cater for the majority of receivers designed to operate within these areas. Mr. Turner regards the highly selective and sensitive receiver as the normal type, whereas I consider the receiver designed for use within a service area to be more representative of the average present demand.

Several speakers refer to the upper audio-frequency limit of 5 kilocycles per sec. as being too low. I agree with Mr. Barton that a cut-off at 5 kilocycles per sec. does definitely detract from the reproduction of much orchestral music and speech, but I maintain that this upper cut-off figure is governed by the international frequency allocation and that, so long as this is as low as 10 kilocycles, there is no merit in aiming at anything higher. Furthermore, the remarks of Dr. Smith-Rose show that few commercial receivers give a response at frequencies above 5 kilocycles per sec.; hence the limitation is more academic than practical with present designs.

Mr. P. K. Turner suggests that the line BC in Fig. 8 should represent the mean of the area and not the value at 400 cycles per sec. In the original specification this was done, but it involved the calculation of this mean value for each curve. Since our experience was that no receiver tested showed any marked resonance at 400 cycles per sec., we found that the difference between taking BC as a mean value and as the value at 400 cycles per sec. was so slight as not to justify the extra labour involved in computing this mean value; and, since it was desired to make the tests rapid, the 400 cycles per sec. value was adopted. I agree that a decibel scale would be preferable in this case. I cannot agree that all the receivers tested were bad—they were submitted for test as being distinctly better than most, and in fact were suggested as being patterns upon which a limiting specification could be drawn. With reference to Mr. Turner's remarks on Section (1) of the paper, I will give the following information regarding the valves used. The oscillator and modulator valves may be any small power valve such as the P240, and the output valve is a fairly large power valve such as the LS6A. The coupling condenser between the oscillator and the modulator, together with the bias of the modulator, are so adjusted as to give a linear relationship between the anode voltage of the modulator and the output current, and it is found that these values are not critical and, if once set, remain valid over a very large working frequency-range. The variation in frequency by means of a variometer inductance is a helpful suggestion, but is not quite so convenient in practice as a variable condenser. A linear modulation meter could be used, but is not suitable in the present case, since a much larger input would be required and a linear modulation meter can only be operated up to 70 or 80 per cent modulation. There is no difference in operating behaviour and accuracy, and, owing to the greater sensitivity of the square-law meter, it was adopted. There is nothing more to add to the information given in the paper regarding the details of the attenuator, which was fully described in my previous paper (*loc. cit.*). Capacitance effects to the screen were made small by careful calculation, and checks have been made to demonstrate that these potentiometers give reliable results at frequencies as high as 30 000 kilocycles per sec. The difficulty with a valve voltmeter as the final instrument upon which the accuracy of the measurement depends is, that for small currents the series resistance across which the voltage has to be measured must be large, which involves uncertainty at very high frequencies. It was more convenient to make this final measurement in terms of current, and, since such a current measurement is probably more accurate and requires no auxiliary apparatus, it is preferable to the valve-voltmeter method. The bridge described in the paper for measuring harmonics may be used to pick out individual frequencies if desired; but, if this were done, the measurement would become very involved and it is doubtful whether the information so obtained would be of much value in a specification. Grouping of the harmonics forms a simple means of assessing distortion, and is adopted in American specifications.

In reply to Mr. Barton, cabin A is 12 ft. × 8 ft. × 9 ft. high. For the testing of frame-aerial receivers, a small series resistance is inserted, the input e.m.f. being applied across this and a calculation made to allow for the slightly increased frame resistance. Similarly, if no earth connection is provided, a balanced condenser-system can be attached to give the required signal e.m.f. This has been done at 40 000 kilocycles per sec. when testing a short-wave frame direction-finder. Standard signal generators give a fair degree of accuracy, but the equipment described in the paper must obviously be superior in performance since it can be used to calibrate such signal generators. Although quite satisfactory for their purpose, much has to be sacrificed for portability and robustness. The apparatus described in the paper can readily be used for testing receivers having automatic volume controls. The reply to Mr. Barton's remaining remarks is contained in my reply to Mr. Cooper.

Mr. Scroggie raises the question of the value of the output load of 60 ohms. This value is determined by the attenuator network, and for the ratios used 60 ohms was a suitable load. One does not build an attenuator to match a valve, but to have as low a resistance as possible to give the required voltage range. High-resistance attenuators should be avoided at high radio frequencies owing to the difficulty of self-capacitance effects. The coils are chosen to have an inductance such that a maximum wavelength change can be covered on each range. Regarding the use of two cabins, the function of cabin A is to render outside field strengths negligible, and that of cabin B is to screen the oscillators effectively. Although, no doubt, some simplification of these screens could now be effected, it must be realized that the apparatus was built for many purposes other than testing broadcast receivers; unscreened apparatus may therefore have to be erected quickly in the large screened cabin B. This is quicker than building a complete screened set for every special measurement required. Mr. Scroggie's remarks on the harmonic bridge seem to be superfluous, as they describe what is done in the present bridge. His remarks on service areas show that he is thinking of a special type of sensitive receiver and not of a typical broadcast receiver designed for use within a service area. Regarding the testing of receivers without their associated loud-speaker, I have repeatedly urged that this type of comprehensive overall measurement is desirable, but a strong feeling has hitherto existed that a receiver should be designed to operate any loud-speaker and that compensation should not be resorted to. I prefer such an overall measurement and would welcome a request to test receivers in the manner suggested, by adding acoustic measuring apparatus to the existing electrical gear. I notice with pleasure that Mr. Scroggie agrees that at present a 5-kilocycle upper frequency limit is imposed by the present frequency allocations. The remaining points which he raises are dealt with elsewhere in this reply.

I am glad that Mr. Oliphant appreciates the object of the paper, namely, to stimulate interest in the standardization of test procedure. Regarding his remarks on the dynatron oscillator, I would point out that certain rough tests have been made on it and that this type of circuit appears to be quite satisfactory. The testing apparatus was constructed, however, before this work was completed and hence the dynatron oscillator has not been used. Doubtless, if more work were done, the dynatron oscillator might be shown to be preferable to the present triode generator. I am indebted for his correction of my figure of 40 per cent modulation.

I thank Dr. Smith-Rose for his remarks, which do not call for any reply but add useful information to the paper and in themselves answer several points raised by speakers.

I have already partially answered the point raised by Mr. Brown in regard to checking the attenuator at high radio frequencies. I would add, however, that it is possible to establish the accuracy of the system by cross-checking on various attenuator settings with different current values and at different frequencies. The results of numerous such tests establish the fact that the order of accuracy of the present design is well within 1 per cent. I have already replied to the point as to testing the receiver with the loud-speaker. The next point raised by Mr. Brown is covered by the sensitivity classification. If the ganging were bad, the receiver would not give satisfactory results in the particular class in which it gave optimum results, and it would have to be classified separately for different wavelengths. This would immediately demonstrate its failings as regards sensitivity. The necessity for testing at the maximum output is due to the fact that all tests must be made with some definite signal; and since one of the tests, viz. purity factor, demands maximum output, it is preferable to maintain this output for all the other tests. I disagree with Mr. Brown as to the best method of testing selectivity. The case cited is not normal but is obtained when a receiver is used to receive a weak signal in the presence of an interfering strong signal. This condition is important in assessing the properties of a powerful and selective receiver, but for the vast majority of receivers the interference is not greater than the desired signal. Hence, if the output obtained at the desired frequency is known, and the output at some frequency removed slightly from the desired frequency is also known for the same setting of the receiver, this information enables a precise picture of the operating conditions to be made. The introduction of a suitable numerical coefficient in the definition of selectivity meets Mr. Brown's final criticism; such a coefficient would be determined by a Standards Committee.

I am inclined to agree with Mr. L. B. Turner that the method which I have adopted of defining selectivity does not sufficiently grade performance. A suitable numerical coefficient would, however, be preferable to expressing a poorly selective receiver by a higher figure than a good receiver. I am afraid the latter method would lead to confusing results, particularly from the advertisement point of view.

In reply to Mr. Cooper, the harmonics which are always present are almost certainly due to the detector. It would be nearly impossible to test selectivity in the manner suggested. If two signals were imparted to the aerial system and the wanted and unwanted signal were varied in value and frequency over a range commensurate

with actual working conditions, the mass of results would be prohibitive. Admittedly, selectivity does in practice depend upon the precise method of excitation, but any specific conditions can be obtained by calculation from the simple selectivity characteristic suggested. I cannot see how a poorly designed portable generator can give results superior to those with a generator in which every point has been most carefully examined and where efficiency and precision have not been sacrificed for portability.

In reply to Mr. Nisbet, I prefer to take the line BC at the mean value or at some mean frequency such as 400 rather than at the peak value, as the latter method would not differentiate between a receiver with a sharp resonance at some frequency and one in which the resonance rose to a high value over a large band width. The point in regard to selectivity has already been answered in my reply to Mr. Cooper. The manufacturer would classify the receiver, and the testing laboratory would give figures for that class, or, alternatively, the laboratory could give figures for more than one sensitivity class. I am inclined to agree that the numbering and lettering could be improved. Naturally, these points are all open to discussion.

The encouraging and helpful remarks of Dr. Rayner are welcome. It must be realized that many of the suggestions put forward by several speakers would involve a prohibitive amount of testing, and the results would probably be of little practical value. The problem which I have attempted to solve is that of providing a simple test schedule to act as a basis for discussion, and although in detail it may be subject to many academic criticisms, I maintain that the essential points do form a definite criterion of receiver performance upon which present-day receivers could be approximately graded according to their relative effectiveness.

Most of the points raised by Mr. Voigt have already been answered. I am not very favourably disposed towards a system of merit figures which inverts the performance. A more steeply graded system is possibly desirable, but I feel that the perfect receiver should be assessed as 100 per cent and not zero.

DISCUSSION ON "A METHOD FOR DETERMINING THE EFFECT OF THE EARTH ON THE RADIATION FROM AERIAL SYSTEMS."*

Mr. J. A. Ratcliffe (*communicated*): In Section (1) the author remarks that the Fresnel reflection formulæ are only valid provided that the point of observation is not close to the surface of the earth. Both theoretical and experimental considerations lead me to believe that this proviso is unnecessary, and, provided only that the incident waves are plane and are incident sufficiently steeply, the Fresnel reflection formulæ will give the correct result, even when the field is measured just above the ground surface. The theoretical deduction of the reflection coefficients, either by the boundary-condition method of Fresnel, or by the method of Darwin,† does not seem to indicate any breakdown of the theory, even at distances less than one wavelength from the surface. I think that we have experimental confirmation of the theory in some experiments described by Barfield.‡ He tested a loop receiver situated near the surface of the ground, using an elevated transmitter as a source of downcoming waves, and he found that his results agreed with theory when the effect of the ground was taken into account. I believe that this effect was calculated by using Fresnel's reflection coefficients, although this is not expressly stated in his paper. The wavelength used was 21 metres. I am especially interested in the very elegant explanation of the shadow effect observed by Barfield and Munro, and I should have liked a little more information as to the exact method of calculation of the theoretical curves of Fig. 4. How was the image effect of the lower portions of the re-radiating aerial calculated? There is reason for believing that the Fresnel formulæ do not give the correct result when the incident ray is very close to grazing incidence. This introduces difficulties in integrating all along the re-radiating aerial, and I should like to know how they were overcome. I imagine that the resultant field (incident + re-radiated) will vary, both in magnitude and in phase, up the final receiving aerial. Is the field represented in Fig. 4 some kind of mean value?

Dr. L. C. Verman (*communicated*): In the first section of the paper the author refers to some of my work and suggests that the discrepancies between the reflection theory and my measurements close to the surface of the earth were due probably to the proximity of the ground rather than to that of the various objects, stray reflections from which could easily mar the accuracy of the measurements. I pointed out in some detail the reasons for my belief.§ The author, however, does not give reasons for his criticism. He agrees that the reflected ray can be considered to be due to the currents set up in the earth by the incident ray. I clearly stated this view in my paper (*loc. cit.*, p. 1400)

* Paper by Mr. J. S. McPetrie (see vol. 70, p. 382).

† C. G. Darwin: *Transactions of the Cambridge Philosophical Society*, 1924, vol. 23, p. 137.

‡ R. H. Barfield: *Journal I.E.E.*, 1930, vol. 68, p. 1065.

§ *Proceedings of the Institute of Radio Engineers*, 1930, vol. 18, p. 1422.

and pointed out the error on the part of some workers who considered that the earth currents could have an effect additional to causing the reflected wave, although no such effect has been specifically calculated or experimentally observed. Hence it is clear that the mere proximity of the ground cannot be held responsible for the discrepancies observed. Perhaps the author has in mind the effect of the non-planar character of the wave front, which he rightly thinks will cause errors in the neighbourhood of the radiating antenna. However, such conditions do not apply to my observations. I was studying a wave radiated from a station some 250 miles away. The wave-front was found to be essentially plane and the polarization elliptical.

Mr. J. S. McPetrie (*in reply*): I am indebted to Mr. Ratcliffe for his interesting comments on the ray theory of reflection. Fig. 4 in the paper was deduced by integrating the effect of the dipoles in the shadow aerial at one point in the receiving aerial. This would lead to a little inaccuracy. The problem at the moment was not, however, to deduce from Mr. Barfield's experiments the electrical constants of the earth but to show that when reflection of the waves at the earth's surface was taken into account the experimental results could be explained by the ordinary theory. Fresnel's formulæ were used to determine the amplitude and phase of the wave reflected at the earth's surface; but since the calculation was made I have come to the conclusion that the conditions at the receiver were such that the formulæ could not be applied accurately. This inaccuracy is such that the conductivity calculated by Fresnel's equations would be smaller than the true value. This idea is corroborated by experiments made by Dr. Smith-Rose and myself, which indicate that at the frequency used by Mr. Barfield the conductivity would have a value several times the values given in Fig. 4. Mr. Ratcliffe suggests that Fresnel's formulæ are accurate, when the receiver is close to the earth's surface, so long as the wave reaches the earth with a sufficiently small angle of incidence. I can see no theoretical reason for this limitation. If Fresnel's formulæ apply to a receiver close to the earth and with small angles of incidence, they must apply under the same conditions with large angles of incidence. I suggest that the obvious errors introduced when using Fresnel's formulæ to find the field at points near the earth's surface are due to the fact that they apply only to plane waves. If the receiver is near the earth the re-radiation from the earth's surface cannot be considered to be plane at the receiver (i.e. both the main and the reflected waves at the receiver must be plane). The distance at which the formulæ cease to be applicable is difficult to determine, but, as suggested by Mr. Ratcliffe, it is probably less than a wavelength. If Mr. Barfield could be induced to repeat his kite experiment for different heights of the kite transmitter, we should obtain valuable information as to the applicability of the ray theory at high angles of incidence.

Dr. Verman has apparently misunderstood my explanation that one might expect discrepancies between experiment and theory (using Fresnel's equations) in investigations such as his when making measurements of the field strength near the earth's surface. The wave reflected from the latter is due to the currents set up in that surface by the incident wave from the transmitter. Fresnel's equations give the magnitude of this field at points distant from the reflecting surface such that the field from these currents may be considered to be plane at the receiver. When the receiver is very near the earth Fresnel's equations cannot be used, as this condition is not fulfilled. For this reason I suggested that Dr. Verman might expect discrepancies when he applies Fresnel's equations to find the field at points near the earth's surface. Dr. Verman admits that errors would occur if the equations were applied near the radiating antenna, but he states that in his case the transmitter was 250 miles away. He forgets, however, that there are really two sources of radiation—the transmitting antenna and the earth, owing to the currents set up in the latter by the plane incident field from the transmitter. Dr. Verman is inconsistent, therefore, when he will not admit the discrepancies due to the proximity of this second radiator, the earth. In the paper the radiation from the earth's surface is not taken into consideration twice. I have considered, first, the plane wave from the transmitter, and secondly the wave (the reflected wave) radiated from the earth's surface. I do not suggest that all the discrepancies which Dr. Verman found are due to this effect. Neighbouring objects probably did play an important part, but what I state in the paper is that one might expect discrepancies even without any disturbance due to neighbouring objects.

THE ATTENUATION OF SHORT WIRELESS WAVES AT THE SURFACE OF THE EARTH.*

By G. H. MUNRO, M.Sc., Associate Member.

(*Paper first received* 18*th May*, 1931, *and in final form* 9*th January*, 1932.)

SUMMARY.

An apparatus is described for measuring relative field intensities of wireless waves of the order of 20 metres, and the results of a series of measurements taken with it on wavelengths of approximately 25 metres for distances of from 200 ft. to 60 miles from the transmitter are shown as "Intensity/Distance" curves. For distances greater than 2 miles the decrease of intensity is found to be approximately proportional to the inverse square of the distance as predicted by the theory of Sommerfeld. For shorter distances, however, the curves are much straighter than predicted by theory. This is attributed to penetration of the waves to layers of higher conductivity below the surface. This is supported by the increase in the variations in attenuation with change of surface observed on a wavelength of 18 metres and by measurements on the "tilt" of the electric vector of the wave-front.

In all cases, marked changes in intensity and attenuation were found to occur with apparently slight changes of surface and slope of the ground.

INTRODUCTION.

Attention was drawn to Sommerfeld's theory of the propagation of wireless waves over the earth's surface by a paper by Smith-Rose and Barfield† in which some of the mathematical expressions were reduced to forms more suitable for numerical calculation. The theory was later tested by Barfield,‡ and independently by Ratcliffe and Barnett,‖ and found to be substantially in agreement with observed conditions. Further observations of attenuation on broadcasting wavelengths have since been made in various countries by different workers, but little has been published on attenuation on shorter wavelengths. It is desirable that the theory should be checked over as great a range of wavelengths as possible, and particularly for the shorter waves which have come into such prominence of late years. The following investigation was therefore undertaken to obtain attenuation curves for wavelengths of the order of 20 metres.

As it is much easier and more accurate to take measurements on a steady carrier wave than on telegraphic transmission, 5SW, the experimental short-wave station of the British Broadcasting Corporation at Chelmsford, then on a wavelength of 24 metres, was selected as the most convenient source.

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

THE MEASURING APPARATUS.

The first receiver developed for the purpose was an adaptation of one which had been used for intensity measurements on the broadcast band of wavelengths. An oscillating detector tunable to the required high frequency was coupled to the tuned grid circuit of this receiver, producing, in effect, a supersonic heterodyne type of receiver. The essentials of the circuit are shown in Fig. 1. The Hartley circuit was used for the oscillating detector, the tuned grid circuit of the intermediate

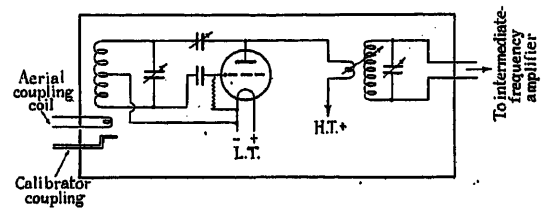

FIG. 1.—High-frequency unit of short-wave receiver.

frequency being coupled to the high-frequency choke. An untuned aerial was used, loosely coupled to the oscillating coil. The recording galvanometer was in the anode circuit of the second detector valve, which was an anode-bend rectifier.

A calibrating oscillator was also loosely coupled to the grid coil of the first detector. The circuit of this oscillator is shown in Fig. 2. It also is a Hartley circuit. The thermo-junction heater is connected in the

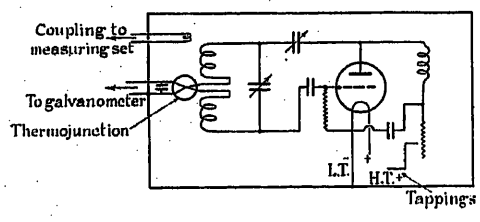

FIG. 2.—Calibration oscillator.

centre of the oscillator coil, and one of the couple leads is earthed directly to the screening box to minimize leakage of the high-frequency current along the galvanometer leads. The anode H.T. voltage could be varied by tappings and by a variable series resistance to give a continuous range, and with the microammeter in use on the thermo-couple a workable intensity ratio of 10 to 1 was obtainable. To increase this either the thermo-junction or the coupling coil was changed. In

a later modification, a small, enclosed, brass shunt-box was incorporated in the screened lead to the receiver, and with three values of shunts the range could be extended to 100 to 1. As the oscillator output to the receiver was varied mainly by reducing the current in the tuned circuit of the oscillator, the ratio of signal received by leakage to signal via the coupling was constant. It was easy to ensure that it was sufficiently small. A copper lid with flanges fitting closely inside the box and clamped to it by screens was quite satisfactory. The thermo-junction was calibrated on direct current and the calibration was assumed to hold for the high frequency (remembering that we are concerned with relative values only).

This apparatus was installed in a motor van. A telescopic aerial of aluminium tube could be projected through the roof, and a counterpoise was run down both sides of the van outside, close to, but not touching, the sides. In taking an observation the station was first tuned in and the deflection noted. The grid circuit was then mistuned just clear of the station, and the calibrator was tuned in and adjusted to give the same deflection. The difference in tuning was not enough to cause an appreciable error.

After the 1928 observations on 5SW the apparatus

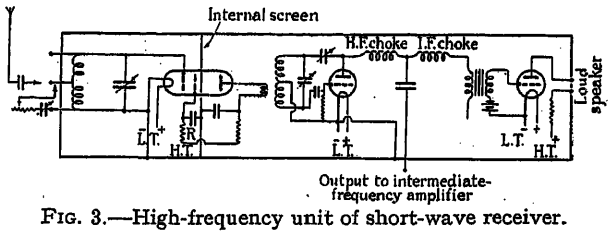

FIG. 3.—High-frequency unit of short-wave receiver.

was reconstructed to improve both the sensitivity and ease of control. A screened-valve high-frequency stage was used, transformer-coupled to the oscillator-detector, and a supersonic unit tuned to about 3 000 metres for the intermediate frequency. The circuit of the high-frequency part of the apparatus is shown in Fig. 3.

The aerial was connected through a condenser of small capacitance to the centre point of the tuned coil in the grid circuit of the screened valve. This was found entirely to eliminate stray body-capacitance effects unless the aerial were approached very closely. (The set was, of course, completely enclosed in a metal-covered box.) A variable condenser of very small capacitance was connected in parallel with the main oscillator condenser for fine tuning. This, as well as the main condenser, was fitted with a slow-motion dial, so that excellent control of tuning was obtained over a wide range of wavelengths. The main condenser motion was sufficiently slow for "searching," and the station, once heard, could be tuned in very accurately with the smaller condenser.

A capacitative coupling was used to the intermediate-frequency amplifier, which allowed of better choking in the detector anode, resulting in a smoother control of oscillation at the threshold. This was of importance as the high-frequency unit, which is a complete short-wave receiver in itself, was used alone without the intermediate-frequency unit for measuring very strong signals. By means of plugs and jacks the indicating galvanometer could be plugged in to either the first or second detector anode circuit. This galvanometer was fitted into a screened box with a series of shunts and an arrangement for "backing off" the steady anode current if necessary.

It was later found that greater sensitivity could be obtained by using as intermediate frequency a "two screened-valve portable receiver" tuned to the longer-wave band, the high-frequency unit providing a sensitive and convenient "short-wave adaptor." For measurement work such a receiver was adapted suitably and enclosed in a screening box. The receiver thus produced was very sensitive, but easy to control, free from stray capacitance effects, and constant in use. The requisite batteries were either fitted inside the box with the receiver or provided with a separate screened box and connected by screened leads. In the latter case it was found convenient to include in the various H.T. leads suitable resistances so that only one value of H.T. voltage was necessary.

The calibrator was permanently coupled to the first tuned coil. When using the calibrator the aerial was disconnected and replaced by a compact equivalent circuit consisting of a small, screened, variable condenser and a non-inductive variable resistor of a few ohms in series with it connected between the earth end and the centre-point of the coil. The values of capacitance and resistance were adjusted to give the same effect as the aerial itself. The pick-up on this "dummy" aerial was very slight, but actually there was just enough to produce an audible heterodyne between the station and the calibrator, and this was found useful in checking the tuning.

For long-distance work the apparatus was installed in the motor van with a telescopic aerial as before, but a counterpoise was not necessary with this coupling. Tests were carried out to see whether there was any directional effect due to the van, but it was found to be negligibly small. For shorter-distance work on a local transmitter the apparatus was mounted on a wooden frame on wheels.

In all the above receivers it was possible to listen on a loud-speaker or headphones to the transmission without disturbing the measurements. It is of great advantage to be able to hear the signals that are being measured, and to know that they are free from interference and undue modulation fluctuations.

For the short-distance observations a small portable transmitter was constructed. A PM252 valve was used in the circuit shown in Fig. 4. To the oscillator coil was loosely coupled a split aerial coil with plugs for connecting a thermo-couple heater in the middle. The contact type of thermo-junction was used, with one of the couple leads connected to the metal screening box so that the middle of the aerial coil was effectively connected to the box. Leads from this coil were taken out of the box to the telescoping aluminium tubes which served as aerial and counterpoise. Generally the aerial was vertical and the counterpoise horizontal, with the coil connected to its mid-point. The complete oscillator and the aerial coil were enclosed in a copper

" plymax " box so that radiation took place from the aerial system only. Leads were taken out from the thermo-couple to a suitable microammeter, one of these leads being connected to the box, as mentioned above, and a 1-μF condenser was placed across them to bypass any stray high-frequency currents. Screened leads were taken to the batteries in another screened box. The whole apparatus was mounted on a wooden stand with the aerial system fixed on a block of ebonite. The aerial was tuned to the required frequency by choosing a suitable number of turns for the coupling coil and then adjusting the lengths of aerial and counterpoise until the maximum deflection was obtained on the thermo-junction galvanometer. With a range of 4 thermo-junctions measurable currents of from 1 to 800 mA could be obtained in the aerial, so that the apparatus was very convenient for checking the receiver calibration. Modulation for speech was provided by including in the anode circuit a 2 000-ohm resistance which was also in the anode circuit of the second valve of a two-stage low-frequency amplifier working on a microphone. This worked quite well on all the wave-lengths and was found very useful.

The receiver was checked against the transmitter for

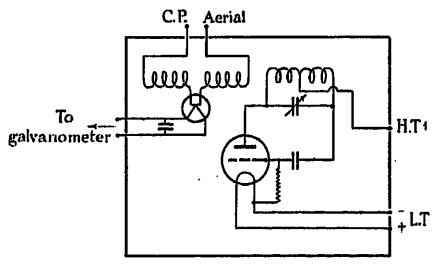

FIG. 4.—Transmitter circuit.

relative strength of signals. The agreement was within 5 per cent for the intensity range used, which was quite satisfactory for the work.

OBSERVATIONS OF 5SW.

The first run was taken in a westerly direction over ground with slight undulations but of a fairly uniform average level and with few trees. These conditions hold for some 12 miles until Epping Forest is reached. Observations were tried within the forest but the signals were too weak for measurement.

A further run was then taken more to the northward where the distance could be extended to 20 miles, but the ground at that distance became more uneven and the signals too weak for accurate measurement. This was partly because of the presence of a marked shadow, apparently due to the masts supporting the 5SW aerial. The signal strength in the line of the masts was only one-quarter of its value at the same distance in a direction 30 degrees more to the southward, the change being gradual.

The results of these two runs are shown in curves I and II of Fig. 5. The intensity is plotted against the distance from the transmitter in miles. Logarithmic paper is very convenient for the purpose as it allows the intensity scale to be changed by any multiple without affecting the shape of the curve. In Fig. 5 the intensity scale is the same in both cases, the difference in the intensities for the two curves being due to the mast shadow. The dotted lines represent average curves through the points. It will be seen that up to 8 miles the points lie fairly smoothly about the average, but beyond that great variations occur for small changes of distance. These variations are somewhat exaggerated owing to the points at this end of the curve coming

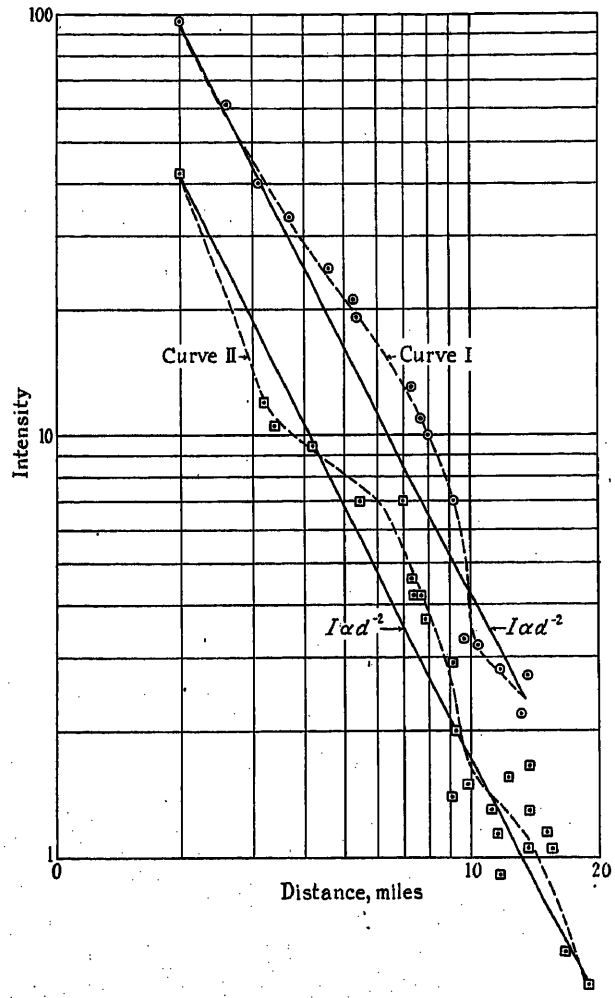

FIG. 5.—Attenuation of 5SW. (The intensity values are relative only.)

closer together for the same actual distances apart. The straight line is the curve for I against I/d^2 and it will be seen that the overall attenuation for the 18 miles approximates to that. In order to get a good average curve it therefore seemed desirable to take more observations at the shorter distance and to extend the measurements to greater distances. For this purpose the sensitivity of the apparatus was further improved and a run taken to the north-west. In this direction the country is rather more wooded and the level rises gradually to the top of the ridge over 400 ft. in altitude, at a distance of 27 miles from the transmitter. Behind the ridge the intensity decreased very rapidly,

so measurements were not taken beyond the summit. The observation points are not all accurately on the line chosen, but as near as possible to it and never more than ½ mile off it. The positions were all chosen as being good sites with no likely sources of disturbance other than the ground itself in the immediate neighbourhood of the receiver.

The results of this run are shown in curve III of Fig. 6, with the same scale as in Fig. 5, all the values observed being shown. It will be seen that the only possible average curve in this case is the straight line shown, the slope in this case being 61°. The scatter of the points gives an indication of the variations which may be expected on good sites, reckoning the accuracy of the measurements as being within 10 per cent. In some cases a reason could be found for the variations. For instance, the intensity was always greater than the average on a slope facing the transmitter and less on one facing away from it. In many cases, however, no cause was evident, so that no attempt has been made to sort out or apply corrections to the values.

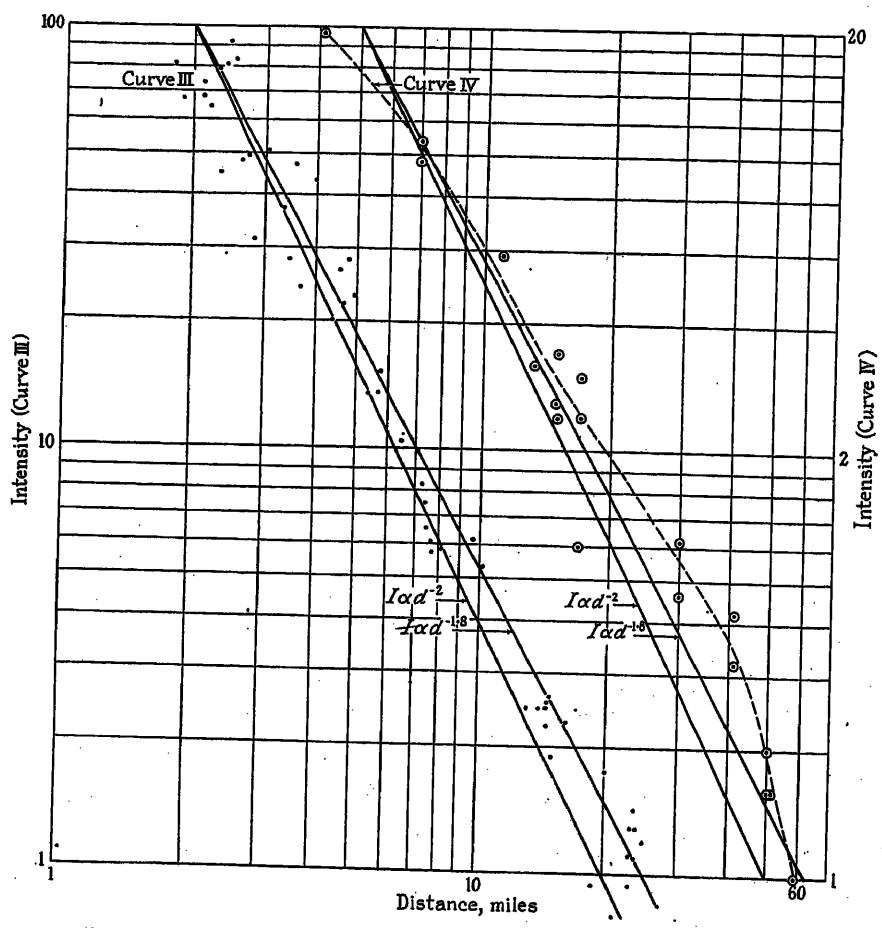

FIG. 6.—Attenuation of 5SW. (The intensity values are relative only.)

[illegible] results were considered as good as could be [illegible]nder the conditions, so it was decided to [illegible] further measurements at short distances [illegible] chosen for its uniformity, using a local sites were more difficult to find. Up to 40 miles fading was slight and little distortion was noticed, but both increased rapidly at greater distances. At 50 miles the average night intensity was 25 per cent greater than the day value. A check on this at Slough at about the same distance gave a ratio of about 2 to 1. These are, of course, isolated observations and may vary from night to night.

The results of this run are shown in curve IV of Fig. 6, the intensity scale being one-fifth that of curve III. The points are rather too few and scattered to give a satisfactory curve, as curve III shows the unreliability of isolated points for giving an average curve. The lines shown are drawn parallel to those in curve III for

One final run on 5SW was, however, taken in 1929 with the improved apparatus to see how far normal attenuation persisted and where fading and distortion due to reflected rays became troublesome. A north-easterly direction was chosen for this as, though fairly thickly wooded, the country was of a uniform level to a distance of 65 miles. Observations were taken to a distance of 58 miles, at which distance the signals were as weak as could be measured, and fading and distortion were considerable. Fewer observations were taken on this run as it was intended merely as an extension of the previous ones, and, moreover, good

reference. The last point is probably not accurate to much better than 50 per cent, owing to fading and the decreased accuracy of the measurement for such a weak signal, in addition to its being an isolated one.

These curves will be discussed more fully later in the paper.

Short-Distance Observations.

For the shorter-distance observations Dorney Common, near Windsor, was selected as a convenient and suitable site, and tests were carried out there on wavelengths of 25 and 17 m, using the portable transmitter already described. The output from this could be kept constant to within 1 per cent, so that the accuracy of the measurements is within 5 per cent. The results obtained there are shown in Fig. 7. The curves for the first two runs ($\lambda = 25$ m, curves I and II) fall practically on straight lines. To extend the available distance a line was taken in a different direction diagonally across the common, but at a distance of 1 400 ft. there was a sharp rise in level of some 5 ft. and beyond this the strength fell off with remarkable rapidity. This is shown in curve III. Owing to the weakness of the signal at the last point there is a possible error of 20 per cent.

Some observations were next taken on 17 m as it was expected that the attenuation would be greater on that wavelength than on 25 m. The results are shown in Fig. 10. It was found that while the curves had the same general slope as those for 25 m they were much more irregular. Curve I is particularly interesting. In this case, to get the maximum distance at a uniform level a line was taken passing within a few feet of the edge of a depression at the bottom of which, 4 ft. lower, was a pond in the bend of an almost dry stream. It was found that at a point 50 ft. beyond the bend, the strength of the signals was greater than at a point on the same line 50 ft. before the bend, and the improved strength appeared to be maintained beyond that point. The effect was carefully checked and confirmed. Measurements were taken at two points at corresponding distances from the transmitter but 60 ft. further from the pond, and the effect, though still present, was less marked. These points are shown with circles round them on the graph. It appears as though there is some "feeding-in" by refraction from the direction of the pond. It was hoped to investigate the effect more fully but it was not found possible to do so. Since the local surface effects seemed much more marked on this wavelength, it was abandoned in favour of 25 m.

Observations were then taken on 25 m on the upper level of the common. There the surface was very uniform and a good curve was obtained. It is shown as curve IV in Fig. 7. Again it is practically a straight line but with a different slope from the ones taken on the lower level.

Finally a series of measurements were taken on Crookham Common near Newbury where a level site, apparently very uniform, 2 miles in length was available. The results are shown in Fig. 11. For distances up to 1 500 ft. very good results were obtained, as shown in curve I, the slope of which is almost identical with that obtained for the upper level of Dorney Common over the same distance (see curve IV of Fig. 7). Beyond 1 200 ft., however, there is an appreciable departure from the straight line. At these distances there are changes in the ground-level which, though slight, may, judging by the observations on Dorney Common, be sufficient to cause departures of the order shown. With increased output from the transmitter further measurements were taken up to a distance of 12 000 ft., or over 2 miles. The results are shown in curve II. Though the points are somewhat scattered they give a reasonable average.

This completed the series of measurements. Obvious extensions of the work are suggested, and there are several points which are worthy of closer attention, but

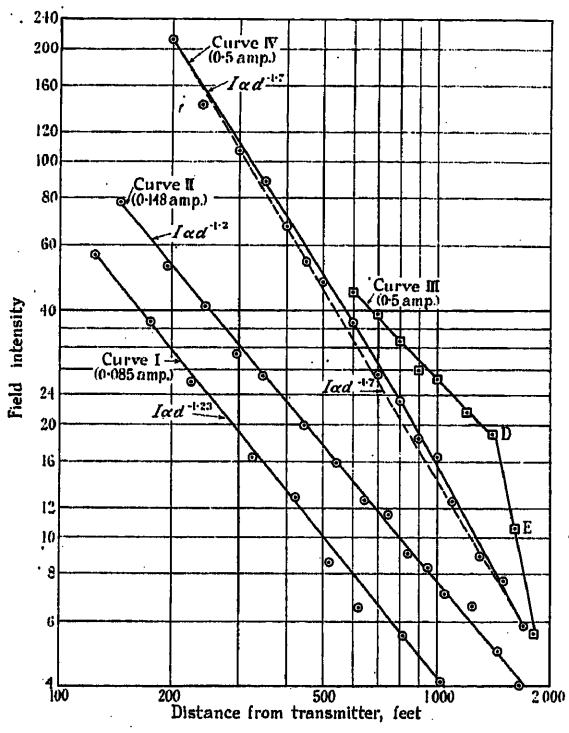

Fig. 7.—Attenuation on 25 m (Dorney Common.)
(The intensity values are relative only.)

no more was possible at the time. The curves shown, however, cover distances of from 200 ft. up to 60 miles, and much information can be gained from them in addition to that gleaned during the taking of the measurements.

Theoretical Discussion.

Various workers (e.g. Ratcliffe and Barnett,* Barfield,† and P. P. Eckersley‡) have used Sommerfeld's formulæ to produce theoretical curves to match those found experimentally and so get the value of the conductivity of the earth. An important factor in the derivation is what Sommerfeld calls the "numerical distance," the value of which is given by the expression

$$\rho = \frac{\pi}{\kappa'} \cdot \frac{x}{\lambda}$$

* See Reference (3). † *Ibid.*, (2). ‡ *Ibid.*, (4).

where x = distance from transmitter,
λ = wavelength considered,

and κ' is given by

$$\kappa' = \kappa - j2\sigma/f$$

where f = frequency of the wave,
σ = ground conductivity in electrostatic units,
and κ = dielectric constant.

If $2\sigma/f$ is greater than κ, the calculation of the theoretical curves is greatly simplified. This is certainly the case for broadcasting wavelengths, and also for wavelengths of the order of 25 m unless the ground

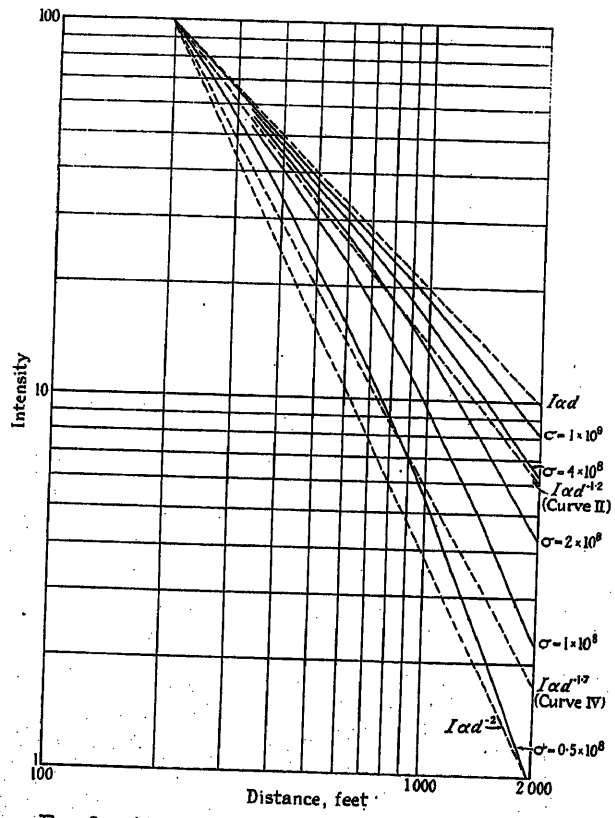

FIG. 8.—Attenuation on 25 m (Sommerfeld theory).
(The intensity values are relative only.)

conductivity is very low. Thus if $\sigma = 1 \times 10^8$ electrostatic units, a normal value for flat country, $2\sigma/f = 16{\cdot}6$ for $\lambda = 25$ m. Rolf* has published sets of curves taking full account of the dielectric constant of the earth, and the results of the present investigation have been compared with them. It is found, however, that the practical intensity/distance curves do not show the marked variations in slope predicted by Rolf. The simpler curves from the Sommerfeld formulæ are therefore used for comparison with the practical ones.

Consider first the short-distance observations on 25 m on Dorney Common shown in Fig. 7, where the intensities are plotted against distance from the transmitter in feet. The intensities are in arbitrary units but with the same units for all four sets of measurements. The transmitter current was, however, varied, the values being noted on the curves. Since the points are plotted on logarithmic paper any straight line will represent a falling-off in intensity according to a power law, the power being given by the tangent of the angle which the line makes with the horizontal. It will be seen that for curves I and II the points lie quite closely along straight lines which have practically the same slope in the two cases. These were both taken on the lower level of the common. Curve III shows the great increase in the attenuation on proceeding from the lower level at D to the higher level at E (Fig. 9). The difference in levels is about 5 ft., and the surface of the higher level appeared much drier as the grass was quite brown at the time, whereas at the foot of the slope it was green. Curve IV was taken entirely on the upper level; the much greater slope will be noticed. There is in this case a slight variation from the straight line. In Fig. 8

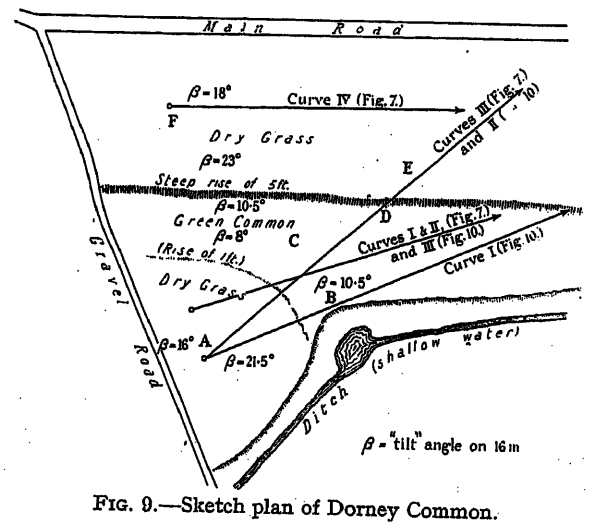

FIG. 9.—Sketch plan of Dorney Common.

are shown the Sommerfeld curves for 25 m for the distances 200 to 2 000 ft. for various values of ground conductivity (σ), with the slopes of curves II and IV of Fig. 7 for comparison. It will be seen that in each case the practical curves are much straighter than the theoretical ones, though the slopes do give possible average values for the conductivity of 3×10^8, and $0{\cdot}8 \times 10^8$, respectively.

It is interesting at this stage to consider the change in the nature of the earth surface which produces this change in conductivity, and in Fig. 9 is shown a sketch plan of the common. The measurements were taken in the summer during dry weather. Level A where the transmitter was situated was dry, with the grass mostly brown. There was a slight drop of about 1 ft. to level CD where the vegetation was much greener, and then a steep rise of 5 ft. to level FE, which looked the driest of the three. The surface soil is mainly gravel. The variations in the curve slopes with change of surface are even more marked on 18 m, as shown in the curves of Fig. 10. In curve II the first steep slope is on level A, the more gradual one from 400 to 1 200 ft. is on the CD level, while beyond 1 200 ft. on the upper level the

* See Reference (5).

intensity fell off to a value which was too weak to measure in a few hundred feet. In curve I, as already mentioned, the intensity actually increased with increase of distance near the pond at B. It is also of interest to note on this curve that the decrease in intensity between the two extreme points is less than for a $1/d$ variation.

It was found possible to check these differences in conductivity by observations on the " tilt " of the wave-fronts. The method of finding the ground conductivity by observations of the " tilt " of the electric vector in

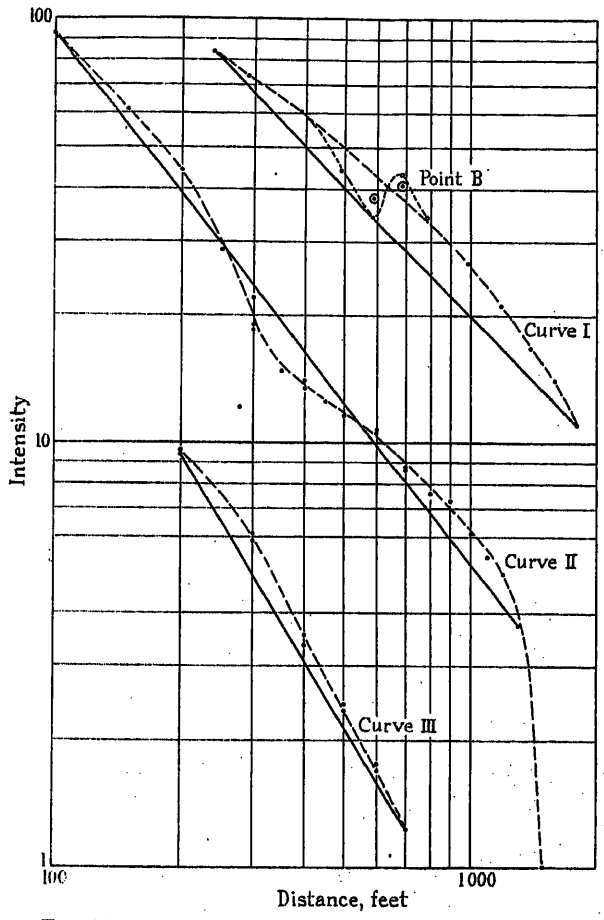

FIG. 10.—Attenuation on 17–18 m (Dorney Common). (The intensity values are relative only.)

the wave-front was used by Smith-Rose and Barfield* for broadcasting wavelengths. Mr. Barfield has since designed an apparatus for the measurement of " tilts " on shorter wavelengths, and the author is indebted to him for permission to use here the results obtained with his apparatus.

These observations were taken on 16 m on the parts of the common where the intensity measurements had been made. The observed tilts were on level FE, 18° to 23°, level CD 8° to 10½°, and level A 16° to 21°. The corresponding conductivities derived from the formula $\sigma = \frac{1}{4}\cot^2\beta . f$, where σ = conductivity in electrostatic units, β = observed angle of tilt, and f = frequency of wave, are $0{\cdot}3$ to $0{\cdot}4 \times 10^8$, $1{\cdot}5$ to $2{\cdot}5 \times 10^8$, and $0{\cdot}4$ to $0{\cdot}6 \times 10^8$ electrostatic units respectively. The relative values thus agree well with those derived from consideration of the attenuation, though the absolute values as obtained from the tilt measurements are smaller. This may be due to some extent to the shorter wavelengths used for the tilt observations, but it must be remembered also that the practical and theoretical curves did not fit well, so that there is some latitude in interpreting the conductivity from the comparison.

Consider now the observations on Crookham Common. Here the ground was almost level and of apparently uniform surface for a distance of 2 miles. Two sets of observations were taken, one for distances from 200 to 5 000 ft., and the second from 2 000 to 10 000 ft. (approximately 2 miles). The two sets of points have been plotted together in Fig. 11, and the appropriate Sommerfeld curves and slopes drawn for comparison. Here again it will be seen that the falling off of intensity can be best represented by a simple power law, the slope in this case being $-1{\cdot}7$ (the nearest Sommerfeld curve giving $\sigma = 0{\cdot}8 \times 10^8$). This is the same as for the upper level on Dorney Common. Tilts were also measured on Crookham Common at one point only, the value found for 16 m being 17°, giving a value for σ of $0{\cdot}5 \times 10^8$, which is in fair agreement with that derived from attenuation measurements. Again, it will be seen that large variations occur for apparently short changes in distance at the greater distances, though this effect is exaggerated by the logarithmic distance scale. The variations are considered to be due to surface changes in the path, this being borne out by the fact that similar variations were experienced if observations were taken at similar distances over slightly different paths.

These observations therefore all appear to indicate that the attenuation on the wavelengths under consideration depends largely on the immediate surface, the variation with changes of surface being more marked on 18 m than on 25 m.

The realization that such changes in conductivity can occur owing to the ground surface alone on what appears to be a uniform site will lead us to expect greater ones in the case of the observations at greater distances on 5SW where changes of level and the interposition of objects such as trees add their effects to that of the earth itself. The variations in the points on the curves of Fig. 5 are thus not very surprising. It is perhaps more surprising to find that the points for curve I lie so closely along the dotted curve between 1 and 10 miles. The straight lines drawn are in each case of slope -2, that is $I \propto 1/d^2$, and they will be seen to give a satisfactory average. The appropriate Sommerfeld curves for this distance approximate to this line also so they have not been drawn.

Fig. 6 shows well the " scatter " of the points for selected good sites, and suggests that the apparent regularity of the previous curves for the shorter distances may have been due to fortuitous choice of sites. The best average in the case of curve III of Fig. 6 is again a straight line, though the slope in this case is less than -2, being approximately $-1{\cdot}8$. From Som-

* See Reference (6).

merfeld's theory the curves for all values of conductivity will take up the slope -- 2 at distances of the order considered here. In this case, however, the measurements were taken on ground which rose steadily to a height of 400 ft. at the maximum distance (27 miles), so that a smaller attenuation would be expected than over level ground. Curve IV suffers from insufficiency of

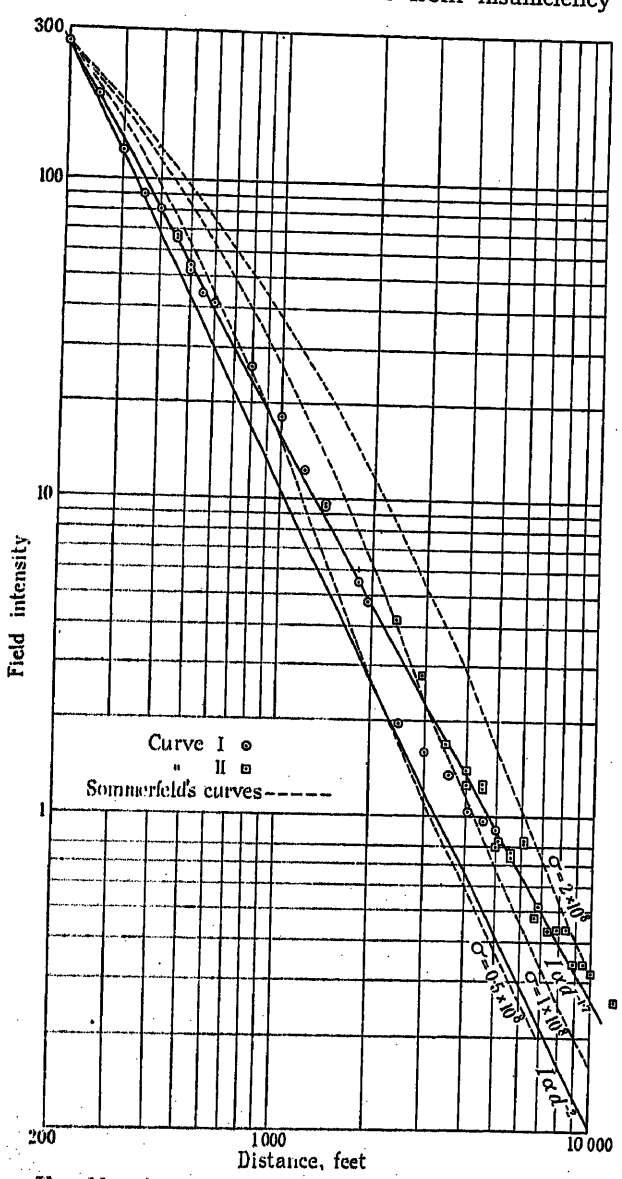

FIG. 11.—Attenuation on 25 m (Crookham Common). (The intensity values are relative only.)

points, but it shows that the same order of variation persists up to 50 miles by day. As this run was taken over level country it is probable that the curvature of the earth is also having some effect and may be in part responsible for the sudden drop which occurs between 40 and 60 miles.

Considering the complete set of observations, the following conclusions may be drawn concerning transmission on a wavelength of 25 m.

(1) For a surface of conductivity of 1×10^8 electrostatic units or less the decrease of intensity with increase of distance from the transmitter assumes, within a few hundred feet of the transmitter, an inverse-power law approximating to the inverse-square law.

(2) In all cases for conductivities ranging from $0{\cdot}5 \times 10^8$ to 1×10^8 the intensity variation is best represented by an inverse-power law for distances between 200 and 2 000 ft.

Ratcliffe and Shaw* have obtained in measurements on 30 m a bulge in the curve at 600 m from which, by comparison with the curves of Rolf, they were able to deduce a value for the dielectric constant of the earth. No such bulges were found in the present series, however, except where they could readily be traced to changes in the conductivity of the surface. It was unfortunate that the curves for the surface of higher conductivity could not be extended to a sufficiently great distance to show where the slope changed to the inverse-square law, but a suitable site of sufficient length was not available.

(3) For distances beyond 2 miles over level country, up to 60 miles—the greatest range dealt with in the experiments, great variations may be expected in the intensity at points within a few hundred feet of one another, but an inverse-square law of variation will give sufficiently good average values for practical purposes.

The deviation from the theoretical curves, and the marked changes in attenuation with change of surface, confirmed by the tilt measurements, are consistent with the supposition that the immediate surface plays a large part in the attenuation on the wavelengths under consideration, particularly if the surface conductivity is high, but where it is relatively low there is sufficient penetration to better conducting levels below the surface for these to have an appreciable effect on the (attenuation) conductivity, the resultant attenuation being a compromise between the two. As the theoretical curves are calculated for a homogeneous medium this will account for the non-coincidence between the practical and theoretical curves. Moreover, the results suggest that the surface effect is greater, and the penetration therefore less, for shorter wavelengths. This is consistent also with the observations of Smith-Rose and Barfield,† where the actual surface was found to have a relatively small effect on the "tilt" of the wavefront and, therefore, presumably on the attenuation, on broadcast wavelengths.

ACKNOWLEDGMENTS.

This investigation was carried out as part of the programme of the Radio Research Board of the Department of Scientific and Industrial Research, whom the author wishes to thank for permission to publish the results. He is also indebted to Mr. R. H. Barfield for suggestions during the course of the work.

INSTITUTION NOTES.

Membership Subscriptions.

As announced at the Annual General Meeting held on the 5th May, the Council have decided to reduce the membership subscriptions to the minimum figures permissible under the Bye-laws, namely, to those in force in 1913. In the case of Companions, the class established in 1929, the reduction will be to the same rates as those of Members.

The actual reductions to be effected are relatively small, being on the average approximately 3s. per member, but in this connection it will be remembered that the higher rates fixed to meet the new conditions after the War had already been reduced, in 1924, by 10s. per member in the case of Corporate Members and 5s. in the case of Graduates. The estimated loss of revenue to the Institution due to the new reductions will be about £2 200 per annum.

Written Contributions to Discussions from Members Overseas.

Members overseas are especially invited to submit for publication in the *Journal* written contributions to the discussions on papers read before the Institution, or written communications on papers published in the *Journal* without being read. In such cases the contributor's country of residence will be indicated when the contribution is published. In this connection a number of advance copies of all papers read before the Institution are sent to each Local Hon. Secretary abroad to enable him to supply copies to members likely to be in a position to contribute to the discussions.

Council's Nominations for Election to the Council.

The following have been nominated by the Council for the vacancies which will occur in the offices of President, Vice-Presidents, Honorary Treasurer, and Ordinary Members of Council on the 30th September, 1932:—

President. (*One Vacancy.*)

Prof. E. W. Marchant, D.Sc.

Vice-President. (*One Vacancy.*)

H. T. Young.

Honorary Treasurer. (*One Vacancy.*)

P. Rosling.

Ordinary Members of Council.

MEMBERS. (*Three Vacancies.*)

T. Carter. Prof. J. K. Catterson-Smith. H. W. H. Richards.

ASSOCIATE MEMBER. (*One Vacancy.*)

W. S. Burge.

Premiums.

The Council have made the following awards of Premiums for papers read during the session 1931–32 or accepted for publication:—

The Institution Premium (*value* £25).

J. BRUCE. "Modern Boiler Plant."

The Ayrton Premium (*value* £10).

F. LYDALL. "The Electrification of the Suburban and Certain Main-Line Sections of the Great Indian Peninsula Railway."

The Fahie Premium (value £10).

H. KINGSBURY and R. A. GOODMAN. "Methods and Equipment in Cable Telegraphy."

The John Hopkinson Premium (*value* £10).

H. W. CLOTHIER. "Metal-clad Switchgear, Automatic Protection, and Remote Control, with Particular Reference to Developments during the Last Seven Years."

The Kelvin Premium (*value* £10).

Prof. W. M. THORNTON, O.B.E., D.Sc., D.Eng., and W. G. THOMPSON, B.Sc. "The Absolute Measurement of High Electrical Pressures."

The Paris Premium (*value* £10).

E. W. DICKINSON and H. W. GRIMMITT. "The Design of a Distribution System in a Rural Area."

A Premium (*value* £10).
Dr. F. LÜSCHEN. "Modern Communication Systems."

A Premium (*value* £10).
Major E. H. E. WOODWARD, M.C., T.D., B.Sc. (Eng.), and W. A. CARNE, B.Sc. (Eng.). "An Analysis of the Costs of Electricity Supply, and its Application in Relation to Various Types of Consumers."

A Premium (*value* £5).
H. BLADES and A. C. MACQUEEN. "The Change-over of Low-Tension Distribution Systems from Direct Current to Alternating Current."

A Premium (*value* £5).
R. O. KAPP, B.Sc., and C. G. CARROTHERS, B.Eng. "Faults, and their Clearance on Large Networks."

A Premium (*value* £5).
H. PEARCE, B.Sc. (Eng.), and T. T. EVANS. "Some Notes on Oil Circuit-Breaker Design and Performance."

A Premium (*value* £5).
E. A. WATSON, O.B.E. "Coil Ignition Systems."

WIRELESS SECTION PREMIUMS.

The Duddell Premium (*value* £20).
T. L. ECKERSLEY, B.A., B.Sc. "Studies in Radio Transmission."

A Premium (*value* £10).
B. S. GOSSLING, M.A. "The Flash-Arc in High-Power Valves."

A Premium (*value* £10).
J. A. RATCLIFFE, L. G. VEDY, and A. F. WILKINS. "The Spreading of Electromagnetic Waves from a Hertzian Dipole."

METER AND INSTRUMENT SECTION PREMIUMS.

The Silvanus Thompson Premium (*value* £10).
Prof. J. T. MACGREGOR-MORRIS and H. WRIGHT, B.Sc. (Eng.). "Accuracy of Measurements made with Hot-Filament Cathode-Ray Tubes of the Gas-Focused Type."

A Premium (*value* £5).
S. H. C. MORTON. "The Metering of E.H.T. Supplies on the Secondary Side of Step-Down Transformers."

The award of Premiums for papers read before the Students' Sections will be announced later.

Swan Memorial Scholarship.

A Scholarship administered by the Institution has been founded as a national memorial to the late Sir Joseph Wilson Swan, D.Sc., F.R.S., as the result of the appeal which was made last year for subscriptions by a Committee representative of the County Borough of Sunderland (Swan's birthplace) and the Institution. The first award of the Scholarship will be made this year. The conditions of award are as follows:—

Conditions of Award.

(1) The Swan Memorial Scholarship in Electrical Engineering, which has a value of approximately £140, is tenable for one year and will be awarded annually to British subjects who fulfil the conditions set out below.

(2) Each candidate must be nominated by the professor or teacher under whom he or she is working, or has worked, and satisfy the following conditions:—

(*a*) He (or she) must have undergone a whole-time day course in electrical engineering, of at least three years, and have graduated or obtained a final certificate or diploma appertaining to such course approved by the Institution.

NOTE.—Consideration will also be given to candidates who have, for any reason, been unable to take a whole-time day course of study, but who have obtained the degree of B.Sc. with 1st or 2nd Class Honours, and who have satisfied the examiners in electrical engineering subjects.

(*b*) The candidate must be under 27 years of age on the 1st July in the year in which the award is made.

(3) Nomination forms may be obtained from the Secretary of The Institution of Electrical Engineers and must be returned so as to reach him not later than the 15th August.

(4) In considering candidates for the award, preference will be given to candidates from the Sunderland area. Such candidates must have been either—

(*a*) born in the County Borough of Sunderland, or
(*b*) resident in that Borough for a minimum of seven years, or
(*c*) educated at the Sunderland Technical College.

(5) Other things being equal, preference will also be given to candidates who, without the aid of the Scholarship, would be unable to carry out the programme of research or other post-graduate work outlined in their nomination forms.

(6) The successful candidate will be required to carry out whole-time research or post-graduate work of a nature and at an establishment approved by the Council of the Institution, and to commence such research or other post-graduate work at the beginning of the session next following the award.

(7) The Scholarship may at the discretion of the Council be awarded as a Travelling Scholarship, with a view to study abroad at some approved institution, laboratory, or works. In this event the proposed programme must be submitted to and approved by the Council of the Institution.

(8) The Scholarship is payable in equal quarterly instalments, subject in each case to the professor or responsible authority under whom the holder of the Scholarship is studying certifying that his (or her) work is satisfactory.

(9) Instalments may be withheld or forfeited in the event of an unsatisfactory report being received from the professor or responsible authority concerned.

(10) The Scholarship will be cancelled in the event of the holder relinquishing his (or her) electrical engineering research or other post-graduate work.

ELECTRICALLY DRIVEN UNDERGROUND CONVEYORS IN COAL MINES, AND THEIR ECONOMIC ADVANTAGES.

By W. B. HIRD, B.A., and J. B. MAVOR, Members.

(*Paper first received 21st May, and in final form 22nd October, 1931; read before* THE INSTITUTION *11th February, before the* NORTH-EASTERN CENTRE *8th February, and before the* SCOTTISH CENTRE *12th April, 1932.*)

SUMMARY.

The different kinds of electrically driven conveyors which are used underground for carrying the coal from the face to the haulage road are first described.

The different classes, viz. shaker conveyors, belt conveyors, and scraper conveyors, and, in association with these, gate-end loaders and similar apparatus, are considered in turn.

The special advantages of using conveyors and loaders in groups are discussed and the difficulties to be overcome in using such combinations are described; special stress is laid on the switching arrangements necessary to enable full advantage to be taken of such grouping.

The special points to be attended to in the design of electrical motors to be used for driving this class of apparatus are indicated.

The economic advantages of electrical conveying are then discussed; and examples of typical results obtained, showing the savings gained by the new methods, are given.

GLOSSARY OF MINING TERMS USED IN THE PAPER.

Face.—The face of standing coal about to be worked.

Long wall.—A long face, anything from 50 to 200 yards long, as distinguished from the short faces on which work is carried on in the case of room and pillar working.

Gate, gate-road.—Roads from the face along which the coal won at the face is removed to the main haulage road.

Mothergate.—If the output from a face can be concentrated into *one* gate-road this is called the "mother-gate."

Tram, tub, hutch.—Synonymous terms for the small wagons used to move the coal underground.

To brush.—To increase the height of a road by cutting up into the roof or down into the floor.

To back brush.—To repeat the brushing process; this becomes necessary when the motion of the strata closes the road either by the roof sinking or by the floor rising.

Fault.—Geological term. A break in the strata which have on different sides of the fault slipped to different levels.

Hitch.—A small fault.

Goaf, gob, waste.—That part of the workings from which the coal has already been removed.

Casting coal.—Throwing the coal along the face to the nearest gate by shovelling.

GENERAL.

The use of conveyors underground, whether at the working face or in the roadways of a colliery, is a necessary adjunct of the methods of mechanical coal-cutting now so universally adopted. It is obvious that when increasing the output from any given face an improved system of clearance must be organized, and that the use of mechanical means of removing the coal from the face is the natural complement of mechanical coal "getting."

This paper is confined to the consideration of electrically-driven underground conveyors. The only alternative to electricity which has been employed to any extent is compressed air. Many types of underground conveyor gears of recent design are so arranged that a d.c. electric motor, a 3-phase electric motor or a compressed-air turbine can be interchanged without alteration to any of the mechanical parts. The descriptions of mechanical drives are therefore applicable to any underground conveyor however driven, but since there is no question that electric power transmission is very much more efficient than compressed-air transmission, any claim as to the economic advantages of electrically driven conveyors must be somewhat modified when applied to a compressed-air drive. Compressed air should only be used where the risk of gas being present is so great that the use of electricity at the face is impossible.

British mining conditions yearly become more difficult. Most of the thick seams near the surface have been worked out, and many of those in the deeper strata have been developed until they are now long distances from the pit bottom. The greater part of our coal is won from relatively thin seams of the lower strata.

These conditions have a very direct bearing upon the type and design of conveyors to be used underground. Seams being mined at great depths, under strata which have already been disturbed by the removal of other seams—probably in a less systematic manner than present mining practice dictates—are subject to very acute roof and floor troubles. It is therefore necessary for the mining man to make use of plant which (*a*) will take up the minimum of space so that as little roof as possible will be exposed, (*b*) is of a portable nature so that it can be rapidly moved forward with the advance of the working faces, or withdrawn should conditions become unmanageable due to roof weights or other mining causes, (*c*) will continue to function satisfactorily even when movements in the roof or floor strata, or the presence of water, tend to create severely adverse conditions.

It will be seen from the foregoing that the conveying of coal underground is probably the most complex material handling problem yet tackled by the engineer, and it is hoped that the following descriptions of the progress already made will prove of interest.

Electric conveyors for underground work are usually constructed on one of the three following principles:—

(1) Shaker or jigger conveyors.
(2) Belt conveyors.
(3) Scraper conveyors.

(1) *Shaker conveyors*, as their name implies, convey the coal by giving a reciprocating motion to lengths of troughing by which the coal is made to slide in one direction along the trough.

(2) *Belt conveyors* are similar to the same class of conveyors used for surface work, and carry the coal along an endless belt.

(3) *Chain flight scraper conveyors* push or pull the coal along troughs by scraper bars or flights formed on the links of an endless chain which is pulled through the trough, partly carrying and partly scraping the coal along the bottom of the trough.

(4) *The drag bucket scraper conveyor* consists of V-shaped or rectangular bucket without top or bottom, dragged by a chain bridle attached to a steel-wire haulage rope. The bucket is dragged along the floor with the opening in the direction of delivery and gathers up the coal as it proceeds.

One or other of these types is best adapted according to the conditions under which the work has to be done. Conveyors in underground working are used to convey the coal along the face to one of the gates or roads, and to get it from this feeding point to a suitable loading station, which may be within a few feet of the working face or at the main haulage road. When the loading station is at the face, the face conveyors deliver into a gate-end loader, which simply elevates the coal into the hutches; when in the haulage road, a gate conveyor is used.

The chief difference between underground conveyors and those usually employed on the surface for industrial purposes is that the latter are usually fixed in position, and once installed and put to work remain fixed throughout their useful life. The underground conveyor has to be constantly moved as the work of cutting the coal proceeds. A face conveyor has to move daily, for as the face advances it must be moved laterally so as to keep close to the working face. The operation of moving up cannot be carried out by bodily moving the conveyor as a whole, since the props supporting the roof usually interfere with such an operation. The design of any conveyor used on the face must therefore take account of this requirement. The parts must be in reasonably short lengths easily disconnected and reconnected, and at the same time as robust as the essential quality of portability will permit. In the case of gate conveying, the change of position is not so frequent, but the length of the conveyor has to be continually increased as the face advances, and from time to time the position of the driving gear will have to be moved as new haulage roads are introduced, to prevent the length of the gates and conveyors becoming excessive.

The restrictions in construction imposed by these requirements and also by the fact that the height is in many cases very limited, call for highly specialized design, differing in many particulars from that of the ordinary industrial conveyor.

As regards the methods of use, these underground conveyors fall into two classes, viz. face conveyors working along the actual working face and delivering either into tubs if the tubs are brought up the gate, or to a gate conveyor which carries the coal to the nearest haulage road. As the conditions under which face conveyors and gate conveyors work differ considerably, different considerations enter into the design of shaker or belt conveyors, according to whether they are to be employed as face or as gate conveyors, and it is necessary to distinguish between these two different classes in the ensuing descriptions of the different types of conveyors.

Shaker Conveyors.

Coal was first conveyed underground in Germany about the beginning of this century, when sheet-steel troughs hung on chains were used on the coal face in steeply inclined seams; these troughs were swung to and fro by a boy at the top of the incline in a manner which induced the coal to slide on the pans. The next logical step was to replace the boy by an engine, and compressed air was requisitioned for this purpose. From this beginning the modern shaker conveyor was evolved.

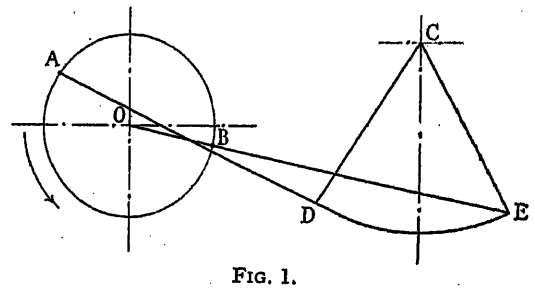

Fig. 1.

The principle of the modern shaker conveyor is to have a length of troughing resting on rollers, each pair of which runs on a specially shaped path. The driving gear is so arranged that the acceleration during the forward part of the stroke is kept down to a low value, whilst the acceleration is very much increased on the backward stroke. The coal moves forward with the trough until the acceleration reaches a definite value, depending upon the coefficient of friction between the coal and trough. At this point the friction of the trough is unable to accelerate the coal any further, and the coal therefore begins to slip. The endeavour is to keep the acceleration below this critical value for the whole of the forward stroke. On the back stroke the critical value is reached early in the stroke and the trough therefore slides back without pulling back the coal, and thus the coal travels from one end to the other of the troughing in steps.

The complete shaker conveyor consists of a driving gear embodying the electric motor and arranged to give a reciprocating motion with a very special acceleration curve to the line of troughs to which it is connected.

The principle of the gear is shown diagrammatically in Fig. 1. The crank pin is driven by the motor at a uniform rate round the centre O, and a connecting rod pivots at one end on the crank pin and at the other end on the end of a lever CE oscillating about a fixed centre C. If A and B on the crank disc represent the points at which the end E of the lever reaches the two

extreme positions of its swing, it is obvious that the distance from A to B in the direction of rotation shown by the arrow is much greater than the return distance from B to A, and since the velocity of the pin is uniform a longer time will be taken on the forward stroke from D to E than on the return stroke from E to D. The end of the lever C E will therefore move with a smaller velocity and smaller acceleration on the forward than on the return stroke. A long coupling rod of adjustable length connects the point E to the troughs, and thus imparts to them a comparatively slow forward motion and a quicker and more rapidly accelerated motion on the return stroke.

Fig. 2 shows a typical velocity curve of the horizontal component of motion of the point E. The slope of this velocity curve at any point represents the acceleration, and it can be clearly seen that the slope and therefore the acceleration is greatest in the portion A to B of the curve.

The first part of the curve represents the forward stroke of the troughing, and the ideal arrangement is to keep the acceleration small enough for the coal to be carried forward throughout the whole of the first half of

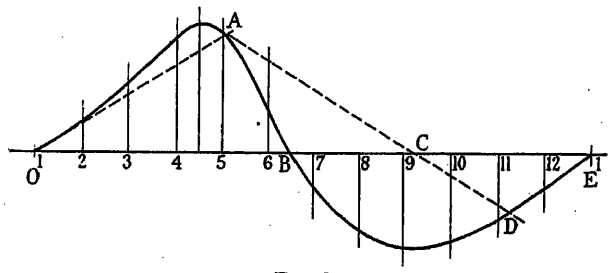

FIG. 2.

the stroke at the same velocity as the troughs. This entails that the acceleration shall at no point be greater than g multiplied by the coefficient of friction between the trough and the material to be conveyed. As soon as the acceleration becomes greater than this value, the friction between trough and coal being unable further to accelerate the coal, the latter begins to slip and goes on travelling with a uniform acceleration independent of the trough acceleration.

In Fig. 2 the thick line represents the motion of the troughs relatively to the ground and the dotted line shows the coal velocity relatively to the ground, showing that it is moving with a uniform acceleration and goes on doing so until the coal-velocity curve cuts the trough-velocity curve, when the coal will again move with the troughs and all slipping will cease. The difference between the areas OAC and CDE is proportional to the distance (relatively to the ground) which the coal will travel for one stroke of the conveyor. The amount of travel will depend on the length of stroke, on the number of strokes per minute and on the method of supporting the troughs. It is usual to provide adjustments to enable the length of stroke and the relative acceleration at various parts of the stroke to be altered. These adjustments may consist in having an adjustable crank-pin which can be moved nearer to or further from the centre of the crank disc, in adjusting the length of the lever CE and also, in some cases, in providing an additional side lever fixed to the same shaft as CE but set at an angle to it, and using the end of this side lever to connect to the troughs instead of connecting them directly to E. It is also necessary that the length of the rod connecting E to the troughs should be adjustable. In some cases springs are introduced to influence the action of the conveyor drive, but the same broad principles apply.

The troughs in the original shaker conveyors were generally suspended by chains from suitable roof timbering, but it is now usual, and has been found more effective, to provide rollers running on suitable cradles and also to fit underneath the troughs runners serving to carry them on the top of the rollers. In some cases balls have been used instead of rollers, the motion of the ball being limited by the use of a trough suitably shaped to contain it.

It is obvious that any apparatus subject to such large and sudden variations in acceleration must suffer somewhat violent shocks. It is therefore essential that all parts of the gear should be especially massive, and all the gear wheels are made as heavy as possible in the space available to act as flywheels and give the motor as much relief as possible from the shocks transmitted from the mechanism.

It is, of course, essential that the troughs should be as light as possible. They are therefore made of light sheet-steel, and one of the most difficult problems in the use of shaker conveyors is to arrange the attachment of the driving lever to the troughs, and also the attachment of each trough to the next one in such a way as to avoid damage at the point where the greatest stresses are experienced.

For this reason a special trough is generally provided for attachment to the driving gear. This is called the "driving trough" and is strongly reinforced so as to distribute the strain over a large surface of the steel.

Various arrangements of the position of the motor and driving gear with respect to the troughs are possible. Three arrangements in particular are in general use: The side drive, in which the driving gear is put down at the side of the troughing and the coupling rod is fixed to one side of the driving trough; the end drive, in which the motor and driving gear are at one end of the conveyor and connected to the end trough; and the underneath drive, in which the motor and gear are placed underneath the troughs.

In the case of the side drive or the underneath drive the gear and motor can be placed practically anywhere along the length of the conveyor. For the end drive they must necessarily be either at the top or bottom end of the troughing. In some cases also it is found expedient to keep the motor and gear away from the line of the conveyor by locating them in a gate-road. The troughing is then driven by means of a bell-crank lever actuated by the gear coupling rod. If this rod is arranged so that its length can be varied the gear can remain in position in the gate for some time whilst the face advances and the conveyor is shifted with it. Only when the coupling rod has reached its maximum length will it be necessary to shift the driving gear.

Face conveyors are not invariably used merely for moving coal along the face, but they are also at times employed to pack material in the waste for purposes of

roof control, and a side-discharge chute is then used. This is a sheet-steel chute one end of which fits into the trough and gradually carries the dirt up and round, discharging it sideways over the side of the troughing at any required point throughout the length of the conveyor.

Whilst shaker conveyors naturally give a greater output when they are conveying the coal downhill, it is quite possible to convey coal by means of shakers not only on the level but even up a gradient as great as 1 in 20, and some shakers extend to quite considerable lengths; 100 yards of troughs each 9 ft. long is not an uncommon length for a shaker conveyor, but it is obvious that the greater the length the greater the strains which will be put on the attachment to the driving trough, and also the more imperative will it be that all the connections from trough to trough shall be without play, as otherwise the cumulative effect of looseness in a large number of joints would throw most excessive stresses on the end troughs next to the engine. Various methods have been adopted for attaching the troughs one to the other, rapidity of making and breaking the joints, and reliability, being the chief considerations.

Belt Conveyors.

The belt conveyor now in general use is a more recent development for underground work, and an extraordinary feature in this connection is that in its evolution for underground use, until a few years ago, designers made no use of the results of the extensive experience and carefully compiled data which had been gathered from surface applications of this appliance. In fact, even to-day belt conveyors which embody defects that were located and eradicated in surface conveyors 20 years ago are still being installed.

The design of belt conveyors for underground work is controlled by the same requirements of portability and of restricted height already noticed in the case of the shakers.

The difficulties to be overcome in the use of belt conveyors naturally focus on providing the proper precautions to ensure as long a belt life as possible. The belting most commonly used for underground coal conveyors consists of a fabric base covered with hard rubber, and the first conveyors of this type put to work failed because of the extravagant cost due to the belt wear.

Gears for driving belt conveyors are not subject to such violent shocks as those used with shakers, and the different parts need not be of such abnormal dimensions as the class used with shakers. Nevertheless they share with all machinery used in pits the necessity of being very robust so as to stand rough usage.

The gears are frequently made so as to be entirely self-contained, the motor and the necessary switches being mounted on the side of the gear itself.

Flat Belt Conveyors.

On the coal face it has so far been found necessary to use the flat belt running between two stationary plates, one on either side of the carrying half of the belt and extending from end to end of the conveyor. This type, except in isolated cases and for very special purposes, has been—on account of its serious inherent defects—discarded by the modern designer of surface conveying plant; but under the conditions at the coal face, where ten or more men are filling on to the conveyor, at intervals of about 10 yards throughout its length, and in very restricted space, the rectangular trough formed by the stationary side plates and the belt render it a useful if mechanically crude compromise.

If it were possible to adjust once and for all, and properly set up a conveyor so that the belt would run perfectly true, these plates might be adequate for the purpose, but in a conveyor frequently shifted and where it is quite impossible to maintain the proper alignment of the belt the wear on the edges of the belt against the plates destroys it in a relatively short time.

Troughed Belt Conveyors.

Though spill-plates or side-plates are a necessary evil on the coal face, they are unnecessary in conveyors used as gate conveyors for conveying the coal from the face to the loading point. For this work a properly adapted troughed belt, as is commonly used for coal-handling on the surface, for grain handling and, in fact, for handling all raw materals in bulk, can be used.

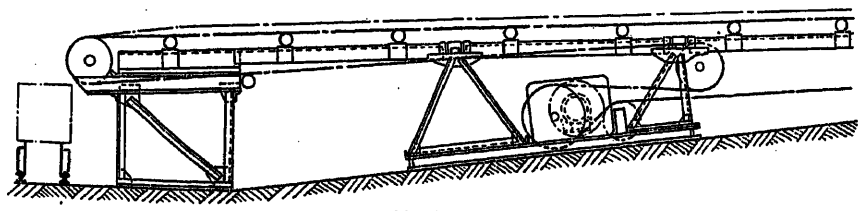
The carrying half of the belt as it leaves the pulley at the receiving end of the conveyor is bent into a trough form by means of 3 or more rollers or idlers, and is retained in this form throughout its length by such idler groups spaced at regular intervals (3 to 5 ft.). After delivering its load the belt returns carried on flat rollers more widely spaced, as their duty is simply to carry the belt clear of the floor.

As pit roads are only used until the area to which they give access is worked out, they are far from being finished tunnels, and a belt of this description requires very adequate protection from injury due to small stones, lumps of coal, and other objectionable materials gaining access to the return belt, which would carry them along until at the end of the conveyor they were crushed under the return pulley which changes the direction of the belt, obviously seriously damaging the belt. Further, the "working" of the strata may make the floor rise in an undulating form or even twist the road slightly out of line. Provision must therefore be made adequately to protect the return belt by means of a decking. This also forms the structure on which the conveyor is built, and by which approximate alignment is maintained. "Approximate alignment" is stated advisedly as constant attention is necessary to ensure even this, but a properly designed troughed belt conveyor can safeguard its belt even when the head and tail pulleys are out of line by as much as 1 ft. 6 in. to 2 ft. in 100 yards.

There is no means of moving coal more economical of power than a well-designed belt conveyor. A consideration of the belt-conveyor designer which is second only to the conveying capacity of his plant is conservation of belt life, as the cost of the belt is roughly one-third of that of the complete conveyor. For ensuring a long life to the belt it is necessary not only that attention should be given to keeping it in correct alignment and to protecting it from accumulation of coal and dirt, but also to pay attention to the way in which the coal is loaded on to the belt. If lumps of coal, sometimes with sharp edges and corners, are dropped on to a moving belt the belt must accelerate them to its own velocity, and in

doing so will get the surface scratched and deteriorated by the sharp projections on the coal. It is therefore necessary to take care that the coal when delivered on to the belt should be already in motion in the right direction, and as nearly as possible with the same velocity as the belt. For that reason special loaders, or a short length of shaker conveyor, are frequently used so that the coal shall be delivered on to the belt at as nearly as possible the right velocity and in the direction in which the belt is running.

The designer of driving gears for underground belt conveyors is subject to the same consideration as those applying to surface conveyors. For face work, however, the use of double-drum type driving gear is imposed, because as a general rule space does not permit of a single drum of adequate diameter or of the necessary belt sag on the return belt normally allowed to secure " wrap " on the driving pulley. The second drum of the double-drum gear ensures that the belt embraces the first drum adequately, but the risk of relative movement or creep



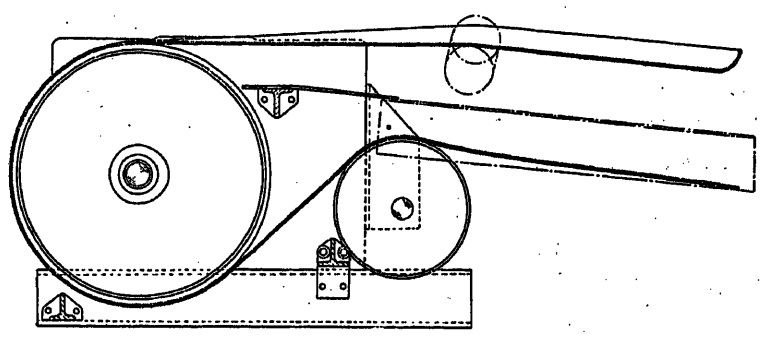


FIG. 3.—Single-drum gear.

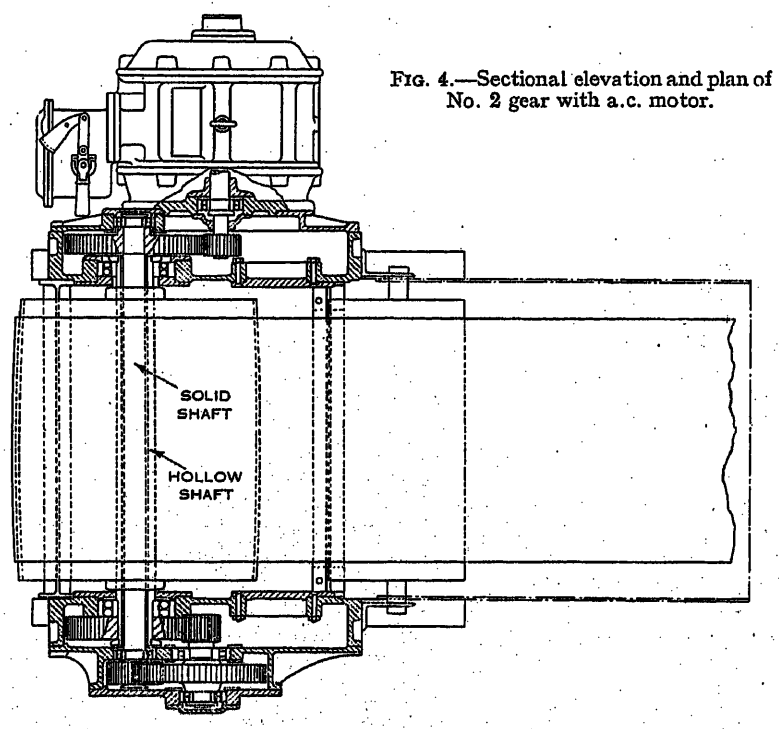

FIG. 4.—Sectional elevation and plan of No. 2 gear with a.c. motor.

between belt and driving drum is serious, and when it occurs the belt will be damaged.

The single-drum gear (Fig. 3) which is used for gate-road work can be designed in relation to the belt to be driven and the power to be transmitted. In the illustration the gear is situated under the conveyor, and as a general rule this has been found advisable because of the advantages accruing from the use of smaller head pulley, which reduces the fall of coal into the hutches, and further, it will be observed, that it permits of an adequate "sag" of belt on either side of the driving gear, thus providing a semi-automatic tensioning to the belt as it passes over the driving drum or pulley.

Fig. 4 is a sectional view of a typical belt-driving gear. It will be seen that the motor gearbox, the driving-drum and the snub pulleys are built into one compact unit, so saving space and maintaining alignment of motor and gearing, even in event of the foundation of the gear shifting—quite a likely occurrence underground.

The Chain Scraper Conveyor.

This was the first type to be applied underground in this country. In the main it has been displaced by the belt, both for face and gate conveying; nevertheless where conditions are wet or on adverse gradients in excess of 18° it still has its sphere.

The commonest form which this conveyor takes consists of a single chain having a rectangular link of malleable iron, about 9-inch pitch, and having flights or crossbars attached to every third link. This chain travels in a carrying trough round a sprocket at the driving head—which is similar to that used for the belt conveyor—thus dragging the coal along the trough to the delivery point and travelling back to the return sprocket through a return trough situated under the carrying trough. This conveyor is capable of being run out of line to quite an appreciable extent without damage, and is a sturdy, reliable appliance. Its inherent disadvantages are (*a*) it requires more power to drive than does the belt, (*b*) coal breakage is liable to occur, (*c*) it will not function satisfactorily on an undulating floor, and (*d*) it is heavier to move up.

A striking comparison was recently made in a case where a scraper and a belt conveyor were running in series in the same gate-road, both being the same length and naturally conveying the same output. The scraper was using 25 h.p. while the belt which was of the flat type between spill-plates (the most inefficient type of belt) was using 10 h.p.

The Drag Bucket Scraper.

This is simply a rectangular bucket having three sides and no bottom. The open end of the bucket faces in the direction of delivery and is hitched by a chain bridle to a flexible wire rope which passes round a sheave in the gate-road to a special 2-drum haulage gear. Another rope is hitched to the closed end of the bucket and passes round a sheave at the remote end of the coal face and round a second sheave to the second drum of the haulage gear. The closed end of the bucket consists of a hinged flap which rises and passes over the coal in its path on its inward journey, while it drops and retains the coal on its outward journey.

The haulage gear used in England generally consists of a motor of about 25 h.p. mounted between two drums to which the power is transmitted by epicyclic gearing, each gear being under control of a brake. The drum pulling the rope attached to the closed end of the bucket is usually geared to about twice the speed of its neighbour.

As applied in this country, guide rails are laid to form a path for the bucket which, travelling to and fro, would otherwise displace roof props and prove a source of danger. Into this path the coal is raked by the fillers, and at a bell signal the haulage operator draws the bucket up the face by the rope attached to the closed end of the bucket; the other rope is dragged out as it recedes from the loading point. The hinged flap of the bucket mounts the coal lying in its way, and as soon as it has passed sufficient coal the signal is given for the return journey and it is hauled out, building up its load of coal as it goes. The process is repeated until all the coal which has previously been freed by the coal-cutter is loaded off.

The limitations of this appliance are:—

(1) Only a comparatively short face can be worked under British conditions, and therefore only a relatively small output can be brought to the loading point, thus, if generally applied, imposing a large number of loading roads and diffuse working.

(2) If the strata forming the floor of the seam be soft it brings dirty coal.

(3) It requires at least twice as much power to drive it as any other conveyor.

At the same time in favourable conditions a very large output can be obtained per man-shift, but it has still to be proved whether this can compensate in every case for the added amount of "dead work" in the maintenance of additional roads and in the increased labour in collecting relatively small outputs per face unit which its use entails.

In its native country (America) the mining conditions—at least so far as underground use is concerned—are not so exacting; roof supports are not required so near the face and the seams are thicker. Cases are known where a rectangular bucket of about 2 tons' capacity is used actually to dig the coal off the face. These buckets are pulled by 150- to 200-h.p. haulages fitted with high-voltage 3-phase motors, and three men have been known to fill off 600 to 650 tons in an 8-hour shift. We, however, exploited our coal seams of this kind before machinery was invented or America was discovered, and now we must dig deeper and work harder for our reward.

Gate-End Loaders.

Gate-end loaders may be described as short lengths of conveyor on to which coal is delivered, say from a face conveyor. Their purpose is to raise the coal to a sufficient height to discharge it into a pit tub.

The original gate-end loaders were of the scraper type and consisted of a steel trough along which worked two chains carrying cross bars which scraped the coal along the bottom of the trough, but it is now quite usual to use belts, both of the troughed and flat type. Inverted steel troughing carrying the idlers acts at the same time as a protection to the return half of the belt.

Lantern slides showing these different types will be exhibited at the meeting.

For some purposes it is of advantage to be able to vary the length of the loader. With a loader used to link up a face conveyor or conveyors with a gate belt conveyor, a telescopic loader, the length of which can be altered, obviates the necessity of daily extending the main belt, and allows this belt extension to be made only at convenient intervals, say at the week-end, so that this extension does not interfere with the normal cycle of operations.

The telescopic loader has also the advantage that it feeds the coal on to the belt of the main conveyor, not from one side but directly in line with the belt and with the coal already moving in the same direction as the belt.

Different Methods of Use.

The simplest conveying arrangement is to have a single-face conveyor bringing the coal from the length of the face to a gate at one end. In some instances it is possible to lower the floor-level in the gate so that the tubs can come below the end of the conveyor, which therefore feeds direct into the tubs. Mining and economic conditions frequently render this method impracticable, and in such cases a gate-end loader may be used to receive the coal from the face conveyor and load it into the tubs. Fig. 5 illustrates this arrangement. The empty hutches are assembled on the right-hand side of the gate-road, and pass singly under the end of the gate-end loader, at the same time crossing over to the left, to be filled and taken outbye.

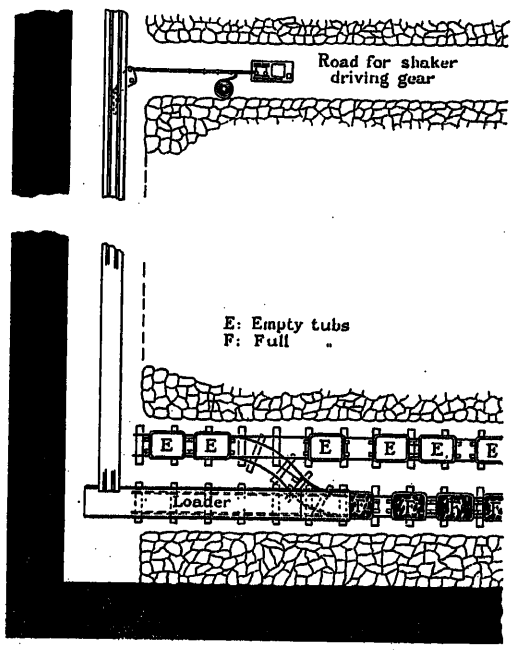

FIG. 5.—Showing joint application of face conveyor (shaker type) and gate-end loader.

Fig. 6 shows a double unit in which the face is moderately inclined, imposing the use of a shaker conveyor to the rise side of the mothergate, and a belt on the dip side. The loader is used in this case also.

Fig. 7 shows a typical example of conveying from two faces being developed to the rise, where the output is conveyed to the main haulage road. The faces in this case are shorter than usual, as the coal seam is comparatively thick, providing a large output from a relatively short face. In this case the most modern practice would be to install a regenerative troughed belt conveyor in the gate-road, which might extend to 700 yards or so before another main haulage level was provided or a new working face started from the same level further along the main haulage road.

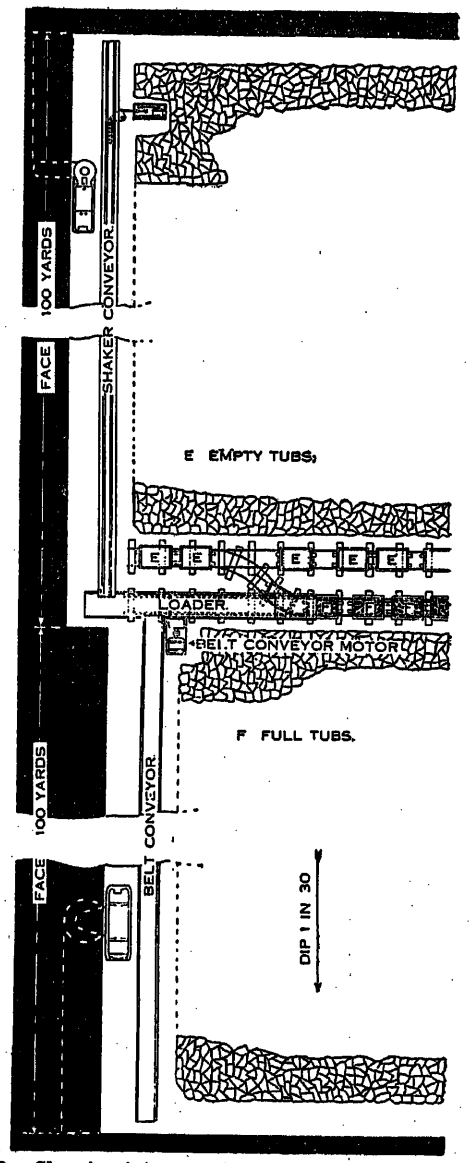

FIG. 6.—Showing joint application of face conveyors and gate-end loaders.

The four foregoing examples serve to illustrate (*a*) a single unit, (*b*) a single unit with gate-end loader, (*c*) a double unit using one belt, one shaker and a gate-end loader, and (*d*) a double unit using two shakers and a gate-belt conveyor. There are many variants of these typical arrangements. For example, where long faces are worked for the purpose of concentrating large outputs to one point it is now common to run two or more

face conveyors in series, delivering on to a gate-belt conveyor, or a loader modified to allow of standage for a complete train of hutches, so that no delay in clearance of the output will take place.

One case requiring special notice is that of a belt conveyor conveying downhill at such a steep angle that the load takes charge and accelerates the belt independently of the motor. In such a case either a 3-phase or a shunt-wound d.c. motor will, when run over speed, automatically act as a brake and put power back into the line, but any failure of supply will, by taking the excitation off the a.c. motor, allow the conveyor to run away, and it is therefore essential to fit an automatic brake which will be applied by a failure of the supply. In the case of a d.c. motor the failure of supply does not take off the excitation, but if the circuit is interrupted, e.g. by a fuse blowing, the speed will increase with no check from the motor, and as this is still excited it is not possible to apply a simple solenoid-controlled brake. If the solenoid is on the motor side of the blown fuse the motor keeps it excited, while if on the other side of the break it is still excited from the main supply; it is therefore necessary to have some arrangement of centrifugal governor to control the mechanical brake, or to fit an over-voltage relay which will trip the solenoid circuit when the motor speed becomes excessive.

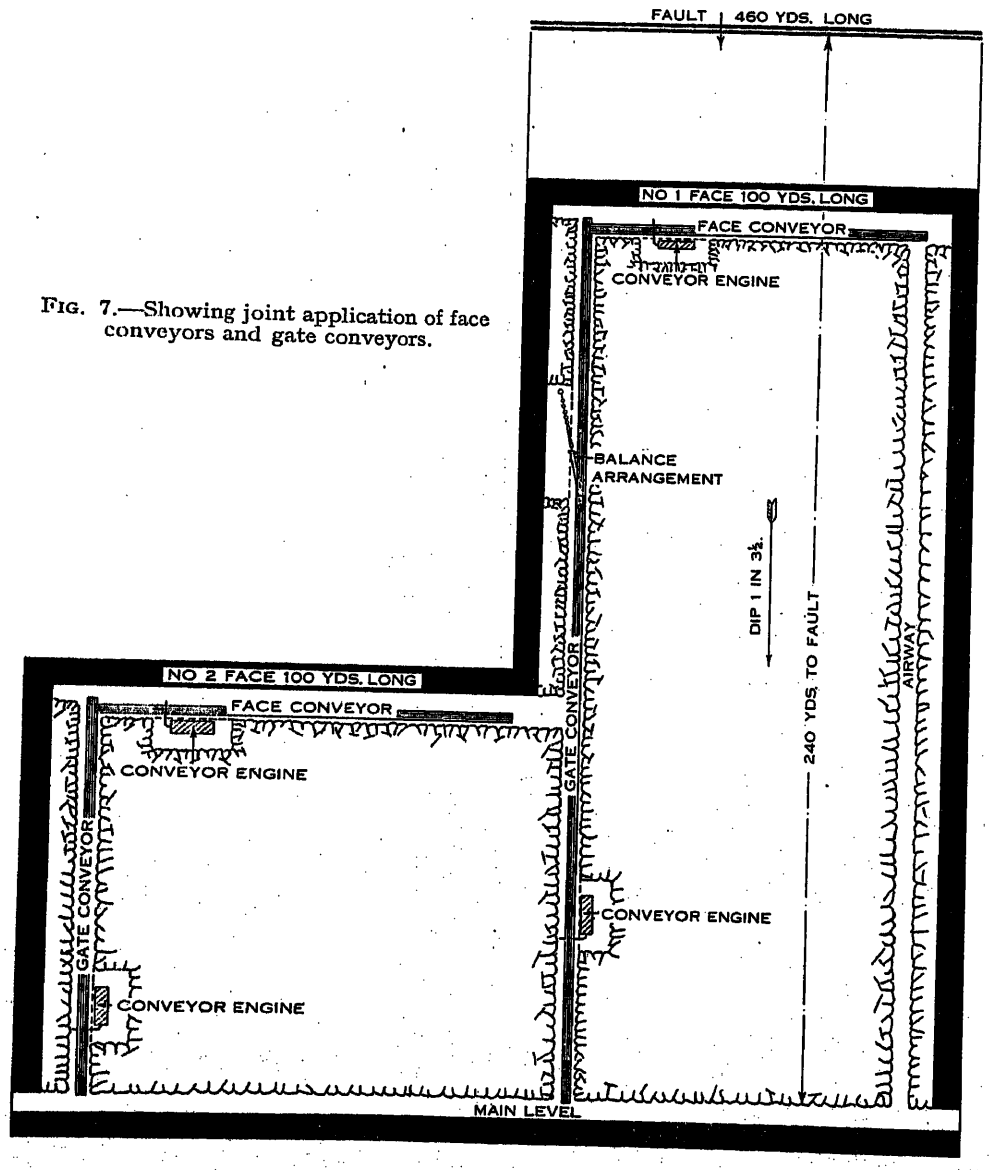

FIG. 7.—Showing joint application of face conveyors and gate conveyors.

When combinations of several conveyors feeding into one another, or combinations of conveyors and gate-end loaders, are used, it is obviously necessary that means should be taken to prevent an undue accumulation of coal at any intermediate point. For instance, if two face conveyors are feeding on to one loader, and the latter has to be temporarily stopped, either through want of tubs to load into or from any other accidental cause, the face conveyors must also be stopped as otherwise the loader will be buried in coal which it is

unable to get rid of. In such cases it is therefore quite common practice to fit distant-control switchgear so that the man at the loader is able to start and stop at will the whole of the machinery, and several systems of such control have been devised to meet special cases.

Switchgear.

The switchgear actually used varies in different cases from simple air-break drum-type switches with a fuse in each line to automatic switches embodying electrical interlocks and a number of safety devices, but all are contained in flameproof cases and are adapted to be mounted either on the side of the gate-end loader or on skids so as to be readily movable with the rest of the gear. Let us take as an example one of the simple cases where two conveyors are feeding one gate-end loader. Three switches of the ordinary air-break type are mounted side by side on the frame of the loader. The main supply is brought in to the three switches by means of a gland connected on to a trailing cable, and the two switches controlling the conveyors also have plugs fitted to trailing cables, taking the output to each conveyor motor. The current to the loader motor can be taken through an ordinary armoured cable, since the motor and switch are both mounted on the loader frame and are never moved relatively to one another.

Mechanical interlocks are provided to ensure that the plugs cannot be withdrawn when the corresponding switch is "on," nor can the switch be put "on" when its plug is not in position. The operator at the loader has thus the three units of the plant under his control and can start and stop them as required.

In the case of a number of conveyors feeding into one another in series, they must, of course, be started in the proper sequence. One of the conveyors must not begin feeding into another which has not yet been started; it is therefore necessary in such cases to provide a mechanical interlock between the switches so that they can only be operated in the correct order.

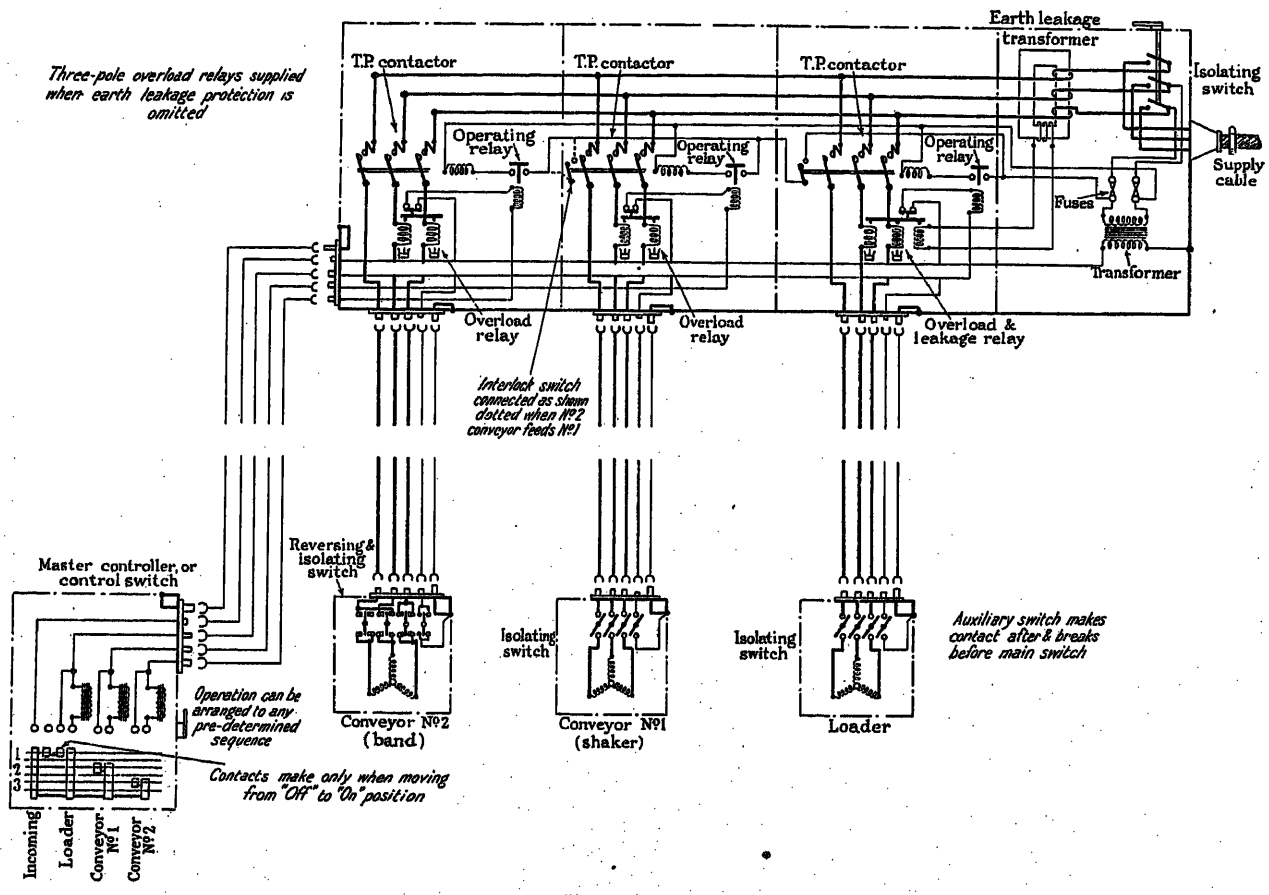

Fig. 8.

A more elaborate switching arrangement is obtained by substituting contactor switches with overload and no-volt trips for the simple drum-type switch with fuses. In order, however, to ensure the maximum possible amount of safety, combined with automatic control of the sequence of starting the different units, it is necessary to install some system of remote control by using a combination of contactor switches with a master controller, giving direct control of all the units.

The simplest of these systems, however, requires a trailing cable with five cores, as a pilot wire is required in addition to the three conductors and the earth wire in the ordinary trailing cable.

Fig. 8 shows diagrammatically the connections for one such system of remote control as applied to three units, say a loader fed by two different conveyors. On tracing out the connections it will be seen that as soon as the isolating switch in the gate-end box is closed the transformer is made live through the two fuses shown. The secondary circuit of this transformer passes along the pilot wire to the master controller, the contacts of which close the pilot circuit (1) to the loader switch, (2) to conveyor No. 1, and (3) to conveyor No. 2. In each case the pilot circuit is closed through the coil of the operating relay, which allows the main coil to take current and closes the contactors.

As the loader contactors close, a small interlock switch which is included in the circuit of the main coil working the contactors of conveyor No. 1 also closes. This switch thus ensures that if for any reason the loader contactors have failed to close it is not possible to start conveyor No. 1. The same connections and series of operations are repeated on positions 2 and 3 of the master controller, ensuring that the loader and conveyors (1) and (2) start in the proper order. Before the master controller reaches position " 1 " it closes two contacts which complete the pilot circuit and excite the coil of the operating relay so as to close the contacts. If for any reason (say the loader being buried in coal) the motor fails to start, the overload coils will open the contactors, but immediately the current is off and the overload relay closes, the operating relay will again operate and put in the contactors, and these will therefore be kept chattering off and on until the obstruction is removed and the loader motor allowed to start. To obviate this the completion of the first step of the master controller introduces into the pilot circuit an inductance so proportioned that it allows sufficient current to pass to hold down the operating relay if this is closed, but insufficient to close it if it is open. This prevents the alternate closing and opening of the contactors if the motor fails to start, but it is obviously necessary that it should not be possible for the master controller to remain in the position where the inductance is not in circuit: this position is therefore not reckoned as one of the steps of the controller, and the star wheel is so arranged that the handle cannot be left on that position.

As a safeguard against earth leakage a transformer can be supplied which, on any out-of-balance occurring in the three mains, operates a coil working the overload relay of the loader motor contactor.

The following safeguards are therefore provided. The contactors of any motor will open (1) if the pilot circuit is broken, the operating relay being thereby opened, and (2) if the contactors of any motor which should precede it in the predetermined sequence come out because the interlock switch comes out with the contactors and breaks the circuit to the following main coils.

The pilot circuit is broken (1) if there is any break in the earth connection, (2) if any plug is pulled out, (3) if the overload or leakage relay operates, (4) by the action of the master controller.

The contacts of all the plugs are so arranged that the pilot wire breaks before and the earth wire breaks after the main contacts. If, therefore, it is attempted to pull out a plug when the circuits are alive, the pilot-wire circuit will be broken and the contactors come out before the main circuit breaks at the plug contacts. On the other hand, the earth wire breaks last so that the apparatus remains earthed until after all the other connections have been broken.

An auxiliary switch working in connection with each of the motor-isolating switches is provided in the pilot circuit; it makes contact after and breaks contact before the main switch, and thus ensures that both make and break take place on the contactors and not on the isolating switch.

It will be seen on consideration of the above points that a system of remote control can be devised which is practically fool-proof, and that it is not possible to attain the same amount of safety except by adopting remote control. In particular there is one feature in any system working with hand-controlled switches and ordinary trailing cables which has been the cause of some fatal accidents. On such a system the plug at the conveyor-motor end of the trailing cable can be interlocked with the motor switch so that it cannot be pulled out when that switch is on, but there is nothing to prevent its being pulled out if the gate-end switch has been left on, and the plug therefore remains alive after it has been taken out and thus becomes a source of danger. It is obviously impossible to make sure that this does not happen except by some system of remote control which will automatically fetch out the gate-end switch when the plug at the far end of the trailing cable is pulled out, and this is one important point in favour of the general adoption of automatic control.

There is one point to be noticed in the construction of the plugs themselves. If for any reason any of the pins make bad contact in the tubes, sparking may take place even when the plug and socket are properly assembled. It is therefore necessary that the chamber containing the pins and tubes should, when the plug is in position, form a flameproof enclosure complying with B.S.S. No. 229. Modern plugs are made to comply with B.S.S. No. 279, which ensures compliance with this flameproof requirement and at the same time fixes certain of the dimensions so as to secure interchangeability.

The British Standards Institution have a specification of a 100-ampere plug suitably designed to meet these requirements, and, while others exist the use of which is permitted, for the purposes of this paper the British Standard plug may be taken as typical.

Designed primarily for use on a 3-phase alternating-current circuit, it is also used on d.c. circuits, the only difference being that one pin contact is omitted.

The plug has four sockets grouped symmetrically in a cylindrical moulded insulator, which in turn is encased in a cast bronze housing to which the earth connection is made. The four contacts provide for the 3-phase leads and for a pilot core when this is required. The socket to receive the plug is provided with four corresponding pins also carried in moulded insulation and encased in a bronze housing. The mouth of this housing contains a ring the internal diameter of which is a fit for the external diameter of the plug. The ring is cut axially to ensure a spring contact on the plug casing, and is of such a depth that the plug is entered $1\frac{1}{4}$ in. into its bore before contact is formed with the pins in the socket.

In this way it will be seen that in entering the plug into the socket two safeguards are provided: (1) The earth circuit is completed through the plug housing and socket, before the live terminals marry, and (2) before the live terminals marry a flameproof enclosure is formed in the contact chamber, so that if the machine be earthed or a fault be present which will cause arcing no danger of external explosion exists. To safeguard against an internal explosion as described in (2) blowing out the plug, the plug is so arranged that it cannot be entered into the socket so far as the contacts before a controlling screw is engaged in a slot provided on the side of the plug body. When a switch interlock is required, as in cases when remote control is not used, a recess is formed in the control screw body into which the interlock plunger drops when the plug is fully engaged.

Usual precautions are, of course, taken against the access of damp to these plugs. In the majority of cases they are used in conjunction with the 4- or 5-core type of cab-tyre flexible cable, i.e. 3 live cores and an earth core, or, alternatively, 3 live cores, a pilot core, and an earth core.

It will be seen that all live contacts are adequately masked, and that the construction is simple and robust. A number of similar plugs are also used, but generally these are engaged by the large circular-nut principle, which involves heavier and more cumbrous construction.

Electric Motors.

The design of electric motors for use at the coal face is restricted in various directions. Firstly, the dimensions of the motor must be kept down to such limits as will allow it to go into and to be fairly easily handled in the seam where it has to work. The height is, of course, the more important dimension and is strictly controlled by the height of the seam. Secondly, it must in most cases be flameproof. Thirdly, it must if possible stand without breaking down whatever treatment it may be subjected to in the hands of an operator whose knowledge of electrical apparatus is strictly limited and whose sole object is to get more and more coal, with in some cases, it is feared, the minimum consideration for the machinery which helps him.

From the manufacturer's point of view the motors of the gears must be standardized and capable of being made in quantities. It is accordingly the usual practice to make flameproof all motors for underground conveying in collieries, the number of collieries in which this precaution is not necessary being relatively small.

The heights of the motors and gears are restricted, and for the thinner seams an overall measurement of about 13 in. to 16 in. is common, whilst for thicker seams the restriction of height is, of course, less important.

The length and breadth of the machines have also to be kept within the smallest possible limits in order that the minimum of unsupported roof may be exposed, and that the machine may be as light and as easily handled as possible, thus facilitating the frequent changes of position of the conveyor.

In present-day practice the supply to the colliery for which the motor must be designed is usually 3-phase. Unfortunately the periodicities and voltages differ considerably from district to district, and there are still a considerable, although diminishing, number of places where direct current is still in use.

The motor used to drive conveyors on a 3-phase supply is almost invariably a squirrel-cage induction motor, and it is the common practice to switch the motor straight on to the mains without any special starting device. In the early days of motors being used at the coal face for coal-cutting and conveying, the more orthodox method of putting in wound rotors with slip-rings was generally adopted. It was found from experience that the greater simplicity of the method of switching direct on to the mains appealed to the colliery proprietors, and that when the current was taken from a public supply or from a private plant of adequate size no ill-effects arose from this method of starting.

In many instances of motors, originally sent out with wound rotors and slip-rings, coming in for repairs it was found that, the starting resistance or switch having given trouble, the colliery electricians instead of having any repairs carried out had merely short-circuited the slip-rings, and thus made the machine into the equivalent of a squirrel-cage rotor. It is obvious that in the case of motors receiving the treatment usually meted out to underground motors it is of the utmost importance that simplicity should be the guiding principle of design, and the advantages of the squirrel-cage rotor without any moving contacts are obvious. Even in those cases where auto-transformer startors were provided they were an additional complication and source of possible trouble, and when any trouble arose with them it was found that the usual practice of the colliery electrician was simply to remove the auto-transformer and only use the switch to put the motor straight on to the mains. This method was therefore almost universally adopted except for motors of the very largest size, and is now practically standardized.

Further difficulties to be faced by the designer are due to the fact that the load of all coal-face machinery is in many cases very intermittent, and worst of all that the demand to be made on the motor will vary largely in different places and under different conditions, and can seldom be even approximately estimated beforehand.

The problem for the designer, instead of being, as is usually the case, to make a motor to give a definite horse-power at a definite speed and to make it as small and as cheap as possible, is inverted in this case, and may be stated thus: Given the maximum dimension which may be used, put into that space the most powerful motor that can be obtained. It is obvious that under those conditions a motor cannot be designed to any of the standard specifications, and the proper attitude for the manufacturer (although it is sometimes difficult to persuade the customer to share this view) is that he is not selling a motor of any given horse-power but that he is selling complete a gear, whether for conveyor, coal-cutter or whatever it may be, embodying that motor which his experience has led him to choose as being the most suitable for that particular job.

The 3-phase motors for conveyor gears are designed to give a stalling torque much in excess of what would be usual in commercial motors, so as to get over the frequent temporary overloads thrown on them, and are

frequently run by the operators at such overloads as to cause very considerable temperature-rise. In the case of 3-phase motors this temperature-rise is the only symptom of the motor being considerably overloaded, but it is possible with improved methods of insulation with heat-resisting material to make motors which will stand high overloads and high temperature-rise without damage to the insulation. In the case of d.c. motors, however, the conditions are different. In addition to overheating, excessive overload also causes sparking at the commutator, and this cannot be avoided.

When a 3-phase motor has been tested at a certain load and is put into the hands of the colliery operators it can be definitely stated that it is capable of a certain average load, and that if it is found to be overheating at the end of a shift it is because it has been asked to do too much.

When a d.c. motor has been tested with the commutator in the best possible condition and with the brushes adjusted by skilled testers, there is no guarantee whatever that in actual working conditions it can repeat the same load without sparking. The condition of the commutator may have been allowed to get much worse, the brushes may be badly out of adjustment, and if the conditions in a thin seam are considered it will be seen that no very great blame attaches to the operator if these adjustments are not always kept at their best. Further, on account of the indefinite and intermittent load only a hit-and-miss type of adjustment is possible while the machine is actually at work. The fact that everything has to be kept down in size and at the same time that the whole of the motor casing must be flameproof makes it exceedingly difficult to make the commutator really accessible, and when manufacturers put forward claims of accessibility for their machines it has to be remembered that the term is relative. Whilst accessibility may be quite rightly claimed for some machine because it is better than in competing machines, nevertheless in a commercial motor where all the above restrictions were absent the commutator would be considered very inaccessible indeed. If, added to this, it is considered that the work of adjustment must be carried out at the face with perhaps only 18 in. between floor and roof, and also that whilst actually at work the machine must be totally shut up so that what sparking occurs can only be seen through small peep-holes, it will be realized that it is next to impossible that the motor should be working under its best conditions. It follows from this that the problem of driving coal-face machinery electrically is easier on a 3-phase than on a d.c. supply.

Although, as can easily be seen from the above considerations, it is not possible to make motors for conveyor work which will comply with the requirements of standard specifications so far as heating and electrical qualities are concerned, there is no difficulty in complying with all the requirements for flameproof enclosure contained in the British Standard Specifications for flameproof enclosure (No. 229) and for motors for use in mines (No. 270). Such flameproof enclosure must of necessity be provided whenever the motor is to be used in a fiery mine, and apart from any danger of explosion the shell must be strong enough to give the working parts reasonable protection against mechanical damage from falls of roof and similar accidents.

Economic Advantages.

The economic advantages of mechanical conveying fall under two different heads. There is a definite saving in the number of men required to clear a face when mechanical means of conveying the coal are provided, and, as will be seen from some of the actual examples given below, this saving more than compensates for the depreciation and interest and running costs of the conveyor; but very much more important than this is the saving realized when mechanical conveying is combined with mechanical coal-cutting, due to the totally different organization of the intensive working imposed by these mechanical aids.

The concentration of the output from a much smaller number of faces is a matter of great importance. The output from very much longer faces can be brought to one "mother gate-road" when worked mechanically than is possible in the case of hand work, and the savings effected by this concentration are extremely important. Not only does it mean a very greatly decreased cost on keeping open roads which can now be much fewer in number, but there is also a definite advantage, and in places where the roof is tender a very considerable saving is frequently realized from the rapid and perfectly regular advance of the face which effects a reduction in the cost of timbering, as much of the timber can be extracted and used again as the face advances.

Instead of working more or less at haphazard the transport of coal can now be definitely organized, much in the same way as the transport of manufactured articles can be organized in a mass-production factory. The same cycle of operations is carried out day by day and every man knows exactly what he has to do. In a properly organized mine the operations are exactly repeated from day to day and a regular advance of the working units of face may be relied upon. In the place of ten or more gate-roads to a working face, to which the coal must be cast and at which the tubs must be filled, then to be pushed by hand to the centre or mother-gate, in which a subsidiary haulage is installed to take the tubs to the main haulage, the centre or mother-gate suffices for loading, and the labour of casting the coal back to the gate-roads and pushing the tubs to the haulage, attaching them thereto and detaching them, again to attach them to the main haulage, can now be eliminated.

The labour entailed in turning over coal which has been cut by a coal-cutter from the face on to a face conveyor is naturally less arduous than that expended in the casting and tub filling as described above; and on a properly organized conveyor face the output per filler is, as a result, at least doubled. Further savings are, in favourable circumstances, effected by the reduction in the number of gate-roads required to the face, though in some cases it is still necessary to extend the work applied to these roads, to gain material to build pack walls to control the roof under the changed conditions.

Offset against these savings is the cost of moving up

the conveyors to follow the face advance, interest, depreciation, maintenance, and power costs on the plant. The latter charge, in a few isolated cases where gate-road troughed belt conveyors are used, has been considerably modified; when the workings are going up an appreciable incline, regenerative conveyors are used, and power proportionate to the output is put back into the line. A case of this kind where the entire output of a colliery, amounting to 3 000 tons per day, is being brought down the hillside from the mine, shows the remarkable regenerative capacity of 50 h.p., which, taken over a year's working, should approximate to a saving equal to the total depreciation and maintenance of the entire conveyor plant.

The old method of longwall working is illustrated in Fig. 9. A longwall face was opened out; its length was indiscriminate, but generally speaking it had a mothergate into every 100 yards of face, running obliquely to the mothergate were cross-cuts, and at intervals of about 45 ft. were gate-roads joining it to the face. These cross-cuts were driven through the waste at intervals so as to limit the length of the gate-roads.

When the coal was hand-won, the face was often allowed to develop according to the capacity of the

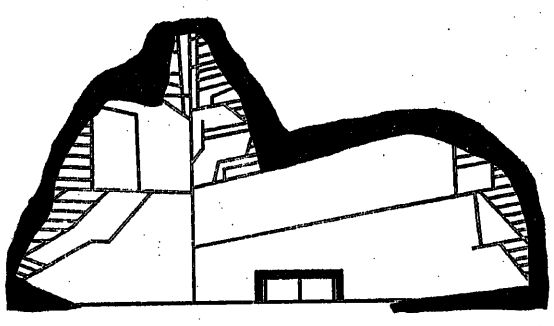

FIG. 9.

individual hewer; he hewed his coal and cast it to the nearest gate-road (i.e. a maximum of about 25 or 30 ft.), which would sometimes under difficult conditions entail three casts. At the gate-road a boy was employed whose duty it was to fill the hutches and push them down the gate-road to the main haulage. Each gate-road had to have a rail track laid in it, and had to be maintained at adequate height to allow the loaded trams to pass; this entailed brushing, and again in most cases back brushing, i.e. cutting up into the roof or cutting down into the floor. The gate-roads in most cases had to be propped by timber. At the mothergate the hutches were marshalled by pony boys, who gathered them from the gate-roads and pulled small trains to the haulage. If the gate-roads were on an up gradient the hutches had to be pulled out to the mothergate by ponies also.

The average output of a hewer in a 3-ft. seam undercutting by hand and drilling and firing his own shotholes was generally in the neighbourhood of 6 tons per shift, say 0·84 ton per yard of face, i.e. one hewer could deal with about 7 yards of face per shift. A comparison on these assumptions of the working of a face 100 yards long by the old hand-working methods as compared with mechanical coal-cutting and conveyors is given below:—

	Man-shifts
Hewers (getting the coal and casting to gate)	14
Drawers (filling the tubs and pushing them to mothergate)	14
Train marshal (getting tubs into small trains)	1
Pony drivers (pulling trains to main haulage)	3
Haulage attendant	1
Fireman	1
Brushers (road maintenance)	7
	41

These figures are for 84 tons of coal, making the weight per man-shift 2·05 tons.

Comparing the above hand-worked face with a similar face 100 yards long worked with a coal-cutter and conveyor, the seam being 3 ft. wide and the coal-cutter undercutting 4 ft. 6 in., the output will be about 1·4 tons per yard of face (the coal-cutter undercutting deeper than is possible by hand). When filling cut coal on to conveyors a man can comfortably load 15 tons in an 8-hour shift, and the number of men required will be:—

	Man-shifts
Coal-cutter attendants, Hole driller, Shot firer } getting the coal	2, 1, 1
Fillers (shovelling on to conveyor)	10
Conveyor attendant	1
Tub loaders	2
Train marshal	1
Conveyor shifters	3
Fireman	1
Brushers	5
	29

The weight of coal in this case is 140 tons, making the weight per man-shift 4·83 tons.

These figures are typical of the savings that can be made by changing from hand-working to mechanical working, and indicate the economies which can be realized with the best conveyor practice; in favourable cases the above figures can be improved upon. It has not been found possible to give actual figures of any given case of change-over; in most collieries the process of changing is gradual and extends sometimes over a very considerable period of time, and colliery records are not usually kept in such a way as to make the required figures readily accessible, even were the management willing to disclose them.

The economies additional to those derived from the increased output per man employed depend on obtaining a greatly increased output delivered to the main haulage at one point. It can readily be seen from the above examples that the more fillers can be employed as one unit the better will be the ratio of fillers to the day workers, i.e. to the oncost men.

In the comparison given above it will be seen that the elimination of all the gate-roads, the conveying being done along the mothergate only, has decreased the number of brushers required. In addition to these,

however, the concentration of output may result in having to keep open a much shorter total length of main roads; it may result in getting the whole output required from one district instead of two or three, with a very considerable saving on maintenance of roads.

The authors encountered an extreme case not long ago where an old colliery was turned over from hand-winning to machine-cut and machine-conveyed coal; before the introduction of machinery the working faces

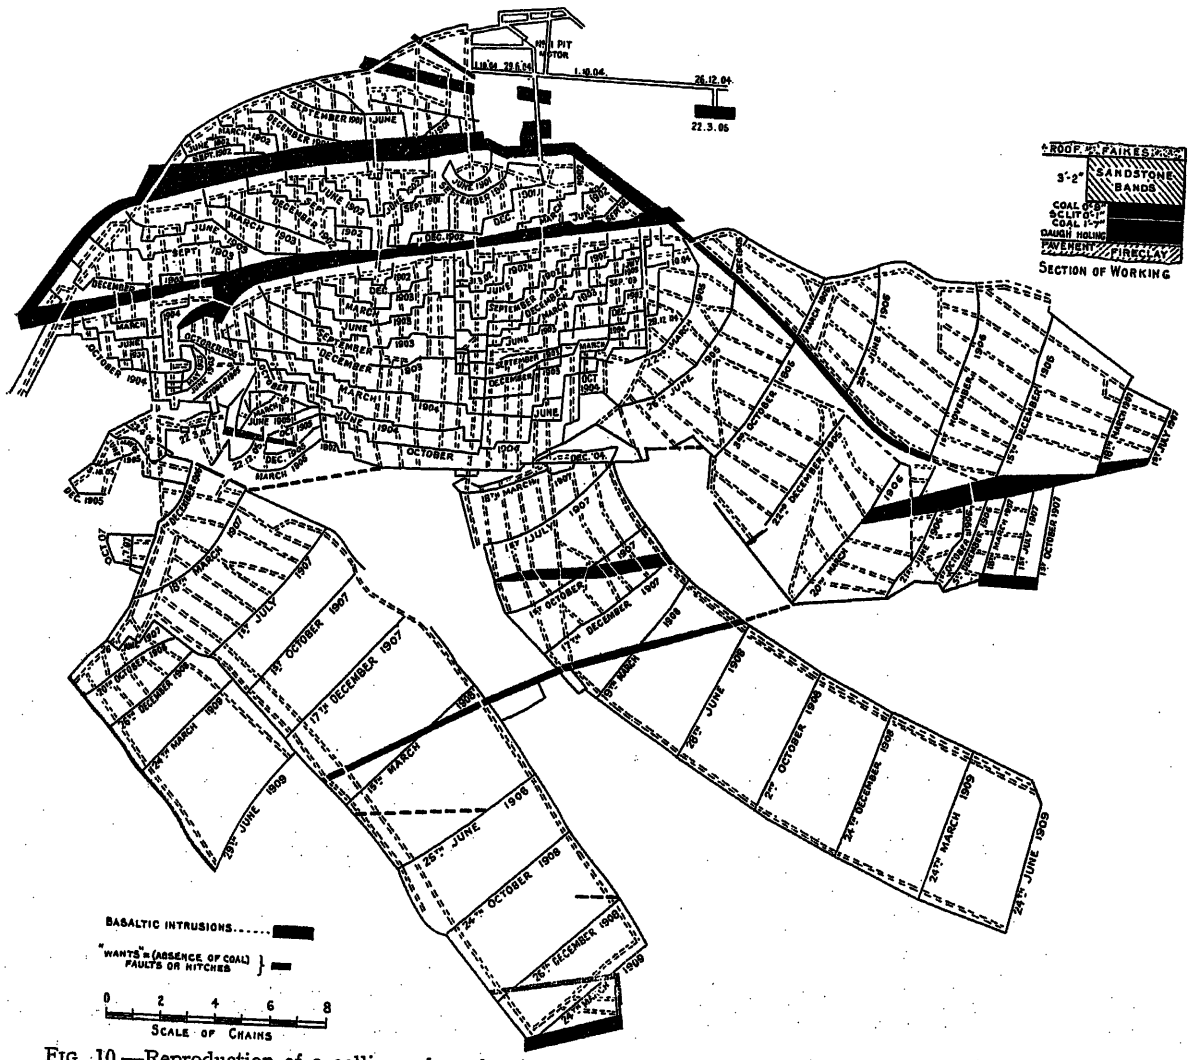

FIG. 10.—Reproduction of a colliery plan, showing the evolution of coal-cutter and conveyor sections from hand workings in a seam troubled with faults.

totalled 2 miles in length and were scattered over several districts. Three 100-yard faces equipped with conveyor units were started, and the rest of the pit was laid idle. Within three weeks the output of the colliery was normal and the output per man employed above and below more than doubled. Before the introduction of machinery more men were actually employed on road maintenance and transport than on hewing coal.

A practical illustration of the concentrative effect of the application of coal-cutters and conveyors is shown in Fig. 10, which is an actual colliery plan; the quarterly survey lines show clearly the rate of advance of the working faces. Where the survey lines appear close together the coal was got by hand; the intermediate stage where the lines become straighter and wider apart, with a number of roadways (shown by dotted lines) to the face, show the start of coal-cutting. The widely-spread surveys with only two roads, one at each end of the face, illustrate vividly the speeding-up resulting from the application of a single-unit conveying system. Fig. 11 is a drawing to a larger scale of two sections of the same plan, showing the hand-won and machine-won faces.

With the introduction of concentrated mining, important research on road-making and maintenance has been started and the science of mining has naturally developed along lines which will assist the reliable function of the machinery and the certainty of obtaining the output regularly and without interruption from accidents to the main roads. In many cases where roadways were maintained only at the cost of repeated

back-brushing (i.e. heightening) and re-timbering, it is now possible so to construct the roadway in the first instance that it will remain in reasonable working condition until the area is worked out.

Taking all the savings which can be effected by changing-over from hand-got to machine-got and machine-conveyed coal, it may be said that savings as great as 50 per cent in the cost of the coal at the pithead have been realized in favourable cases, whilst a saving of 25 per cent is not uncommon.

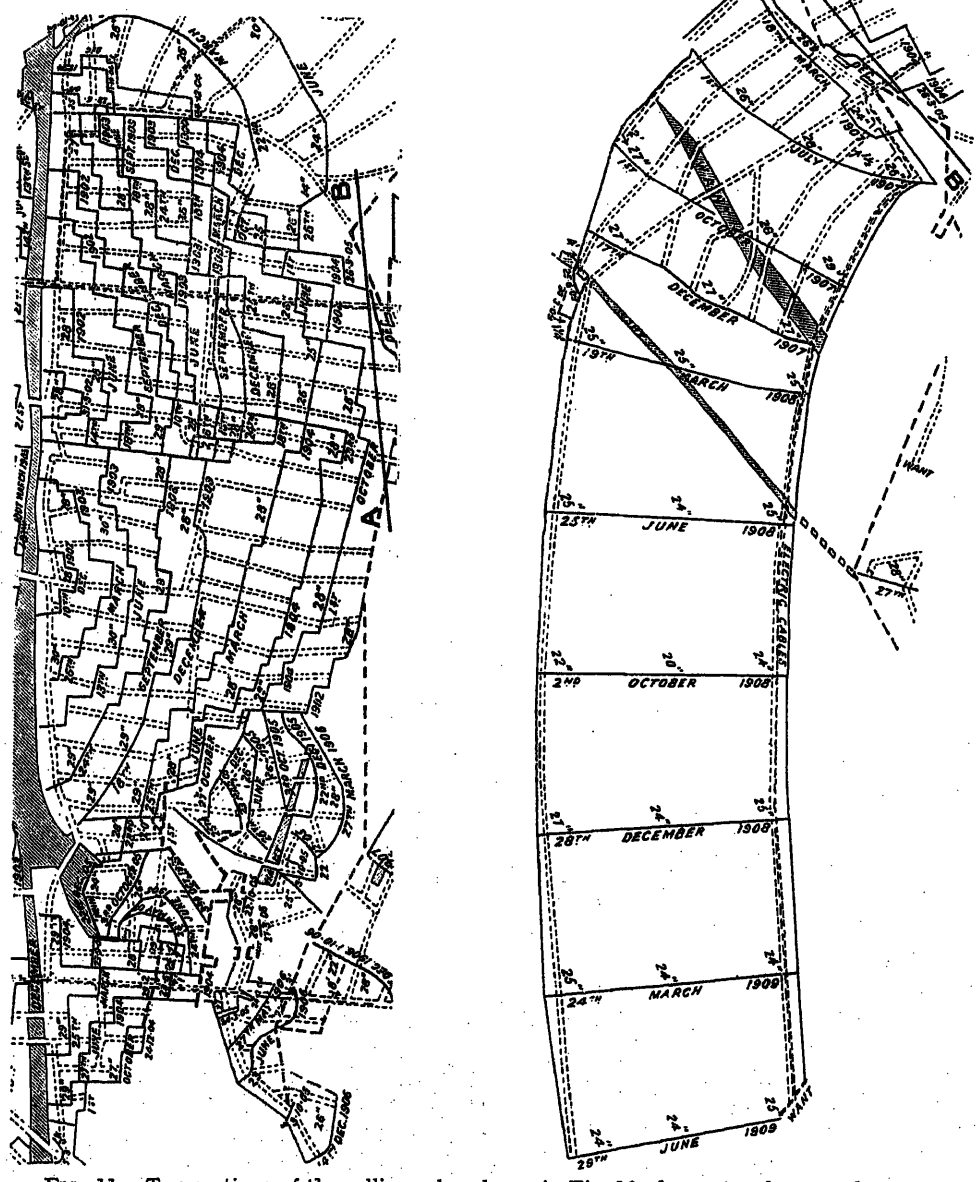

FIG. 11.—Two sections of the colliery plan shown in Fig. 10, drawn to a larger scale.

All the above examples relate to workings on the long-wall principle in this country. So far no economic advantage has been possible from installing a system of conveyors when the workings are pillar and stall, since in our comparatively thin seams the output from any place is not sufficient to justify the first cost and upkeep of a conveyor. In many of the comparatively thick seams worked in the United States the case is different, and conveyors can be economically installed even in room and pillar workings.

The following description of what is probably the longest underground conveyor in use anywhere is included, not as being typical of what can generally be economically accomplished by conveyors, but to show how special circumstances may make it advantageous to use conveyors in a way which would ordinarily be considered quite abnormal. From a coal mine in America an output of 8 500 tons a day was required to be loaded into barges on a river at a considerable distance from the pit; difficulties in obtaining the necessary way-

leaves, and engineering difficulties due to the unstable nature of the river bank, made it inadvisable to carry this output above ground. Extending from the mine to the river, however, was another coal mine which was practically exhausted, and two roads ran from the new pit to the river bank, a distance of over 4 miles. The question was considered of widening and improving these roads, which were in a bad condition, to make them suitable for electric locomotive haulage, but the cost and the difficulties of handling the number of cars which would be required for this output eventually resulted in a system of belt conveyors being installed along one of these roads, thus allowing of the full output being conveyed in one comparatively narrow road, the cost of preparing and maintaining which would be only a fraction of what would have been required had the electric locomotive scheme been adopted. Twenty belt conveyors work along this road in series, i.e. there are 20 complete units feeding on to one another to form one conveyor. The longest conveyor is 504 yards, but varying lengths are required, as the old roadway is not straight; the average length of the conveyors is about 400 yards. The conveyors are of the troughed belt type, the belts being 48 in. wide. Very special consideration had to be given to the belt carriers so as to reduce friction to a minimum. The importance of this will be realized when it is considered that the number of carriers in the total length of conveyor amounts to 6 600. Every bearing throughout all the installation is either a ball or a roller bearing, and special arrangements have been made for regular lubrication. The motors driving the conveyors are situated in rooms constructed at each side of the road, and the power supply is at 2 300 volts, 60 cycles, the motors running at 900 r.p.m.

As the result of actual working it has been found that not only was the initial cost of the belt conveyor system less than that of locomotive haulage, but there is also a considerable saving in running costs.

Conclusion.

It is hoped that this paper will prove of value in indicating to electrical engineers the progress which has taken place in recent years in the mechanical handling of coal underground. Broadly speaking, European conditions have been covered by it and there is no doubt that the best-equipped collieries in Britain now compare favourably with any European colliery on the basis of output per man employed.

Since 1918 the number of underground conveyors in use in this country has increased more than 5-fold, and the rate of progress is still increasing; it is not an overstatement of fact to say that conveying is one of the most important developments in coal-mining, and that the economies accruing therefrom are, as yet, only partially realized.

In one sense the concentration of the whole output of a district on to one or two faces, with an intensive conveying system, may be open to the objection that it is putting all one's eggs into one basket, and it is true that any serious derangement of the conveyor system may temporarily stop the whole output, but it is submitted that it is better to put all one's eggs into one big basket which has been constructed on engineering lines to begin with, and which is of such vital importance that it is necessarily under the constant supervision of the management and staff, than to scatter them into a dozen small baskets which are not under close supervision and any of which may have been leaking eggs for a considerable time before their defects are realized.

The results of using underground conveyor systems on a large scale leave no doubt as to the big basket being the best in this case.

The authors' acknowledgments are due to the South Wales Institute of Engineers for permission to reproduce some of the illustrations which had already appeared in their *Proceedings*.

Discussion before The Institution, 11th February, 1932.

Mr. J. Wayne-Morgan: While I agree with the authors that machine mining would greatly improve the output per man, my own experience has been that there is a great deal of opposition to it, both on the part of the managements and on that of the men. The introduction of mechanical conveyors and coal-cutting will probably entail an entire rearrangement of the price lists, and a manager who has a good price list objects to having to meet the men's committee to rearrange it, particularly as the introduction of something new will probably encourage the men to insist on better terms. A good collier is quite capable of earning his living wherever he has to work, whereas the introduction of machine mining and especially of machine conveying means that the whole output of the coal face has to be pooled, and the good miner has to work harder to make up for the deficiencies of the bad one. When all the coal is put into conveyors the colliery manager is unable to detect the miner who loads small or dirty coal. I have found that these objections are very hard to overcome in South Wales. Although we have tried in several cases to introduce conveyors and coal-cutters, we have always been prevented from doing so by the fact that if machine mining is to come into general use it must be backed up by good team work, which is very hard to get. Unfortunately, in the early days of coal mining in South Wales the only point taken into consideration was which seam could be reached first and which would give the best results financially. When a good seam was found mining engineers did not care what was above or below it; they got out the coal without ever thinking of the future. Ninety per cent of the rubbish in the big tips scattered over the Welsh valleys to-day ought never to have been brought above ground, and it never would have been if the mining engineers of those days had looked ahead a little. The result is that nowadays when we have to work seams above or below those which have been worked and not packed, we have great difficulty at the face in keeping the roof up. Although machine conveying and machine mining call for the longest face possible, it is extremely difficult to get a good face owing to the bad mining work done in

the past. With regard to the future of conveying, I think the belt conveyor will be the most popular in the future. For one thing, it is much more silent that other types, and the collier objects to anything which prevents him from hearing the slightest movement near his working face. At first we had considerable trouble with the belts for these machines, but the quality of the belts has recently been improved and they will now last several years. It is important to ensure that the belt tension is kept as low as possible, and in this connection a useful arrangement to adopt is that of a tension pulley with a spring device attached. Finally, if we are to have machine mining we must have much better lighting, and there are many types of electric lamps now on the market which could be used for this purpose.

Mr. J. A. B. Horsley: The following figures show the use made of conveyors and loaders in British mines in 1930. There were 483 mines using 4 200 conveyors and loaders, 2 050 of these being driven by electricity and 2 150 by compressed air. The distribution as between electricity and compressed air varies very much with the coalfield. In Scotland, out of a total of 829, 796 were driven by electricity and 33 by air. For England with North Wales, out of a total of 2 389, 1 242 were driven by electricity and 1 147 by air. In South Wales, out of a total of 982, 12 were driven by electricity and 970 by compressed air. In the North-Western Inspection Division, which includes the important coalfield of Lancashire, only 10 per cent of the conveyors and loaders were driven electrically. In Yorkshire the corresponding figure was 35 per cent. The authors state that squirrel-cage motors switched straight on to the line are used almost exclusively for coal-face machinery where alternating current is available. It is interesting that this came about from the reluctance of the users to keep in repair starting resistances and auto-transformers. The limitations of space at the machine are severe and therefore it is advantageous to use remote-control starters, which reduce the risk of shock and of explosion because the less frequently apparatus requires to be opened or attended to, the less likelihood is there of accident. The drawback from which the d.c. motor suffers is obvious, not only in manual starting but also in the application of automatic control and electrical interlocks. While it is true that alternating current predominates in this country, direct current is still extensively used. Some 20 per cent of the total horse-power of electric motors installed in mines in Great Britain is still served by direct current, and for Scotland (the scene of the most active development of machine mining, at any rate in the past) the corresponding figure is between 30 and 40 per cent. From time to time fears are expressed in influential quarters as to the risk of explosion to which the workmen are exposed through the use of electricity at the coal face. For the 10 years ending 1929 there were 15 explosions attributable to electricity, causing the loss of 38 lives; these figures compare favourably with corresponding data from abroad. As the authors mention, it is not difficult to design equipment that is flame-proof initially, but the problem of adequate maintenance awaits solution at the hands of the users.

Mr. D. B. Hoseason: I agree that in general the belt-type conveyor produces the best results when operating in the gate roads. For use on the coal face, however, I should like to illustrate the principle of a special type of scraper conveyor (see Fig. A). The chain supporting the cross-members travels along the coal face, dragging the coal with it, and then travels back in the other direction in the vertical steel channel. Actual experience of the working of shaker, belt, and this type of conveyor shows that the individual "fillers" are able to deal with a longer face when operating with this conveyor than with either of the other two, because this type obtains its loading vertically by gravity. The coal is got by operating on the face with a pick instead of by shovelling and lifting, as with belt and shaker conveyors. Gravity really constitutes the loader, and therefore the labour necessary is much less than with the other types. Moreover, in setting up the shaker conveyor or the band conveyor one must leave a minimum of 2 ft. between face and conveyor: thus the filler

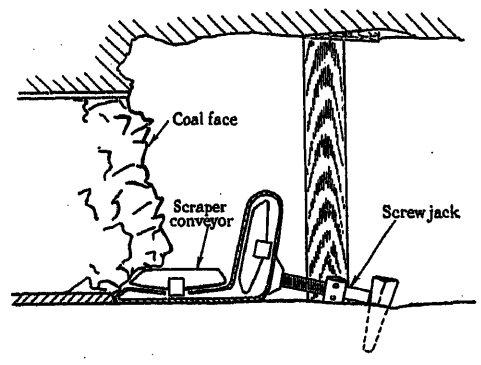

FIG. A.—Scraper conveyor at coal face.

works at first in a very cramped space, lifting the coal and shovelling it into the conveyor. As the face recedes, however, the loading distance increases and at the end of the shift the coal has probably to be moved as much as 6 ft. This point was brought out by one of the photographs shown by the authors. In the case of the scraper conveyor, the conveyor trough is jacked steadily forward as the face recedes. While I agree that the power required for working the scraper conveyor is appreciably higher than for belt conveyors, I do not think that the power consumption per ton of coal raised is seriously affected by the conveying equipment. I can assure Mr. Wayne-Morgan, moreover, that the amount of noise emitted from a scraper conveyor is negligible. Most of the noise near the coal face is usually contributed by the loaders. My second point, with regard to motors for driving conveyors and gate-end loaders, is to emphasize the authors' statements concerning mechanical construction. Practically everything else in the design must be subservient to the mechanical features of the equipment, and it has been interesting during the past 18 months to watch the development of what has become known as the "steel barrel" motor. Fig. B shows one of these machines. It is made from steel boiler-plate, and consequently will not crack under a fall of roof. One advantage of the steel frame is that it enables electric welding to be used by the colliery authorities, and it is generally left

to the colliery staff to weld on fixing appliances wherever they may need them. It will be noted that the laminations are mounted direct in the carcase with a view to dissipating the heat as effectively as possible, in order to reduce the size to an absolute minimum. The bearings of this class of motor are also of considerable importance. In order to obviate the possible entry of dirt and dust into the ball and roller bearings these are enclosed in a cartridge housing independent of the end plates of the machine. The object is to enable the dismantling and inspection to be done without exposing the bearings to atmospheric conditions. In conclusion, I feel that the use of conveyors below ground should be developed as rapidly as possible, because the more conveyors we use in mining the fewer lives we endanger in obtaining the coal which is required. Although temporary unemployment may arise, the more extended use of machine mining must ultimately lead to a healthier and a wealthier nation.

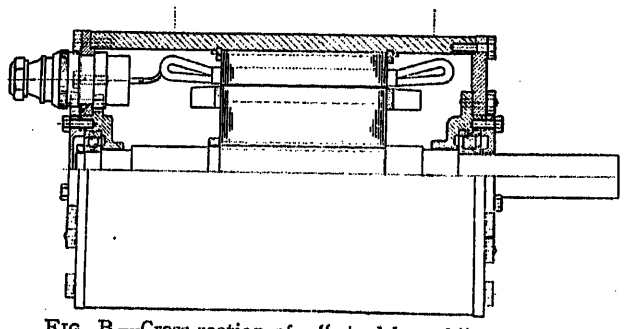

FIG. B.—Cross-section of a "steel barrel" conveyor.

Mr. H. C. Jenkins: Contrary to the statement on page 146 that the first shaker conveyors in Germany were operated by boys, I have a record of the fact that in 1899 the Zwickauer Oberhohndorfer Steinkohlenbauverein were the first to introduce a shaker conveyor hung on chains, and that this was operated by a small single-cylinder air engine, fitted with a flywheel. No further development was made in this direction until about the year 1905, when advances took place in both Germany and Belgium. The earliest record I can trace of a boy being employed to work a shaker conveyor by hand is a reference to some shakers in use on the Rand in 1908. I should like to ask the authors how they propose to use an end drive at the bottom of the conveyor, as mentioned on page 147: I had always understood that this could only be applied at the top of the conveyor. On page 148 they state that shakers have been used for conveying coal up a gradient of 1 in 20, but I have actually seen 40 tons per hour delivered up a gradient of 1 in 8 to 1 in 10. Shaker conveyors up to 150 yards long are working satisfactorily to-day. As regards the statement on page 148 that the first belt conveyors failed because of the extravagant cost due to belt wear, 10 years ago if a belt lasted 6 to 7 months under coal-face conditions it was considered to be satisfactory, but improved methods of construction both of the belt and of the mechanical part of the gear have increased the life of the belt 4 to 6 times. On page 149 the authors mention that special loaders or short lengths of shaker conveyors are frequently used to deliver on to the gate belt. While this is technically correct, not more than 10 or 15 per cent of the gate-belt conveyors at work in this country adopt this method. The modern type of tension drum is usually moved up each day, thus doing away with the added expense of the special loader. I do not agree that a double-drum type driving gear is a necessity for face work, as there are a larger number of special single-drum driving gears working on the coal face to-day the design of which is so arranged that "creep" between the belt and driving drum is eliminated. As to the authors' view (page 150) that only chain scraper conveyors can be used on gradients in excess of 18°, I would point out that belt conveyors are working to-day on gradients of 20°, and if a chain scraper will work on such a steep gradient I am quite sure that a belt conveyor will convey the coal more economically on the same gradient. Belt conveyors are also working under wet conditions, being fitted with a special device to overcome the tendency to slip on the driving drum. It is economically much better to use a belt conveyor, as experience has shown me that the horse-power necessary to work the latter is only one-fifth of that required to operate a chain scraper. The shaker driving gear with a bell-crank arm shown in Figs. 5 and 6 is surely becoming out-of-date, owing to the difficulties which it involves. Of the total number of shaker conveyors employed in this country only a small percentage embody this type of drive. I am not clear about Fig. 7, which shows a gate conveyor 240 yards long with a balance arrangement fitted to the driving engine. Is this 240-yard shaker gate conveyor driven by a single engine? As regards switchgear (pages 153 and 154), while I agree that the push-button type of control is the ideal, owing to the heavy expense involved very few of these equipments are actually in use. Could the authors state what relation between starting torque and running torque they find most satisfactory for use with the conveyor motors they are installing? Regarding the relative merits of a.c. and d.c. motors for driving coal-face machinery (page 156), in many cases it has been found that collieries fitted with d.c. plant have had a longer experience of underground machine mining and their officials are giving the equipment better treatment. I should like to know whether the authors can confirm this from their experience. The case mentioned on page 158, where a colliery was changed over in 3 weeks from hand to machine mining, is surely a very exceptional one. As a rule it takes from 1 to 2 years to effect such a change-over in connection with a large colliery. The Frick conveyor installation in the United States (see page 159) is surely an exact duplicate of a standard surface installation put into a special tunnel underground. In their Conclusion the authors suggest that the use of an intensive conveying system is like "putting all one's eggs into one basket"; a large number of colliery companies are, however, fully satisfied that the modern belt conveyor is sufficiently reliable to do this. I know of cases where underground belt conveyors have been at work from 1 to 2 years without a single involuntary stoppage. In many instances they constitute the most reliable form of underground transport. There is no doubt that British manufacturers have given a lead in underground belt-conveying, par-

ticularly to Continental and American mines. Perhaps this type of conveyor has been more applicable to our own than to foreign conditions; the more extensive use of electricity underground in connection with longwall working has also aided the development of British conveying equipment.

Mr. A. R. Cooper (*communicated*): It is suggested in the paper, and is certainly borne out in practice, that the overall dimensions of a driving unit should be kept as small as possible. The compression of a driving unit into the smallest possible space has, however, a number of attendant disadvantages. For instance, I suggest that instead of a motor being built integral with its gearbox it should be connected to it by a simple coupling, or a universal joint, so that by removing three bolts, or, better still, a single pin, it would be possible to disconnect the motor from its gears. This arrangement would possess the following advantages. (*a*) It would remove the danger of oil working back from the gearbox into the motor. (*b*) It would facilitate the changing of motors in the event of a breakdown. (*c*) It would enable the electrician to determine in the shortest possible time whether the trouble was mechanical or electrical. This would be a decided advantage where shaker conveyors are used, for when a conveyor of this type breaks down the trouble is usually due to driving rods hitting the floor, conveyor pans becoming fast, or bearings becoming seized up. I should like an expression of the authors' opinion regarding overload protection. The high-torque squirrel-cage motor is undoubtedly the most desirable form of prime mover for underground conveyors, but it has the disadvantage that high starting currents are taken from the line. To cope with these peak currents it is necessary either to fit the solenoid type of overload protection with long time-lags or to set the protective devices to trip at abnormally high values. In practice it is usually found that this type of overload device is set to operate at current values as much as 150 per cent in excess of the normal working load, making it possible for a motor to work with a continuous overload of about 100 per cent without cutting off the supply. Would the thermal type of overload, if it could be suitably applied, solve this problem? With reference to the interlocking of conveyors, is it not probable that by taking such pains to make the electrical apparatus foolproof we are introducing a number of disadvantages? The whole purpose of interlocking two conveyors and a loader is to prevent the conveyors delivering their coal on to the loader belt when it is at rest. In practice we almost invariably find that there is a workman near the face-conveyor driving unit who can stop the machine as soon as the loader stops. If a little coal is spilled it is rarely a serious matter, as it can be cleaned up by hand at the end of the shift. By cutting out the interlocks on a system of this nature the switchgear would be considerably simplified, there would be fewer contacts and less wiring to give trouble, and the location of electrical faults would be considerably facilitated. The class of switchgear described in the paper will do, and undoubtedly does, all that is claimed for it, but when it has to work in atmospheres so humid that every switchcase is wet with internal condensation, when a fault on the interlock wiring can shut down all three machines, and when this fault has to be located by the type of underground electrician prevalent a few years ago, I should certainly prefer the simplicity of three standard conveyor controls with the possibility, if the worst occurred, of having to dig out the loading end of a gate-end conveyor.

[The authors' reply to this discussion will be found on page 167.]

North-Eastern Centre, at Newcastle, 8th February, 1932.

Mr. S. Burns: The general adoption of intensive machine mining has enhanced the difficulty of transporting coal from the face to the haulage landings, owing to the resultant rapid rate of advance of the working faces. The ultra-modern appliances described by the authors represent only the beginning of the struggle to overcome the increasing difficulties of mining thin seams of coal not worked by preceding generations. I am surprised that the paper does not include among the advantages of machine mining absence from electrical and mechanical breakdown. In designing conveyors the problem is to rectify faults without at the same time introducing others which are just as troublesome; for example, a real danger was removed by enclosing the lower belt of a belt conveyor to prevent spillage on to it, with the result that when a fracture of this belt does develop its location and repair are rendered more difficult than ever. I suggest that the manufacturer of machine-mining equipment should resist the natural temptation to be continually effecting so-called "improvements" to the detail design of his plant; that he should keep a properly indexed record of complaints on the one hand and of renewals orders on the other; and that only those parts should be modified in regard to which complaints have been justified by replacement orders. Although frequency standardization is not mentioned in the paper, it is important that coal-face machinery sold into this area during the next few years should be suited for operation by 40/50-cycle inter-frequency motors. The gears and other power-transmission arrangements should be so designed that an ultimate 25 per cent increase of motor speed will not necessitate troublesome structural alterations.

Mr. G. Clephan: The authors state that by means of shakers it is possible to convey coal up a gradient as great as 1 in 20, but while I agree that this can be done I feel sure that uphill conveying is not a commercial proposition. What are the practical limits of use of shaker conveyors? In my opinion, except where the gradient is regular and approximately 1 in 18 in favour of the load, or steeper, the belt conveyor is a better proposition. The modern improvements in belt-conveying have restricted the field of use of the shaker conveyor to conditions highly favourable to it, and its application is gradually becoming more and more restricted. According to the authors' opening remarks,

belt conveyors still embody defects that were eradicated from surface plant twenty years ago. I should be glad of some further information on this point, as many of the surface belts running in collieries to-day are, I consider, worse from the engineering point of view than anything of the kind I have ever seen underground. With regard to the life of face belts, I should welcome any information as to the progress of research on rubber belts. Why do the authors condemn the use of flat-belt conveyors except at the coal face? Although I agree that the flat belt is not so perfect as a troughed belt, in practice the difference is not so marked as they suggest. I have found that troughed centre-gate belts require much more attention and alignment than is indicated in the paper. With regard to the loading of coal from one conveyor to another at right angles, what do the authors consider to be the most satisfactory method, apart from the use of a telescopic scraper loader? Also, what is the maximum length over which it is economically possible to convey coal with belts? Has this length increased since the Frick installation was laid down in the United States? I consider that in the colliery of the future the coal will be conveyed to the shaft bottom on belts. With regard to the question of remote control of conveyors, it would be interesting to know whether any reliable data are yet available as to the first cost and maintenance of the two systems. While underground conveyors have many economic advantages, without the necessary organization behind it no conveying system can be made a financial success. The collieries are handicapped in this direction because the staff has to be built up from the beginning from unskilled labour, a fact which is often ignored by both the manufacturer of conveyors and the electrical engineer.

Mr. R. W. Mann: Five or six years ago the mining manufacturing industry ridiculed remote control, yet it is now preferred to a system of switch-fuses. I should like to see the use of switch-fuses entirely abandoned, particularly as it is doubtful whether they meet the requirements of the Memorandum on the Regulations as to the use of Electricity in Mines, which calls for a piece of apparatus capable of isolating the supply under all fault conditions. Of the multi-panel system of control, I would say that this is developing on lines which wide experience suggests are wrong. The practical requirements of pit conditions necessitate the continual changing both of methods of control and of the apparatus to be controlled; the necessary flexibility is only obtained by single-unit equipments. The system of multi-control shown in Fig. 8 has the following drawbacks. (*a*) One isolating switch interrupts power to all circuits. (*b*) A leakage fault on one unit shuts down the entire equipment and does not indicate the circuit on which the fault occurred. This is also true of interlocked overload tripping. (*c*) The master controller ties the groups of three permanently together. (*d*) The system of intermediate contact for short-circuiting the choke reset coil is impracticable in operation, as the rapid movement of the contact finger does not always give sufficient time for the operation of the contactor. (*e*) Direct-acting leakage does not give fine enough settings and does not appear to discriminate visually between overload faults: furthermore, from the diagram it would appear to be self-resetting, so that the operator could reclose the contactor under fault conditions. As regards the auxiliary switch working in conjunction with the motor isolating switch (see page 154), this interlock will probably race the contactor on fast operation of the isolating switch. Turning to the subject of motors, the design requirements of machines for driving all types of conveyors are similar in many respects, and suitable ratings for such motors can be, and have been, determined. In their statement of the problem for the designer: "Given the maximum dimension which may be used, put into that space the most powerful motor that can be obtained," what do the authors mean by "powerful"? I can design a 10-h.p. motor to take up half the space occupied by a 5-h.p. motor having the same working speed. The appropriate rating of a machine to suit a given purpose can only be arrived at by a complete technical investigation of the requirements: trial-and-error methods take far too long. In my opinion there is no reason why colliery engineers should not be able to specify a motor having a definite horsepower, speed, and rating, and apply such a machine to any orthodox type of conveyor. The time will come when a mining-conveyor manufacturer will find it unnecessary to use a special built-in motor of unorthodox design and rating.

Captain S. Walton-Brown: I shall confine my remarks to the drag bucket scraper, or scraper loader, which I was the first to introduce underground into Great Britain. Equipment of this character has been regularly working at Seghill colliery since the beginning of 1928. Subsequent to its introduction at Seghill the scraping system was employed for heading purposes in the driving of the Halkyn drainage tunnel in South Wales, and also for the Grampians power scheme. During 1929 other collieries commenced to utilize scraper loaders, and the number of such installations is now steadily increasing. An important factor involved is that the scraper scoop is either wholly or partly self-loading, and always self-emptying; I shall return to this point later on. The three other types of conveyor referred to by the authors all become costly to work when the height of the coal seam falls below 2 ft., and for such seams it has at many collieries been the practice to revert to gate-way working as being the more economical method. The scraper loader has altered this situation. It also operates on gradients on which other types will not function, and it involves a very low cost for moving up. The system is still in its early days in Great Britain, and it will probably be much improved during the next few years. The V-type, as we employ it under a good roof, requires a clear space (without roof supports) of 6 to 8 ft. from the cut face. The face is shot down and the scoop started. The hinged end travels inbye along the face and on the return journey the open mouth meets the coal, or is kicked into the pile of coal and loads itself. The whole face can be loaded without manhandling any of the coal, thereby saving both time and energy. At the discharge point the scoop empties itself into tubs, conveyors, or another scoop system. The box type with hinged flap usually requires a good proportion of the coal to be moved into the fixed path in which it runs, but the coal has only to be slid and not lifted. Much larger pieces of coal can be handled with this type than with

the other types of conveyors mentioned in the paper. I do not agree that the scraper loader is subject to the limitations stated by the authors. Faces up to 100 yards long on each side of a mother-gate can be worked in the same way as with other conveyors. If increased capacity is desired, or the bottom is soft or wet, my method is to run the scoop in a light trough with low sides which is set on the floor and is capable of being easily moved up. As a result of the action of the troughing a short scoop is practically converted into a very long one, and 3 or 4 tons of coal at a time can easily be slid along the trough to the delivery point. If the trip along the face is considered to be too long, two scoops are fitted in tandem on the same rope so that each covers rather more than half the face, the far scoop leaving its load just past the centre and the second scoop picking it up and delivering it at the discharge point. As a single trip for a 100-yard face (in and out) takes less than 3 minutes (assuming a scoop speed of 100 yards per min.), if 3 or 4 tons are handled on one trip it does not take long to move 100 tons. With scoops in tandem the time can be halved. By placing a number of scoops in series in the trough and reciprocating them over any given short distance, a steadily-moving delivery system with adequate capacity is provided. As with other types of conveyors, it is essential that the men should be thoroughly trained, fond of machinery, and anxious to take care of it, realizing that in return the machine will do all the hard work and give them satisfactory earnings. The scraper loader system is much more economical than other types in canch work at the head end where discharge takes place, as no extra height has to be made. While the motor employed is of a larger horse-power than in the case of other types of conveyors, the total cost for power used in running is small and the item is not of great importance in view of other economies. The scraper loader is of service in any system of mining, and it can be advantageously utilized in bord and pillar so as to serve several headings, as the haulage can be moved from one place to another during the course of the shift. This cannot be done with the other types. By the use of a third drum on the hauler the scoop can be made to operate around corners and so travel the mother-gate as well as the face. The driving of drifts can be greatly speeded-up by the use of scraper loaders for the purpose of removing the loose material after blasting. On the faces we have hitherto used conveyors of one of the first three types mentioned by the authors, followed by rope haulage to the shafts: before long, however, the order may be reversed—so as to utilize rope haulage (in the form of the scraper loader) on the faces and one of the other types of conveyors (in my view the belt type) towards the shafts.

Mr. H. W. Clothier (*communicated*): I should like to refer first to some of the mechanical difficulties encountered in moving the coal from the face. The shaker or jigger conveyor has a hard jerky action which is bad for any type of mechanism. The belt type runs more smoothly, but it is dependent upon material which seems unsuitable for such hard wear. The scraper types have to provide for the return of the scrapers or buckets. An alternative, which has been proposed by a local engineer who works at the coal face, might be called a "pusher" type. The trough is made to reciprocate at an even steady motion, slowing down at each end of the stroke, and the coal is pushed along the trough by plates which hinge in the form of a non-return valve. Whilst this conveyor may prove to have disadvantages of its own, it would appear to be worth a trial as a means of overcoming some of the objections to the types described in the paper. The author seems to retain a regard for the simple drum-switch and fuse protection, but I agree with Mr. Mann that fuses are inadequate. The question of renewal of fuses also gives rise to some difficulty, as either spare fuses of correct rating have to be stored in a compartment in the switch fuse-box or the renewal of the fuse is dependent upon the presence of a responsible person who, even if available, may not have the correct size of wire with him. This gives rise to the danger of fuses being renewed by wire of unsuitable rating. Moreover, as stated in the paper, with merely mechanical interlocking at the motor switch there is nothing to prevent the plug from being pulled out even if the gate-end switch has been left on, the plug therefore remaining alive. Effective electrical interlocks have been successfully applied in a number of cases without the additional elaboration of complete remote control for the coal-cutter or conveyor motor. In their spoken abstract of the paper the authors mentioned oil circuit-breakers, and I would point out that these are in extensive use for gate-end service, particularly for coal-cutters; conditions are similar for conveyor circuits. The advantages of the oil circuit-breaker cannot be overlooked: for example, the immersion of insulation reduces the internal clearances, and therefore the overall dimensions, for a given breaking capacity. Thus, as compared with air-break contactors, oil circuit-breakers are more competent to withstand the impulse stresses to which they may be subjected in dealing with short-circuit currents, and the smaller volume for the intake of explosive gases means less risk of such gases exploding than in the large enclosure required for air-break contactors of the type shown in Fig. 8. The requirement in regard to strength of enclosure is at present under discussion, and in this connection the relative air spaces enclosed in the various types are of paramount importance. The operating conditions—particularly in thin seams—emphasize the need for remote control, and this need cannot be met in a "simple" manner. For reasons of economy the trend of development is along the lines of air-break contactor starting gear backed up by oil circuit-breakers at distributing centres. The scheme of connections might be such that the oil circuit-breaker dealt with short-circuit faults, and the contactors only with overloads, with thermal time-limit control. It is satisfactory to note that the British Standard plug (B.S.S. No. 279) is becoming increasingly popular. The fact that other makes of plugs are, as mentioned in the paper, heavier and more cumbersome is a testimony to the work of a Standardization Committee. Amongst colliery engineers there appears to be a wide diversity of opinion on what is the most suitable apparatus to meet the conditions, even in adjacent mines in the same coalfield. This applies not only to conveyor plant but to electrical applications in general, and particularly to switching requirements.

Mr. E. E. Grover (*communicated*): I do not agree with the statement (page 156) that " there is no difficulty in complying with all the requirements for flameproof enclosure contained in the British Standard Specifications for flameproof enclosure (No. 229) and for motors for use in mines (No. 270)." B.S.S. No. 270 calls for terminals to be external to the flameproof enclosure, a desirable feature which cannot easily be achieved on some types of conveyor motors. One method is of meeting this requirement by means of a detachable dividing box which can be withdrawn like a plug from the stator terminals. In the section dealing with switchgear no mention is made of the difficulties which are experienced by manufacturers in constructing flameproof enclosures. One of the requirements for a flameproof enclosure mentioned in the Appendices of B.S.S. Nos. 126 and 127, is that the enclosure shall withstand an internal pressure of 110 lb. per sq. in. I do not agree with the authors' statement that there is no difficulty in complying with this requirement, and I should be interested to know how such compliance is achieved. Fig. 8, which is intended to illustrate a system of remote control applied to three units, shows earth-leakage protection on the switch controlling the loader. This is the wrong position for such protection, as it is preferable to keep the gate-end switch as simple as possible. The better position for the leakage trip is on the next outbye switch controlling the supply to the 3-panel board. The only advantage of fitting each conveyor and loader panel with earth-leakage protection would be to obtain selective protection, but it would not be satisfactory to shut down the loader motor and keep the conveyor motors running.

[The authors' reply to this discussion will be found on page 167.]

Scottish Centre, at Glasgow, 12th April, 1932.

Mr. J. Bentley: Although motors used in colliery work underground have to stand a great deal of ill usage, I do not see why such motors should not comply with the appropriate British Standard Specification. The motors, although of special design, have to be made to give an output, the horse-power and rating of which can be estimated. By using Class A insulation the temperature rating can be fixed at a high figure; in fact, some of the motors made for the Admiralty have to work at an ambient temperature of 150° F. and have a final temperature of about 200° F. The design should be controlled by the use of the most economical materials in respect of weight and space factor. The cost of materials and labour should be regarded as of only secondary importance. What appears to be required is a motor which will give a relatively high torque for starting and overcoming momentary overloads, and which will stall should the torque exceed a safe limit. These requirements call for the use of some such system as the constant-current or Ward-Leonard. The cost of stoppages due to breakdown must be credited to the capital-outlay account. The motor should have a high starting torque in order to overcome the difficulties of high static friction, momentum, and momentary overloads. To obtain this feature other desirable characteristics have to be sacrificed; unless an auto-transformer starter is used excessive stresses are put on the gearing, owing to the motor starting up with a jerk. The use of slipping clutches to solve this problem is well worthy of consideration. These clutches are used extensively on ship deck machinery to get over similar difficulties. The small angular slip gives an appreciable extra torque from the armature momentum without overloading the motor. These slipping clutches do not, however, help in the case of sustained excess torque; they are only designed to avoid excessive stresses on the gearing until the overload release acts. Overload releases do not save the gear from excessive stresses, as the overload is applied before the release operates. The use of the crank motion in combination with the flywheel, as advocated by the authors, successfully overcomes the difficulty of momentary overloads. The crank provides extra torque at a certain part of its stroke to replace any loss of kinetic energy of the flywheel due to overloads. If the flywheel could be started up after the motor had got up speed, the crank motion would also help considerably to reduce the starting torque required.

Mr. W. J. Cooper: I should like to refer to an incident which happened many years ago, in order to indicate the magnitude of the difficulties with which the designer of electrical plant has to contend. I was called out in the middle of the night to attend to a defect in some colliery machinery, and with some difficulty I got as far as the gate-end boxes. I discovered that the designer of the fuse gear had unfortunately provided a space in the jaws of the latter which fitted the half of a collier's pick. The operators informed me that when a coal-cutter became jammed by a fall of coal the pick head allowed the motor to clear the cutter.

Mr. J. Gogan: Manufacturers have placed in the hands of colliery engineers plant which satisfactorily meets the demands made upon it. However, I see no reason why motors of a standard horse-power should not be used in conjunction with coal-conveying plant.

Mr. P. W. Yuille: I should like to know whether anyone has ever suggested a scheme whereby the electrical drive could be retained at a distance from the coal-face and the power transmitted by means of a fluid such as water. Has a development of the system put forward during the War by Mr. Georges Constantinesco ever been adapted for underground work? This system has the advantage that it will allow of all electrical gear associated with conveying plant being kept away from the coal-face, thus eliminating fire risks. Regarding the method of motor drive for limiting the starting current, would not a hydraulic-turbine-cum-pump drive be suitable for this purpose? Such gears are now made totally enclosed in one casing, and are very robust.

Mr. R. E. Keelan: I should be glad if the authors would say what is the power factor of a.c. coal-cutters, in view of the fact that, according to the authors, they have to be capable of developing from 100 to 250 per cent starting torque, and possess extraordinary high

stalling-torque characteristics, to say nothing of their having to be capable of working frequently to stalling point. Under such circumstances it would appear that the power factor would be very bad.

Prof. S. Parker Smith: Are the authors troubled by excessive voltage-drop? It seems to me that in view of the very long drives which are necessary, voltage-drop might be almost a limiting factor, as was the cost of cables. With regard to the cage motors, can sufficient torque be obtained with the single-cage type, or must a double-cage construction be used? It would be interesting to know the starting conditions with which conveyor motors have to contend.

Dr. M. G. Say: In some mines the working faces may be 3 or 4 miles from the shaft, and it would seem that under such circumstances the voltage-drop would be considerable. In ordinary supply practice it appears to be the custom to restrict direct switching of motors to comparatively small sizes. Underground, however, the 30-h.p. size is apparently not too big for this drastic method of starting. I should like to ask whether this practice is usual. Of course, if one could reckon on a line drop of the order of 42 per cent, a star-delta starter would be unnecessary.

Mr. S. Mavor: With reference to the transmission of power by means of fluids, I once discussed with Mr. Constantinesco the application of his system to coal-cutters, and I am satisfied that so far as the wave-generator and the wave-motor are concerned the scheme is feasible. The difficulty at that time was the lack of a flexible pipe suitable for underground service and capable of withstanding the high pressure. Even now a flexible pipe suitable for the purpose does not seem to be available. Proposals have been made from time to time to drive coal-cutters by hydraulic means, but certain practical difficulties associated with hydraulic plant have not yet been overcome. One of these is the danger of water leaking from the joints: in many collieries such leakage would cause disintegration of the strata, and this might be disastrous. Certain classes of shale are converted to mush by contact with water, even in comparatively small quantities. One of the lines of future progress will be in the direction of mechanical loading of face conveyors. This is already an accomplished fact in the thicker seams, and experience will enable us to reduce the limit of thickness of seam in which mechanical loading can be applied.

Mr. D. H. Bishop: In connection with starting by direct switching, has any difficulty been encountered in practice, due to the rapid rate of acceleration? I understand that in America, where direct switching seems to have been frequently employed for industrial purposes, the motor makers recommend that pulleys and belts should be 25 per cent wider than the standard, owing to the wear otherwise produced by belt slip during starting periods. Do the belts of the conveyors suffer in any way due to this cause? I have found from experience in cases where direct switching is carried out for very frequent starts, that designers do not always appreciate the abnormal amount of heating produced in the motors. This point should not be forgotten when laying out an installation. With slip-ring motors, of course, conditions are very different; much of the heat produced is external to the motor, and the current-rushes are smaller. Do the authors incorporate any extra resistance in the rotors of mining motors?

THE AUTHORS' REPLY TO THE DISCUSSIONS AT LONDON, NEWCASTLE, AND GLASGOW.

Messrs. W. B. Hird and **J. B. Mavor** (*in reply*): Mr. Wayne-Morgan has given us a rather pessimistic view of the position of mechanical conveying and coal-cutting in one particular district, but this is far from being typical of the attitude of management or men throughout the country.

We are confident that we are expressing the feelings of members in thanking Mr. Horsley for the valuable statistics he has put forward.

In reply to Mr. Hoseason, the conveyor described has so far proved to be very limited in its application. General mining conditions in this country do not appear to lend themselves to its successful use. The motor described by Mr. Hoseason is a robust construction, but the space required by such a motor is a serious disadvantage.

In reply to Mr. Cooper, who inquires as to the registering of motors on the gearcases, it is suggested that the advantages from doing this far outweigh the disadvantages mentioned. The motors can be secured by four or five bolts or set-pins and require no holding-down bolts, so that it is really more simple to remove the spigot-registered motor than the motor with a flexible coupling. It is submitted that it is not possible to make a base-plate to carry the motor independent of the gear which will withstand the strains imposed upon it by pressure from roof props or due to heaving pavement.

Theoretically the thermal type of overload protection most nearly conforms to electrical requirements, but in practice the mechanical limitations of the thermal strip and the necessary heating element result in construction much less robust and suitable to mining conditions than those usually associated with the best designs of solenoid trips with time-lags of the oil dashpot type. The most satisfactory form of overload protection so far used is the circuit breaker with the solenoid type of time-lag. With the high-torque motors now in use starting is so rapid that the time-lags do not need to be set nearly so high as heretofore. When outputs approaching 600 or 700 tons per shift are being brought to one loading point, sequence control of the conveyors is essential. With a properly sequence-controlled conveyor unit, the attendant at the junction of the conveyors has time to spare to fill coal and therefore be on the productive wage list. There are now many instances of sequence-control equipments of this kind which have functioned in a trouble-free manner over long periods. The added complication is not great and the economies are material. We agree with Mr. Cooper that it is thoroughly wrong to complicate either a conveying or a conveying-control system unless the savings resulting from such complications can be clearly defined.

Replying to Mr. Jenkins, we agree that special loaders or short lengths of shaker conveyors are not essential in

the operation of gate-belt conveyors. Nevertheless, it is at all times desirable, from the point of view of belt life, to load the belt in the direction of travel. In most cases nowadays, however, it is considered more expedient simply to load the belt direct from the face conveyors without any connecting link. The only other device known to us as a substitute for the double driving drum, where small-diameter driving drums are in use, is one in which the belt is held in contact with the driving drum by means of a spring-loaded roller. On a normal conveyor the duty of the belt is to carry the load and transmit the power necessary to transport the load. It may be in the future that the technique of belt manufacture will permit of the mangling stress set up by a roller of this kind without any destructive results, but belts as at present constructed are very liable to be damaged if rolled between two rollers as described.

We are aware that a large number of belt conveyors are working to-day on gradients as high as 20°, but as this is just a fraction beyond the normal angle of repose of coal on a conveyor belt 20° may be taken as the limit, and even at this angle success or failure may depend on the character of the material being conveyed.

We agree with Mr. Jenkins that, wherever possible, the belt conveyor is to be preferred to the chain flight scraper conveyor, but when the gradients become too steep it is necessary to use chain flight scraper conveyors with special flights to meet such conditions. We are aware of belt conveyors a considerable section of which is running under water, but this is an altogether undesirable case for belt service, because of the impaired belt life. Mr. Jackson mentions a device for avoiding belt slip, but as the belt gets cut and abraded each cut and abrasion is a point at which the water can get in to destroy the belt.

Figs. 5 and 6 were simply inserted to show the lay-out of the coal faces. The 240-yard conveyor illustrated was actually driven by a single engine over a period of months; back-balances and springs were used as counterweights for the pans on the inclination. It is our experience that in the old-established collieries using direct current the mechanics and electricians are in the main more sympathetic towards machinery underground. As to remote-control switchgear, it is common experience that new devices are in the first instance adopted only by the more progressive firms, but since the introduction of this method of control its use has steadily increased and is now increasing more rapidly as its advantages are realized. In no instance that we know of has remote control equipment, once installed, been replaced by other types. On the contrary, users have extended the use of this method of control. It is difficult to answer the question as to ratio of starting to running torque, because this necessarily varies considerably in different cases, but by the use of special high-torque motors it is possible to get a starting torque of $2\frac{1}{2}$ times the rated full-load torque of the motor. There is no reason why underground belts, in a gate-road especially, should not run for longer periods than one or two years without an involuntary stoppage, and they are doubtless the most reliable form of underground transport when properly designed and installed.

In reply to Mr. Burns, the enclosing of the lower belt has in practice proved a great advantage from the point of view of eliminating unexpected belt breakages. Does Mr. Burns seriously propose that an addition to the design, which minimizes the possibility of stoppage, should be left out because if a stoppage does occur, due to breakage, the addition of the appliance makes the repair a little more troublesome? The designs of underground machinery are actually developed, as he suggests that they should be, from a properly indexed record of complaints and difficulties experienced underground with the machinery. It is agreed, however, that the utmost simplicity possible, making allowance for the proper functioning of the machinery, is desirable before anything else.

Replying to Mr. Clephan, the reason why the troughed belt is preferred to the flat belt wherever it can be used is that without external aids the troughed belt has a carrying capacity 100 per cent greater than the flat belt. The usual practice in underground flat belts is to increase the capacity of the flat belt by using spillplates to enable the load to be piled up as it is in the troughed belt. This means that while conveying is being performed at full capacity the coal piled on the flat belt must of necessity rub along the spillplates. As the belt requires running clearance from the spillplates, spillage between the belt and spillplate when the belt is fully loaded is inevitable. If Mr. Clephan has found in practice that the difference in power required between troughed and flat belt is not very marked, it indicates that his belts are rarely running loaded to full capacity. Tests under duplicate conditions with both types of conveyor set up properly, and conveying each to the full capacity of the troughed belt, revealed that the flat belt requires 50 per cent more power under these circumstances, this power being expended in overcoming friction, which is destructive to the belt. Negligence in maintenance of a troughed belt in a gate-road can lead also to excessive power consumption. We recently had experience of a troughed belt which was using double its designed power for this reason. An hour's attention by the supervisor reduced the load to normal. Care in design and maintenance of belt conveyors, with a special view to the avoidance of friction losses, is always amply repaid in reduced belt maintenance charges. With regard to the maximum economic length over which coal can be conveyed, this depends very largely upon circumstances and environment, also on the amount of coal which has to be conveyed. It is not possible, therefore, to generalize on this subject, but one of the authors was assured on the occasion of his visit to the Frick Belt that under their special conditions they would have put in a belt 10 miles in length, and that their experience with the existing belt justified this decision from an economic standpoint in view of the very large daily output which they handle.

In reply to Mr. Mann, when remote control was first talked about it was received with a considerable amount of caution, but to describe the attitude as one of ridicule is to go far beyond the facts (see our reply to Mr. Jenkins). It is not suggested that remote control is the only alternative to switch fuses. The methods in the paper were given as examples from the simplest to the most advanced forms at present in use, and the mention of

the fact that plain switch and fuse are still in use does not imply any special liking for this method. (This replies also to one of Mr. Clothier's remarks.)

The unit method of control as contrasted with the multi-panel system has some advantages chiefly from the manufacturers' point of view, but the multi-panel system also has compensating advantages, and it is obvious that when dealing with 3-unit conveyors these advantages become paramount. The extended use of multi-panel equipments by collieries having experience with them shows that practical requirements of pit conditions do not necessitate the continual changing Mr. Mann imagines to be the case. The system of multi-control shown diagrammatically in Fig. 8 is merely an example of the latest tendency in matters of control. The general scheme is obviously capable of detailed variation, and Mr. Mann's detailed criticism is therefore rather off the point.

(*a* and *b*) It is obvious that isolating switches and also leakage protection can be introduced in each panel if the user desires it and is willing to pay for it.

(*c*) Of course, the master controller ties the three motors together; that is its purpose, and is necessary to give the fullest control and protection to a 3-unit conveyor of large capacity. Schemes comprising three conveyors and multi-panel control on the general lines indicated have been installed for some years, and have worked daily during that time, and the conveyors are still working together in the same group.

(*d*) Both experiment and actual experience in practice have shown that the switch cannot be manually operated to beat the magnetic relay. Far from being impracticable, numerous examples of the construction have been in successful operation for years.

(*e*) Leakage relays with fine setting can obviously be used instead of direct leakage trips, and without in any way altering the general scheme. Experience in mining conditions, however, soon shows that portable gate-end control gear is not the place for delicate relays, however suitable they may be for stationary equipment outbye, and a somewhat coarser direct trip of robust construction which remains in working order is to be preferred to a fine-set delicate relay apt to be frequently damaged.

Fig. 8 purports to be only a diagram of connections and does not show relatively unimportant details. The actual equipment does, however, provide the visual discrimination Mr. Mann asks for. Moreover, the leakage relay is not self-resetting, and the operator cannot reclose under fault conditions. Mr. Mann's assumption as to the probability of the interlock racing the contactor has been dealt with above.

We are not in agreement with the statement that the time will come when a mining conveyor manufacturer will find it unnecessary to use a special built-in motor, as the tendency appears to be increasingly in the direction of using built-in motors and dealing, therefore, with the motor and conveyor as one unit.

Mr. Mann also asks: "What do the authors mean by the word powerful?" (as applied to the motor). That is the real crux of the difficulty. The horse-power at which a motor is rated should, of course, depend upon its being able to give that power for a specified time without exceeding a specified temperature. The motor of given dimensions which could be rated at the highest horse-power under these conditions would be the most powerful motor. Unfortunately, the operator does not accept this definition, and in 3-phase work he talks of a motor being more powerful if he finds it more difficult to make it stall. He considers a d.c. motor more powerful if he is able to drive it harder and get more coal without making it spark, and it is largely the necessity for meeting such demands, in addition to keeping down temperature-rise under normal working conditions, which makes the design of coalcutter and conveyor motors unorthodox.

In reply to Capt. Walton-Brown, the scraper bucket type of conveyor has certainly a useful place in the conveying system used in this country, but is limited in its application so far to good floor conditions, and relatively small outputs per face unit.

The conveyor described by Mr. Clothier would appear to be limited in its application to seams producing small coal, such as coking coal, because if the size of lump were not controlled jamming and breakage would be prevalent as the flap passed over each pile of coal formed by the reciprocating movement. The drum-type switch with fuse is still in very common use in spite of all the well-known drawbacks recapitulated by Mr. Clothier, the reason being its great simplicity. It may, however, be pointed out that the fusible cut-out is not alone in the possibility of being tampered with; the protective devices of oil circuit-breakers can be rendered ineffective, and cases are known where the heating elements in thermal overloads have been short-circuited.

It is not, of course, necessary to employ remote-control gear in order to get improved protection in comparison to that obtained from the simple drum-type switch and fuse. There are, as indicated in the paper, any number of intermediate arrangements possible between these two extremes. We agree that the advantages of the oil circuit-breaker cannot be overlooked, but Mr. Clothier's remarks, particularly in his reference to short-circuit stresses, are really more applicable to distribution switchgear further outbye than to the actual control gear at the gate-end. The latter is designed primarily to control the conveyor motor and does not need to have the same rupturing capacity as the distribution gear behind it and on which it is entitled to depend in case of severe short-circuit. We share Mr. Clothier's satisfaction in the increasing popularity of the British Standard plug, and agree very completely with his concluding remarks.

In reply to Mr. Grover, the requirement of B.S.S. No. 270 relative to the terminal box being external to the flameproof enclosure is a very natural one and is merely another way of saying that the flameproof enclosure must be external to the terminal box; that is, flameproofness must not be dependent on the terminal box. The construction specified in B.S.S. No. 270 presents no difficulty and is incorporated in all motors purporting to meet the specification. In reply to Mr. Grover's question as to how compliance with B.S.S. No. 290 is achieved, we need do no more than suggest that there is no difficulty in designing and constructing enclosures to withstand very much higher stresses than

those specified in B.S.S. Nos. 126 and 127. Remote-control gear of the general type shown diagrammatically in Fig. 8 has been constructed with fabricated steel enclosures tested at the manufacturers' works at 150 lb. per sq. in. hydraulic pressure, and for flameproofness at the Mines Department's Testing Station at Buxton; also standard cast-iron enclosures similar to those employed for the simple drum-type switch and fuse mentioned in the paper have been tested hydraulically to destruction at a pressure of 200 lb. per sq. in.

Mr. Grover's remarks on leakage protection are interesting as being in effect a reply to Mr. Mann, and by comparison therewith fully bear out Mr. Clothier's concluding remarks concerning diversity of opinion.

The question of working to a British Standard specification is again raised by Mr. Bentley, and also Mr. Gogan. B.S.S. Nos. 168 and 270 deal with machines with Class A insulation only. If a higher heat-resisting insulation, for instance Class B, is used (which we take it is what Mr. Bentley means in his remarks), the temperature-rise can be fixed at a higher figure, but there is no British Standard specification dealing with this temperature-rise or with the ratings of the machine.

The performance of the motors as designed at present is on the whole so satisfactory that it is quite unnecessary to consider the introduction of any complication such as the Ward-Leonard or some similar system. Slipping clutches have often been tried, but their use is open to the objection that they are easily tampered with. As soon as the operator's output is restricted by the clutch slipping, he tightens it up and either the clutch does not slip, and is therefore useless for the purpose for which it was intended, or it goes on slipping at excessive overload and rapidly deteriorates. The length to which any safety device is liable to be tampered with in a colliery is well exemplified by Mr. Cooper's remarks.

Mr. Yuille's questions as to fluid transmission of power were very adequately answered in Mr. Sam Mavor's remarks.

Prof. Parker Smith and Dr. Say raise the question of drop of voltage. In some cases this is certainly fairly serious, but if a motor is designed with a sufficiently large normal starting torque it is found in practice that it can still function quite satisfactorily with very considerable drop in the line.

Mr. Bishop asks whether conveyor belts suffer from the rapid acceleration due to starting the motor by direct switching. The belts have not been found to suffer from this cause unless they are inadequate for the load. This is partly due to the fact that the belt speeds of conveyors are very low, generally only from 100 to 200 ft. per min., and also to the fact that considerable flywheel effect can be introduced in the gear-wheels, so that the jerk at starting is considerably reduced before reaching the belt.

COMMERCIAL COOKING BY ELECTRICITY.

By T. SETTLE, Ph.D., Member.

(*Paper first received* 13*th July*, 1931, *and in final form* 2*nd January*, 1932; *read before* THE INSTITUTION 18*th February*, *before the* SOUTH MIDLAND CENTRE 29*th February*, *and before the* SCOTTISH CENTRE 22*nd March*, 1932.)

SUMMARY.

The development and advantages of commercial cooking by electricity are set out in detail, and particulars are given of the types of apparatus used in this country and abroad.

Representative installations in establishments of different characters are described, and the effect of the commercial cooking load on central stations in various countries is discussed.

The term "commercial cooking" may be taken to apply to all cooking operations catering for a larger number of persons than is usually found in a domestic establishment.

The ground to be covered, therefore, includes complete electric kitchens, and also installations where special cooking operations are carried out on a commercial scale for the purpose of supplying certain specialities to a considerable number of customers, e.g. such installations as luncheon counters, grill rooms, and, particularly in this country, fried-fish shops.

For the correct working of any organization of a reasonable size the kitchen is essential. This condition applies to welfare installations such as hospitals, educational establishments, workhouses, prisons, and asylums; further, to factories and large business houses; and, finally, to pure catering establishments such as boarding houses, hotels, restaurants, and passenger ships. Quite recently, electric cooking has also been introduced on railway trains. Generally speaking, the above condition applies to all organizations where a large number of people have to be supplied with food once or more during the day. Obviously, kitchens of this type have to be equipped in the most modern way.

The use of electricity for kitchen equipment developed in the normal way. Lighting came first, motor-driven mechanical appliances next, and cooking last. It was difficult to persuade users that electric cooking was competitive, and the progress of commercial electric cooking was bound up with the reduction of rates for electric current. During the last few years very considerable advances have been made.

It would seem superfluous to-day to point out the advantages of electric cooking, but in order to give a complete review of the subject it may not be inappropriate to draw attention to certain well-known facts.

The principal advantages of the use of electricity for large cooking operations are cleanliness, speed, and economy.

The cleanliness of electric kitchen equipment is obvious, because there is no storage or moving of fuel and residue, no lighting of fires, no cleaning of grates and chimneys, no fumes or soot, and no evil-smelling gases or combustion products which may find their way into the atmosphere. This means that the rooms and apparatus remain perfectly clean, and the health of the kitchen staff is much improved, which can easily be confirmed by anyone running a large electric kitchen.

The speed of service is bound up with the nature of the electrical equipment. Whilst the heating-up and maintenance of boilers or coal fires take a considerable time, electrical equipment requires only the handling of a few switches in order to make everything ready for working.

One of the principal points of economy is that electric heat acts direct on the food materials, and nearly the whole of the electrical energy supplied is used for heating the food. Furthermore, all electrical apparatus is properly lagged, so that heat losses by radiation can be ignored. This means that the efficiency compares very favourably with that of fuel-fired apparatus.

With the latter, exact calculation of the quantity of fuel required for each process is impossible, but with electric heating it is fairly easy, because, as soon as a switch is turned off, the supply of heat ceases. At the same time the residual heat can be used to advantage.

With no other form of heating can regularity be so easily maintained. Once the correct degree of heat is obtained the supply is always constant, and it can be distributed uniformly over a large surface. The food is of regular quality, more tasty, and more easily digested.

It has been definitely established that, owing to reduced shrinkage, a saving of up to 10 per cent can be obtained when roasting meat. The reasons for the smaller shrinkage are principally the more easily adjustable temperature-control of the electric oven, the absence of any necessity for opening the oven door, and the steam-tight construction of the electric oven as compared with fuel ovens, which latter are designed to circulate the combustion gases about the food.

It has been proved in various countries that the saving when roasting meat in large establishments more than fully covers the cost of the electricity used. There is also a considerable saving in fat, because food can mostly be prepared in its own juices.

There is also, generally speaking, a saving in floor space when electrical apparatus is installed, there is a lower maintenance cost as compared with fuel- or even with gas-fired apparatus, and the fire risk is reduced to a minimum.

The selection of suitable apparatus depends entirely upon the purpose of the kitchen. The demands, for instance, for a works canteen are entirely different from those for an hotel or a large restaurant, but in every case the number of people to be catered for is the principal consideration.

In laying out electric kitchens certain advantages of electric cooking have to be borne in mind, such as the elimination of storage for fuel and ashes, and the elimination of brickwork, flues, chimneys, and other accessories necessary when coal or gas is being used.

The electrical installation has to be carefully designed. A main switchboard and distribution board are desirable, and all wiring must be easily accessible and laid in such a manner that flooding during cleansing operations is avoided.

For larger kitchens it is advisable to have a pilot-light indicator board, so that the supervisor can see at a glance which apparatus is in use.

The use of electric heating for heavy-duty or commercial cooking equipment is perhaps not so far advanced or general in Great Britain as it is in various parts of the Continent and the United States, yet, from inquiries made, it would appear that the question of heavy-duty installations was probably first tackled in Great Britain. The earliest record of such an installation is that of Messrs. Pimm Brothers in Dublin, who put in an equipment containing roasting-ovens, fish-fryers, vegetable-boilers, etc., in 1907 or 1908. This was to cater for their staff of 350–400 people, and was in constant use until 1929, when their staff ceased to live in. This is not a bad record for an early effort.

The earliest development on the Continent took place in Switzerland, very likely owing to the general use of water power for generating electricity. The early realization there that electric cooking on a large scale, with the possibility of cheap electric supply, offered so many advantages over other forms of heating, led to very rapid advances being made. The author believes that the earliest efforts were in connection with bread-baking, and general installations followed very quickly.

Developments in Germany came later, but very rapid progress has taken place during the last few years.

France is beginning to become interested, and other countries on the Continent will no doubt follow.

The author has no information with regard to Sweden and Norway, where water power is also available, but a few years ago inquiries made in Stockholm failed to provide any information with regard to large cooking installations.

After the early installation referred to above, progress in Great Britain was rather slow. About 1910–11, however, a start was made and some large installations were connected up, one of the first being Messrs. Debenham and Freebody's original equipment.

The introduction of nichrome wire in place of eureka and other older resistance wires greatly assisted the development of heavy cooking apparatus. As this wire was in general use in the United States some time before it was available over here, American manufacturers were able to make big strides forward, whilst we in this country were still struggling with the various types of black-heat resistance wires which were then available.

The Electrical Exhibition of 1911 helped matters forward, and some progress was made between that date and 1914. During the War, surprising as it may seem, quite a number of cooking equipments were connected up in munition factories, aerodromes, hospitals, etc. Real progress, however, as far as this country is concerned, only dates from 1920–21, and to-day heavy-duty electric cooking is everywhere a thoroughly established fact.

It is most noticeable that by far the larger proportion of heavy-duty cooking equipment is installed in works canteens, institutions, hospitals, and similar classes of premises. Several factors account for this. In this kind of establishment or, generally speaking, in public institutions, the decision as to the use of electricity is not left to the chef and kitchen staff, as is very often the case in restaurants and hotels. It is usually dealt with by the engineering staff and the management. Very often the supply of electricity is taken in bulk for power purposes, and a few thousand units more or less for cooking purposes would not affect materially the cost of the supply.

In most works canteens the cooks are women, who are not so much imbued with old-fashioned ideas as the average chef. Naturally, also, the nature of the meals to be prepared, which are far simpler and are not left so much to the discretion of the people who have to eat the food, has something to do with this more rapid development. It is obviously easier to prepare stereotyped meals for a canteen, school, hospital, or other similar institution, than to cater for the very varied demands and tastes which are met with even in small restaurants and hotels, and certainly in the larger establishments of this type.

As far as the attitude of the chefs and hotel or restaurant cooks is concerned, they are very reluctant to alter in the slightest degree their established ways of cooking. They want apparatus designed to suit their methods, and they are not prepared to alter their methods to suit more modern apparatus which may have to be used in a different way from that to which they have been accustomed, possibly for some generations in the same family. This attitude of the chefs is met with much more in England than on the Continent—with the exception of France—or in America. In Switzerland, Germany, and the United States, the cooking fraternity is much more open-minded and progressive, and this attitude has done much to assist in the general advance that has been made.

In developing electric cooking apparatus it has been necessary to scrap some old-fashioned ideas and put forward some altogether new designs, just in the same way as the steps forward from the old-time wood-fire to the coal-range, from the coal-range to the gas cooker, and thence to the present-day electric cooking appliances, each in their turn necessitated the scrapping of ideas held sacred by the cooks of the period.

Electric cooking equipment ought to be designed specially for electricity and should not be a fuel-fired or gas-fired appliance adapted to use electricity. It is quite true that to a large extent the development took place on these lines, but improvements in design have recently been made, and we can speak to-day of real heavy-duty electric cooking apparatus.

The principal feature which enabled designers to construct an entirely different type of apparatus is the entire absence of the products of combustion.

With properly-designed electric cooking equipment

much more can be done than has hitherto been possible, and the comparative ease with which electricity enables just the required amount of heat to be applied where and when it is wanted is impossible with other methods.

The kitchen staff must also be taken into consideration when laying out an electric kitchen.

In a works canteen kitchen, where usually one or two women cooks are employed, the type of complete range with boiling-plates mounted over the roasting-ovens may be used, because under such circumstances it is possible that one cook only will attend to the roasting of meats in the ovens as well as the receptacles for cooking on the hob. On the other hand, where a number of different cooks are employed who carry out various operations in the kitchen, differently constructed types of apparatus must be used, with separate roasting-ovens for special cooks to look after, whilst vegetable boiling, preparation of sauces, etc., are carried out under the control of the cook directly responsible for that class of work.

The use of electricity allows of the easy separation of apparatus in this way, and thereby results in far greater flexibility and efficiency in the working of the modern kitchen.

In selecting the necessary apparatus for large kitchen equipment, local circumstances have to be taken largely into consideration. Where, for instance, steam is available for manufacturing or other purposes, it would not be advisable to put forward appliances in which steam would have to be generated by electricity, such as steamers, soup-boilers, large vegetable-boilers, etc. All these appliances can be heated electrically and are giving satisfactory service, but the cost of generating steam electrically would probably exceed that of the available steam.

Types of Apparatus.

Generally speaking, the following types of apparatus are universally used, although the construction varies to some extent in different countries. There are, in addition, some appliances, referred to later on, which are peculiar to certain countries.

Roasting-ovens; cabinet roasting-ovens; complete ranges, comprising one, two, or more roasting-ovens with a hob-table carrying various numbers of boiling-plates (sometimes also a grill); boiling-tables; hot-cupboards (often fitted with carving-wells and covers); bains-marie (sometimes embodied in hot-cupboards); pastry-ovens; bread-baking ovens; fish-fryers; toasters and grills; steaming-ovens; stock-pots; soup-boilers; vegetable-boilers; urns; water-boilers; coffee-percolators; storage water-heaters.

The electrical equipment for all these appliances is composed of heating-elements, which may differ according to the type of apparatus, the necessary wiring, switches, and fuses. The two last-mentioned are sometimes mounted on the appliance itself, although the practice varies in different countries. Especially for larger appliances, separate control-boards are fitted carrying switches, fuses, pilot lamps, and other electrical accessories.

The author does not consider it to be within the scope of this paper to give details of the mechanical construction of the various apparatus, although some salient features may be referred to when the appliances are dealt with in detail.

For the internal wiring of practically all appliances, it is the practice in this country to use bare wires wherever possible. Beaded wires are fitted in some cases, but, generally speaking, the author does not recommend this practice. In America, special impregnated asbestos-covered wire is mostly used. It has to be borne in mind that, in the case of many of the appliances, wires have to be brought through lagging, and care has to be taken to avoid any chemical effect of the lagging material on the wiring material.

Roasting-Ovens.—These are made in various sizes. For smaller installations, and particularly where roasting-ovens form part of a complete range which carries also the necessary boiling equipment, the well-known normal type of roasting-ovens of various sizes can be used, either singly or in multiples.

The average electric loading depends on the cubic capacity, which would be in this country, for ovens of about 7 000–8 000 cubic inches, at the rate of 0·5-watt per cubic inch. It is found that as the capacity of the ovens increases, so, *pro rata*, the loading per cubic inch tends to decrease.

The position and type of the heating elements in roasting-ovens vary in different countries and with different manufacturers. No particular system appears to be preferred.

In Great Britain we have mostly side-mounted elements, but top and bottom elements are used by some manufacturers, and in some cases both side and top and side and bottom. Much can be said for both of these systems, but, generally speaking, side elements are found to be acceptable.

In Switzerland, Germany, and the United States, top and bottom elements are mostly in use, but this may be due to the fact that whilst in Great Britain the doors of roasting-ovens are mostly arranged for side opening, in the countries referred to drop-down doors are generally fitted.

The average loading of roasting-ovens in Germany is 0·7 to 0·5 and in America 0·6–0·4 watt per cubic inch.

The elements themselves are composed of nichrome spirals usually fitted on refractory panels, but in some cases mounted on porcelain insulators or cleats or wound on mica strips.

The lining of the ovens is worth mentioning, as black steel is sometimes used. Mostly, however, vitreous enamelled surfaces are preferred, and recently monel metal has come into use.

The oven elements are usually arranged for series-parallel 3-heat control. They must be properly protected from splashes by splash-guards. Connections must be arranged in such a way that the elements can be removed easily in case an exchange becomes necessary. Quite recently, both here and abroad, efforts have been made to use elements of the plug-in type, but plugs and sockets are likely to give trouble with heavy demand.

With regard to American ranges, it is to be noted that they are usually built up from single units, each comprising a roasting-oven, the necessary control equipment, and hob equipment.

Cabinet Roasting-Ovens.—These are usually installed in this country where larger roasting operations are carried out; they are simply roasting-ovens very much on the lines of the smaller ovens, but of much heavier construction.

On the Continent and in the United States, there are used for large roasting operations ovens which are more like the type of bread-baking ovens in use in this country and abroad.

Complete Ranges.—These consist of one or more roasting compartments and a hob carrying various numbers of boiling-plates and also, as far as this country is concerned, a grill, which varies in size according to the available space. These boiling-plates are one of the most important items in electric cooking; they are still the weak point of heavy-duty electric cooking equipment and the one which causes most trouble with the personnel of the kitchen.

The main duty of the engineer responsible for the design and construction of electric boiling equipment is to give at the same time rapid heating, high efficiency, and long life. It is sometimes very difficult to combine these three requirements.

The development of hot-plates for heavy-duty apparatus followed very much on the lines of the boiling-plates used for domestic purposes. A few years ago open-coil boiling-plates were used practically exclusively. They gave rapid heating and also good efficiency, but their life was dependent upon the avoidance of spilling, boiling-over, or similar mishaps.

At the present time the open-coil boiling-plate has gone out of use almost entirely, and enclosed hot-plates of various types are now the general practice.

The older types of hot-plates consisted of cast-iron tops fitted with elements of the clamp type. The possible loading of these hot-plates, particularly of the larger sizes, was severely limited. Now in practically all countries hot-plates of the embedded type are the general practice.

The expression "embedded type" defines a construction which consists of a cast-iron top provided on its under side with grooves containing the coils of resistance wire. These coils are embedded in refractory mixtures of various compositions, and the entire plate is then baked at a temperature which may vary according to the composition of the refractory. This practice applies to practically all British and Continental hot-plates, although hot-plates of other constructions are still in use.

Considerable attention is being given all over the world to improvements in the design of the heavy-duty hot-plate, and the author thinks that the next few years may see considerable changes.

Manufacturers in this country are continually pressed by users to reduce the heating-up time of hot-plates by increasing the number of watts per square inch, and in many cases the danger point has been passed in trying to meet the wishes of the consumers; with the result that hot-plates under heavy-duty use do not have a reasonable life. The author thinks that a reasonable loading is from 28 to 30 watts per square inch. He is not aware of any hot-plate of the modern embedded type in this country larger than 12 in. × 8 in., but bigger surfaces, of course, can be built up by using smaller units.

For restaurant cooking, a fairly large surface has to be maintained at a high temperature, and at the same time the hot-plate must have a long life in spite of the rather rough usage to which it may be subjected and the fact that it may often be left on at full heat for hours without any utensil standing on it. This, of course, must lead to premature breakdown.

Naturally, chefs would like to have as large a boiling-plate as possible in the available area, so that they can use pots and pans of all sizes and slide them about as they wish during cooking operations.

With rectangular plates it is a simple matter to build up large boiling-plates, but with large circular plates this cannot be done. At the same time it is known that pots and pans are usually circular, and if each pot could have its own boiling-plate the use of circular plates might be ideal.

A combination of square (or rectangular) and circular boiling-plates is very much favoured by certain chefs, but from a manufacturing point of view it must be realized that to cater for everybody's wishes and tastes increases the cost and, if insisted upon, makes electric cooking equipment non-competitive.

In the United States, hot-plates are so arranged that they practically cover the entire surface of the hob. The usual commercial units are 12 in. × 18 in., loaded to 4 or 5 kW, and 9 in. × 24 in., loaded to 4 kW. This means 19–23 watts per square inch.

The general practice in the United States is to use hot-plates containing elements of the "Calrod" type, which is a special construction evolved by the General Electric Co. of America. The coils of resistance wire are drawn into a metallic tube and embedded in magnesium oxide. These tubes are then heated and swaged, whereby the resistance wire is firmly embedded in the magnesium oxide. The tubes can then be bent into any suitable shape and cast into cast-iron tops forming hot-plates. It may be interesting to note that elements of this construction are also being used for ovens and other cooking equipment. Elements of this type have quite recently been manufactured in this country.

Circular hot-plates for heavy-duty apparatus are not used in the United States, but in Germany and Switzerland they are often employed either exclusively or in combination with rectangular and square plates. The following are the average sizes and loadings:—

Switzerland.

400-mm diameter, loaded to 4 kW, i.e. 20·5 watts per sq. in.

470 mm × 470 mm, loaded to 4 kW, i.e. 11·6 watts per sq. in.

Germany.

(1) 220-mm diameter, 1·5 kW, i.e. 25·5 watts per sq. in.

(2) 300-mm diameter, 2·5 kW, i.e. 22·7 watts per sq in.

(3) 400-mm diameter, 3·5 kW, i.e. 17·9 watts per sq. in.

The larger German hot-plates are:—

650 mm × 650 mm, loaded to 9 kW,
600 mm × 700 mm, loaded to 11 kW,

i.e. 13·8 and 16·9 watts per sq. in. respectively.

These latter, square or rectangular, plates are recommended for very heavy work.

The case referred to previously, where roasting and other cooking operations are carried out by different members of the kitchen staff, led to the design of boiling-tables.

Boiling-Tables.—These are practically the hob of a complete range, removed and put on a separate stand, except that a grill is never fitted.

Boiling-tables, as we know them here, are not used in other countries. In Switzerland, Germany, and the United States, if separate boiling equipment is installed it is usually combined with warming-cupboards or store cupboards. In America these appliances are marketed under the name of "cooking-tops."

In this country, however, if anything is combined with a warming-cupboard it is usually carving-wells with cover, and sometimes bains-marie. The latter are, in Germany and Switzerland, very often embodied in the cooking range.

There is no need to go into the details of warming-cupboards and bains-marie, as their construction, both mechanical and electrical, is simple and well known.

Pastry-Ovens.—These are very important apparatus in a large kitchen, and in most countries are on similar lines and of the same type and appearance. The loadings vary according to the type of establishment in which they are installed, and to a large extent any variations must be left to the individual ideas of the pastrycooks and to the practice in different establishments and countries.

The temperature at which pastry is baked is usually considerably higher than the ordinary roasting temperature of meat, and therefore the loading is usually about 0·7 watt per cubic inch.

Bread-Baking Ovens.—These also form an important part of the equipment of a large, up-to-date kitchen.

For use in conjunction with electric kitchens, baking-ovens of the Peel type are installed.

Fish-Fryers.—In Germany and Switzerland, where much less frying is done than in English-speaking countries, this operation is probably usually carried out in deep pans on boiling-plates.

In the United States and in this country, however, special apparatus has been designed for the purpose.

The British equipment usually consists of suitable pans heated from underneath, the elements being either attached to the pan itself, which interferes very much with removal and cleaning, or fitted entirely separate from the frying-pan, which is the more recent tendency. According to the size of the installation the necessary accessories, such as draining-racks, provision for emptying the fat, etc., have to be provided.

The loading for these fish-fryers is fairly high, because the cooling-down of the hot fat by the sudden immersion of the material to be fried has to be taken into account. In British fish-fryers the loading is usually 2·5–3 watts per cubic inch of pan.

In the United States special apparatus has been designed, which is marketed under the name "fry-kettles." They are of a very elaborate construction and are fitted with thermostatic control, and it is to be noted that the depth of all classes of the so-called "deep fat-fryers" is considerably greater in the U.S.A. than either here or on the Continent. This apparatus is used perhaps more for doughnuts than for the frying of fish and chips, doughnuts being almost a national food in the United States.

In this country, considerable advances have recently taken place in the design and supply of very large ornamental fish-frying ranges for installation in fried-fish shops. Particularly in Lancashire and Yorkshire this kind of apparatus is becoming popular, and the author does not know of any similar apparatus in any other country.

These fish-frying ranges are usually a combination of a number of fish-frying pans mounted on an ornamental stand, sometimes provided with pictures and mirrors on tiled grounds.

In many cases these ranges are not specially designed for electric heating, and the framework can be used equally well for gas or oil heating.

Grills.—The electric grill and also the gas-heated grill differ from the old-fashioned coke or charcoal grill because the source of heat has to be above and not below the meat to be grilled. This means a reversal of the usual practice, and in many cases chefs object to it.

Various efforts have been made, e.g. globar rods, to mount the heating elements below the meat and either protect them suitably or use material which would not be affected by fat dropping on it, but these efforts have not met with great success. There is not, however, any reason why, with proper handling, satisfactory results should not be obtained with the elements mounted above the food to be grilled; and all the large establishments which have made a practice of electric grilling produce chops and steaks of at least as good a quality as with coal or gas.

Some very large electric grills installed in this country have been fitted with hot-cupboards in addition to the usual grilling surface. Thanks to the use of electricity and the fact that the heating elements are mounted above the meat, all the fat dropping off can be collected in a fat drawer specially provided for that purpose at the bottom of the grill. The value of the fat thus collected amounts to a considerable sum, and the author knows that in one particular case it practically paid for the current used.

Grills are used in all countries. They are of very similar pattern and construction, except that the design of the elements varies. In some cases china-panel elements are used, in other cases coils are mounted on cleats.

In America, grills are called "broilers," and are extensively used in a great variety of establishments. The loadings are:—

England : 20–22 watts per sq. in. of grilling surface.
Germany: 20–22 watts per sq. in. of grilling surface.
U.S.A. : 18–20 watts per sq. in. of grilling surface.

Other appliances.—The author does not propose to go

into the details of steaming-ovens, stock-pots, soup-boilers, vegetable-boilers, urns, and water-boilers, as the construction and use of these appliances are very well known.

In Germany and Switzerland very large boilers arranged for tilting are installed. They are used principally for soup and vegetables, and can be tilted either by hand or, in the larger sizes, by worm gear. They are either equipped with direct side and bottom heat, or heated through a water or oil jacket.

Appliances peculiar to the United States are waffle-irons, griddle-plates, sandwich-toasters, egg-boilers, and the fry-kettles already mentioned. Such apparatus is used in very large numbers as pantry and counter equipment for quick-lunch bars, railway buffets, cafeterias, etc., where electrically cooked food of a limited variety is supplied for rapid consumption.

Quite recently, counter equipment, consisting particularly of sandwich-toasters, waffle-irons, and similar appliances, is being introduced into this country, principally by American firms, but, in view of the increasing demand, British-made articles of this type will soon be available.

An important accessory for any place where commercial cooking operations are carried out is a storage water-heater, which provides at any time water at 180° F. for cooking and washing-up operations. Incidentally, these water-heaters provide a very satisfactory load and diversity factor for central stations.

Marine Cooking Equipment.

An undisputed testimonial to the reliability of present-day heavy-duty electric cooking appliances can be found in their ever-increasing use in the galleys of ocean-going passenger boats, as well as on board the warships of the different navies of the world.

Ship's galley equipment has to be built on somewhat different lines from the usual shore apparatus. The rougher treatment which it has to withstand necessitates the use of heavier-gauge metals, etc., whilst the restricted space usually allowed for a ship's galley calls for a more compact design than is usual. First and last, however, robustness of construction throughout must always be the keynote of manufacture. For example, in connection with certain naval contracts for cooking equipment, one clause states that the apparatus must be capable of withstanding continually the shock of heavy gunfire, without any portion moving, becoming loose, or breaking. Each piece of equipment must be so constructed that any wearing parts, elements, switches, fuses, etc., can be instantly replaced.

On board ship as well as on shore, it is usual to employ, where possible, a certain amount of steam cooking, the necessary steam being supplied from the ship's own boilers.

Main galley ranges usually comprise ovens and boiling-plates, only the grillers being separate units. The oven doors are always of the drop-down pattern, with short, swinging legs which rest on the deck when the door is open, thus forming a platform on which tins of meat can be rested. These swinging legs must be of uneven length to allow for the camber of the deck.

The range hob-tables are fitted with fiddle bars, so that saucepans, etc., will not slide off in rough weather. A protecting hand-rail is also fitted round the edge of the hob-table to prevent the cooks from coming into contact with the heated top.

Similarly, hot-presses (hot-cupboards) with carving-table tops are also fitted with protecting rails, while any covers over carving-wells must be so fitted that when in the raised position they do not swing about with the motion of the ship.

In the hot-cupboards, all plates which are being warmed are housed in suitable plate-creels to prevent them from sliding about and getting broken or chipped.

Urns and water-boilers are fitted inside with splash-baffles, and every precaution has to be taken to make everything perfectly safe and satisfactory in use.

Electric Cooking on Railway Trains.

It may be of interest to refer to electric cooking installations on railway trains, of which a number have been put in use in this country during the last few years.

The advantages of cooking by electricity in a railway train are obvious. The principal one is that the kitchen staff are able to do their work in a cool and pure atmosphere.

The electric cooking equipment on a railway train is usually placed in a separate kitchen car. In the kitchen proper, all the cooking equipment is mounted at one end, which leaves the remaining space for ordinary kitchen work, the food being passed out through serving windows into the corridor.

The equipment usually consists of a cooking-range, which is a composite unit embodying a roasting-oven, with a steaming-oven, a grill, and a hot-water tank mounted above, and a boiling-range with hot-plates for frying, boiling, etc., and a vegetable-boiler of comparatively large capacity. A hot-cupboard is also fitted for heating the plates and dishes required for the service. Arrangements are made for an adequate supply of hot water for cooking and washing-up.

The electrical energy for operating the cooking apparatus while the train is under way is provided by dynamos carried on the under frame of the kitchen car, supplemented by a battery of accumulators to enable cooking operations to be continuous during intermediate stops.

The dynamos are each of 7·2- to 10-kW capacity, with self-contained automatic pole-changers, and they are belt-driven from the axle of the carriage. The machines are connected to the battery and cooking equipment by automatic switchgear, which functions as soon as the dynamos are running at the proper speed, and is disconnected when this speed is not maintained. The usual safety devices are installed for protecting the battery.

Each cell contains from 15 to 19 plates fitted in ebonite boxes with sealed-down lids. The battery usually comprises 90 cells, three cells in a crate, and they are arranged in two boxes on the under frame.

The wiring is carried in enamelled, screwed conduits, which are earthed, as also are the frames or casings of the cooking apparatus.

Representative Installations.

It may be of interest to give some details of actual equipment installed, with particulars of the class of work done.

Restaurant.—In one large public restaurant in London, where the catering is on good-class lines, the equipment was designed to provide about 5 000 meals per day. Such meals would mostly be *à la carte*, with a fair amount of grilling work. The equipment includes:—

One cabinet roaster (51 480 cub. in.).
One 4-oven island range (12 960 cub. in. per oven).
Four grillers (each 864 sq. in. of grill surface).
Five boiling-tables (7 000 sq. in. of plate surface).
Three steaming-ovens (each 17 280 cub. in.).
Four plain hot-cupboards (each 6 ft. × 3 ft. × 2 ft. 9 in.).
One hot-cupboard and carving-table (16 ft. long).
One hot-cupboard and carving-table (12 ft. long).
Two 20-gallon stock-pots.
Three separate bains-marie.
One fish-frying outfit.
Two 2-deck pastry-ovens.
Three half-sack baking-ovens.

The total load connected is over 450 kW.

The initial cost of this equipment was approximately £2 300. The maintenance cost amounts to approximately 2½ per cent per annum. The approximate annual consumption is 365 000 units, or 1 000 units per day.

The number of meals per day varies from 100 lunches and 300 teas up to 5 000 lunches and 12 000 teas, besides various banquets during the year. In one week last year 40 000 lunches and 65 000 teas were supplied.

West End institution.—In the kitchen of a large West End institution, where the equipment was designed to cater for about 2 000 people per day on somewhat simpler lines than the installation just described, the appliances include:—

One cabinet roasting-oven.
One bank of three roasting-ovens.
One 2-deck pastry-oven.
One 3-pan fish-fryer.
One large island-type boiling-table.
Three hot-cupboards and carving-tables.
Two bains-marie.
One double-compartment griller.
Two steaming-ovens.
Four boiling-pans, for vegetables, etc.

And in the tea-room servery there are:—

Two toasters.
Three milk urns.
Three sets of water-boilers for tea-making.
One large coffee-percolator.
One set of egg-poachers, etc.

The total load is 230 kW.

The initial cost of this installation was approximately £1 200, and the maintenance cost is slightly more than 1 per cent per annum.

1 000 meals per day, in addition to 4 000 mixed pastries, are supplied. The approximate current consumption is 138 000 units per annum, which is equivalent to approximately ½ unit per meal.

Hospital.—In a hospital in the West of England, where 120 patients are catered for daily, the electric cooking equipment includes the following:—

Main kitchen:—
One 4-oven range.
One griller-toaster.
One boiling-table.
One fish-frying outfit.
One water-boiler.

Ward kitchens:—
One small range in each.
One water-boiler.
One hot-cupboard.

This represents a total load of 120 kW.

Factory.—In the kitchen of a very large factory in the Midlands the electric cooking equipment supplies, on an average, 6 000 meals per day between 1 p.m. and 2 p.m. The equipment includes the following appliances:—

Two large roasting-ovens, cabinet type.
Two medium roasting-ovens, cabinet type.
Three small roasting-ovens, cabinet type.
Two large fish-fryers.
Two double grillers.
One small range.

This represents a total load of over 100 kW.

The roasting-ovens will cook over 1 000 lb. of roast meat, as well as other food which can be accommodated in them, while the fish-fryers produce 120 lb. of cooked fish and 100 lb. of chipped potatoes per hour.

In this installation it will be noticed that no mention is made of steaming-ovens and similar apparatus. The reason is that a plentiful supply of steam is available from the factory boiler-house, and this steam is used to carry out all cooking work which can conveniently be done by it—a very advantageous arrangement, to which attention has previously been drawn.*

American installation.—The following are the particulars of a large American installation in Chicago, with 250 kW of connected load:—

Two 12-kW, 3-deck pastry-ovens.
One proving-cupboard, automatically controlled.
One twin hot-plate.
Two electric cooking-tops.
One electric range with ovens.
Three 4-kW frying-kettles.
Two 10-kW broilers.
Two 40-gall. stock-pots.
Two 12-kW vegetable-steamers.
Three 6-gall. coffee urns.
One 10-kW double-deck roasting-oven.
One automatic toaster.
One 3-kW griddle.
One electric roll-warmer.
One 2-section waffle-baker.
One 6-kW steam-boiler.

* The average current consumption is 1 000 units per week for 25 600 meals served. Maintenance expenditure is negligible.

One egg-boiler.
Two bain-marie pans.
Four plate and food warmers.
Two special coffee-cup warmers.
One electric batch-warmer for sweets.

The average monthly consumption of this kitchen is 28 000 units, with a maximum demand of 145 kW. The large number of small appliances is to be noted.

German installation.—One of the largest kitchens in Germany, which has a total connected load of 545 kW, is equipped as follows:—

Two large cooking-ranges, fitted with 16 round hot-plates, 4 square hot-plates, and 6 roasting-ovens.
Two boiling-tables, each fitted with 8 round hot-plates, also a hot-cupboard and bain-marie.
One range fitted with 4 round boiling-plates, 2 square boiling-plates and 2 ovens.
Three boiling-tables with bain-marie.

In addition to these there are a large number of tilting boilers, referred to previously, the biggest one with a capacity of 400 litres.

The total load is 160 kW.

There are in addition:—

Two warming-tables.
Seven hot-cupboards.
Two grills.
Three storage water-heaters, each with a capacity of 2 000 litres.

Energy Consumption.

It may perhaps be interesting to give some details of the energy consumption of different types of premises using electricity for cooking:—

(1) A West End drapery establishment using electricity and steam from main boilers and supplying approximately 2 000 good-class luncheons and 2 000 teas per day, 5 days per week, i.e. approximately 500 000 of each meal per year:—
Connected load, 244 kW.
Units used, 146 000 per annum.

(2) A West End institution supplying 600 lunches and 1 200 teas daily, 5 days per week. All-electric (40 weeks per annum):—
Connected load, 100 kW.
Units used, 112 500 per annum.

(3) A West End educational establishment supplying 120 lunches and 350 teas daily. All-electric, but closed for 3 months of the year:—
Connected load, 131 kW.
Units used, 39 761 per annum.

(4) A hospital catering fully for 800 people daily. Equipment partly steam. Three meals per day are given, and all bread is baked electrically:—
Connected load, 150 kW.
Units used, 124 800 per annum.

It will be seen that the current consumption per head per meal for the above four cases is as follows:—

(1) 0·143 unit.
(2) 0·312 unit.
(3) 0·424 unit.
(4) 0·143 unit.

Therefore, where steam is used for certain work, electric cooking for the remainder can be carried out at 0·143 unit per head per meal, and where the installation is all-electric the consumption would be from 0·312 to 0·424 unit per head per meal, according to the class of meal supplied and also the quantity.

The cost of maintenance is an important consideration. It may be divided into two sections: (*a*) mechanical, and (*b*) electrical.

As far as mechanical maintenance is concerned, this will very much depend upon the treatment of the equipment by the kitchen staff. The electrical maintenance may consist of renewals of boiling-plates, elements, switches, etc. The replacement of electrical material depends very much upon the nature of the establishment, and for equipments installed in canteens, hospitals, etc., where set meals and hours are maintained the maintenance costs are very low, averaging between 1 and 1½ per cent of the cost of the equipment per annum.

For equipments installed in busy restaurant kitchens where the appliances are more or less in use for very long hours, the maintenance costs are higher, and may vary from 3 to 5 per cent of the cost of the equipment per annum. Hot-plates left on at full heat all day and doing little work may require fairly frequent replacement. This, however, can be reduced to a minimum if the kitchen staff is properly instructed and uses to the best possible advantage the 3-heat control provided.

Voltage fluctuation may have a certain influence on cost of maintenance. The author has not, however, been able to trace any definite trouble due to this cause. It is obvious that if the voltage rises abnormally the life of heating-elements will be reduced. Generally speaking, however, the elements and boiling-plates for commercial cooking equipment allow for ample margin. If failures occur, it is, of course, very difficult to trace them to a possible voltage-surge.

Bread-Baking.

It may not be out of place to refer briefly to electric baking, because in larger commercial cooking installations it is not unusual for all the bread, rolls, and confectionery to be produced either in the kitchen or in a separate baking establishment.

Since Mr. Ellerd Styles read his paper in 1928,* electric baking has developed very rapidly, not only in this country, but all over the Continent and also in the United States. Quite a number of all-electric bakeries have been installed, and the results are entirely satisfactory to bakers and consumers.

The effect of electric baking on the atmosphere in the bakery, and particularly on the health of the personnel, has become very marked, and it is a well-established

* *Journal I.E.E.*, 1928, vol. 66, p. 569.

fact that bakers who have been accustomed to working in an electric bakery will not agree to work fuel- or gas-fired ovens.

Rates for electric current available for baking have been very much reduced, and there is no doubt that progress in this direction will continue.

Attempts have been made to abolish night baking, but without results. Varying conditions exist in different districts, and the time of starting work is governed by the size of bakery and the output. Laws enforcing a specified time would cause many small bakeries to close and larger ones to double their plant and increase their accommodation for such plant. In crowded areas this would be impossible in most cases. It would probably necessitate moving to an entirely new area, at great expense and inconvenience. Opposition has therefore been met from the large and the small baker alike.

Incidentally, the author would like to point out that if the prohibition of night baking became a fact the electric baking-oven would have a great advantage over any other form. It would be quite an easy matter, by a time switch, to have the electric oven switched on before the workpeople arrived, so that they would find the oven ready and hot when it was time to begin their work. It is true that the question of the preparation of dough has to be considered, but, no doubt, arrangements would be made in that case to prepare the goods in proper time.

The author would like to draw attention to a recent occurrence which throws some light on the existing out-of-date legislation. A year or so ago it was decided to install a baking-oven in a certain district in the London County Council area. The local surveyor insisted that the oven should be mounted on a concrete base 6 in. thick extending 18 in. all round the oven. He produced his authority, and sure enough the bye-law framed over 30 years ago stated that such provision must be made for all ovens except gas-fired ones. Pressure was brought to bear on the authorities concerned, and now the bye-law also excepts electric stoves. As the bye-law naturally covered domestic cookers and commercial cooking equipment, very many supply authorities had been transgressing for a large number of years.

Supply Authorities and Commercial Cooking on a Large Scale.

The development of electric cooking on a large scale is absolutely dependent upon the supply of current at a reasonable rate. Opinions differ as to what is a reasonable rate, but it has been found in practice that commercial cooking becomes a possibility when current can be supplied at 1d. per unit or less.

The comparison of the cost of electric current with the cost of fuel is apt to be misleading, because all the savings in installation and the advantages of cleanliness and hygiene have also to be taken into consideration.

Where gas, however, is being considered, it may be assumed that with gas at 8d. per therm, electricity at 1d. per unit offers the usual advantages as compared with gas. If the price of gas is higher or that of electricity falls below 1d. per unit, the advantages are decidedly on the side of electricity in every respect.

The effect of a heavy cooking load on supply stations varies, of course, according to the nature of the demand. Nowadays, supply stations are very often prepared to give special rates, either on account of the large normal demand or because the maximum demand may coincide with the day valley of the load curves.

As far as canteens are concerned, where a definite meal is supplied at a fixed hour for a fixed number of people, one may assume that the maximum load coincides with the day valley, and a very reasonable rate ought to be quoted.

For hospitals and similar institutions a second meal has to be considered, but again the hours are regular and provision can be made accordingly by the supply authorities.

The actual catering trade, however, is in a different position, and the maximum demand and the diversity factor must vary according to the nature of the establishment. There must be a difference between small boarding-houses, simple restaurants, and large luxury hotels.

The load varies considerably in the larger establishments and it may therefore become necessary to give them a high-tension supply from a transformer station, if electric cooking becomes generally acceptable for establishments of this kind.

In building up the heavy cooking load, it would be of great assistance to consumers and manufacturers if a perfectly clear-cut system of charging for current were available. The author recently came across a system of charging for current which varied with the price of coal, plus a sliding charge per kilowatt of demand, plus a sliding charge for the number of units consumed. The local gas company only charged 7d. per therm for gas. It is obvious that a complicated method of charging must have a deterrent effect on prospective users of large cooking equipment.

In this country some supply authorities have been very helpful towards the development of commercial cooking by letting on hire to their consumers even large installations, and by undertaking the maintenance. Such an arrangement inspires the consumer with great confidence, and it is to be hoped that this policy will gain further ground.

The author is in a position to give some interesting particulars of German and American practice.

In Germany there are at present about 250 large electric kitchens. The annual consumption of each varies between 50 000 and 500 000 units, and it is interesting to note that even the smaller canteens and restaurants have very important consumptions of electricity. For instance, the canteen of a factory employing 350 men consumes annually for its kitchen between 40 000 and 50 000 units.

A restaurant with about 150 seats shows a consumption of 100 000 units, whilst large restaurants and hotels will reach 300 000 units and more.

The maximum demand of an electric kitchen will vary with the habits of each particular country. In Germany a simple canteen equipment will show a maximum load about two hours before the meal hour. In hospitals the morning load is usually heavier than the evening load. In Germany, where it is usual to have

late suppers, the evening load for restaurants and hotels often comes several hours after the peak of the evening load of the supply station.

It has been found that the consumption in Germany is as follows:—

Number of persons	Approximate units required per head per day		
	Canteens	Hospitals	Hotels
25	1·2	1·5	2·5
50	1·1	1·4	2·3
100	1·0	1·3	2·1
150	0·9	1·2	2·0
200	0·8	1·2	2·0
300	0·8	1·2	2·0
400	0·8	1·2	2·0
500	0·8	1·2	2·0

In the United States the energy consumption in hospitals and small restaurants will average 0·2 to 0·5 unit per meal. In a European hotel the average will be 0·3 to 0·75.

In the Commercial Cooking and Baking Sales Manual issued by the National Electric Light Association of the United States, some interesting data are given illustrating the importance of the heavy cooking load to supply authorities. For an hotel with 100 rooms serving an average of 9 907 meals per month, the average revenue was $6 893.53 per month, with a total cost of $57.56 for electric current for cooking and baking.

In a 400-room hotel, the net annual cost of electricity for electric cooking was $4 147.47. The average consumption per meal was 0·71 unit.

Later information from the United States is given in an article in the *Electrical World* of the 23rd May, 1931. It is stated that a survey of 24 representative electric supply companies showed that during 1930 they added 32 000 000 units from commercial cooking and baking equipment. This represents an increase of more than $700 000 in annual revenue. Whilst, in 1925, 15 representative companies had an average of less than 1 000 kW of connected load for commercial cooking, at the end of 1930 the same companies had a total of more than 50 000 kW connected, using an average of more than 1 800 units per year per kilowatt.

The power companies in the United States realize the importance of the market for commercial equipment, and they have rapidly learned to appreciate what rates are necessary in order to sell equipment and current on a sound basis.

The general opinion of American supply companies is that the load due to heavy cooking is worth having, for the following reasons:—

(1) One can expect about 1 kW of potential commercial cooking and baking load for each resident customer.
(2) The load has very favourable characteristics, and can represent 1 500 to 2 000 units per year for each kilowatt connected.
(3) It possesses an advertising value for domestic cooking.

There is no doubt that owing to the clear understanding of the potentialities of the heavy cooking load in the United States, progress during the last few years has been extremely rapid. Most of the larger supply authorities have in their employ special engineers whose sole duty it is to push commercial cooking.

In Germany, progress during the last few years has also been rapid.

In this country, however, the advance has not been so rapid as might be desirable from not only the manufacturer's, but also the supply engineer's and consumer's points of view. There are certain supply authorities who have cultivated this load and are very satisfied with the results. There are others where complicated methods of charging, such as that already mentioned, interfere seriously with progress. There seems to be a little doubt in the minds of some central station engineers as to the desirability of the load, but in every district there can be found establishments with characteristics which will allow the supply authority to obtain a load during its load-curve "valleys" and at the same time not materially increase the "peaks."

Only by the co-operation of all the interested parties can success be achieved, and if this paper can maintain and increase the interest in this kind of load, the author will be glad to have been of assistance.

In conclusion, he desires to express his thanks to his assistant, Mr. R. Hill, for help in preparing the paper, and also to the following firms who supplied information:—Jackson Electric Stove Co., Ltd., J. Stone and Co., Ltd., Westinghouse Electric International Co., Commonwealth Edison Co., Benham and Sons, Ltd.

Discussion before The Institution, 18th February, 1932.

Mr. R. S. Downe: It was 20 years ago that the supply company with which I am associated began to take an active interest in the development of cooking by electricity. At that time the electric cooking equipment available was so unsuitable that we took what was for a supply company the somewhat advanced step of trying to make such equipment ourselves. We were not exactly manufacturers, but we assembled domestic and commercial cooking equipment. In order to widen our experience we decided to open a restaurant, and to build the necessary cooking equipment for it ourselves. The restaurant was run successfully from 1913 to 1926, and in that period supplied about 740 000 meals. The annual consumption was about a quarter of a million units. As a result of that experience we were able to supply a number of equipments to large institutions in this country and abroad. Some of these installations are working to-day. Amongst the multifarious uses of

electricity at the present time, heavy commercial cooking must take a very high place. It constitutes a very desirable load, in view of the fact that it is on for 7 days each week throughout the year. In connection with new buildings, there are large numbers of hotels, boarding-houses, clubs, etc., in our areas where electric cooking is not being adopted, probably (as the author suggests) because of the difficulty of overcoming the objection of the chefs. Hotel and restaurant chefs are artists who have been accustomed to producing results with certain tools, and they do not like to jeopardize those results by using tools to which they are not accustomed. It seems that we shall have to have properly trained assistants to deal with this branch of the business, and we must insist upon having standardized equipment which we can let out on hire in units. As regards the cost of energy, a ½d. per unit unrestricted cooking rate is offered by one London company, while for other companies the figure is ¾d., so that there does not appear to be any difficulty on that score.

Mr. V. C. Hardy: I recently installed an electric kitchen in the Dorchester Hotel and it has proved to be a great success. The chief difficulty encountered was that of educating the people who were going to use the kitchen, and I found that this could be done only by patience and time. I think that chefs condemn electric cooking because they believe it to be unreliable. A similar difficulty occurred when chefs were converted from coal to gas, but it was eventually overcome, and I have no doubt that the use of electricity will spread much more quickly than did the use of gas. Electricity is very desirable as a heating medium, because it is the nearest approach to coal so far as heating effect is concerned. It is useful to impress this point on chefs, who as a rule have been trained to use coal-fired cooking apparatus. This similarity between the heating effects of coal and electricity has been confirmed at the Dorchester Hotel kitchen. So far as speed is concerned, in high-class *à la carte* cookery the speed at which certain dishes have to be cooked cannot be varied, no matter whether coal, gas, or electricity is used. The great advantage of electricity for cooking these dishes is that it enables one to obtain the exact temperature required for the kind of food one is going to cook. Electricity gives better results because it is more scientific than rule-of-thumb methods. On the subject of educating the staff, it is very difficult to get them to accept the change to electric cooking stoves, because to change the methods employed in big kitchens staffed by about 80 chefs is like altering the whole system in a works. It is difficult to dogmatize about the lay-out of kitchens, because each one is designed to suit a special purpose. A kitchen such as that to which I am referring has probably to be much larger than one which caters for three or four times the number of people, all of whom are served with the same dishes at the same time. In a high-class hotel most of the dishes are cooked specially for each customer, so that a large amount of small cooking apparatus is necessary. Special large-size apparatus is also kept for catering for banquets. We have applied electricity to the announcing of orders. Formerly a kitchen clerk was employed who created a great amount of noise by shouting out the names of the dishes required, whereupon every member of the cooking staff concerned in a particular order shouted his assent. We have eliminated all this noise by installing microphones and loud-speakers in the various departments of the kitchen. So far as the type of apparatus is concerned, solidity is the most important point. The average Continental kitchen staff will break anything which is not very solidly constructed. In this connection, if the switches on cooking ranges are placed near to the top of the ovens (as shown in one of the author's slides) they are quickly broken off. They should be placed within easy reach but well away from the range, preferably overhead. Indicating lamps are useful to show whether the ovens are one-quarter, half, or full on. If only one lamp is fitted it is difficult to tell whether an oven is one-quarter or half on, and we therefore provide commutator switches and a bull's-eye arrangement giving one, two, or three lights with one lamp. We employ gas boiling-apparatus throughout, because we found that electrical boiling was too slow and the equipment apt to become damaged through water boiling over on to it. We use a lot of steam for vegetable cooking and big boiling-pans. The ordinary technical wiring difficulties have been overcome. Nickel-chromium strips are necessary instead of copper near the ranges, because of the heat. The loadings which we employ we have arrived at ourselves by experiment. When we first introduced electric ovens the chefs were apt to complain that these were insufficiently hot, but this was only because the ovens had not been switched on long enough. However, we greatly increased the loading, so as to reduce the time necessary for heating up. In the last few months we have gradually reduced the loading again without their knowing! In a big kitchen serving a restaurant where orders are given suddenly, the ovens must be at the correct temperature for cooking what is wanted right away, whether gas or electricity is used. The kitchen porters turn on the electric ovens at a certain time every day, and when they were very much overloaded they often attained too high a temperature and orders were ruined. This overloading was employed in the first instance to show the chefs what could be done, and it worked very well; but we have saved a lot of money lately by reducing the loading of the 8-kW ovens to 5 kW. We have found electric baking to be very successful. All our apparatus is British-made. We have a small oven from which we obtain the large output of from 2 000 to 3 000 rolls per day, in addition to all the usual bread. The baker has so far had no trouble with the electrical equipment. At the price at which we purchase energy, the overall running cost of the kitchen is very low. With regard to the type of apparatus, I think most chefs favour drop-down doors, which can be kicked shut with the foot. Some of the equipment shown in the author's slides was rather highly loaded, probably because rapid cooking was essential. We find that 5 kW is quite enough for an ordinary oven of medium size. Electricity is used throughout our kitchens for washing-up, ventilation, etc., in addition to cooking.

Mr. W. Ellerd-Styles: I think that a better title for the paper would have been "Heavy-Duty Cooking by Electricity." I prefer to use the word "commercial" in the sense of a "commercial proposition," rather than

to apply it to any distinct section of electric cooking. As regards the paper itself, it is stated on page 171 that "all electrical apparatus is properly lagged"; can the author give us any figures of the amount of lagging employed? Dealing with the question of shrinkage, I think he is a little conservative in his estimate of 10 per cent. My experience shows that whereas with electricity the average loss due to shrinkage is 11 per cent, with gas and coal it is 31 and 29 per cent respectively. These figures were obtained from tests with joints of beef and mutton. Turning to the question of the cost of energy, I am informed by a friend in Sweden that Stockholm has a very low cooking tariff of 0·6d. per unit from 11 to 2 p.m., and 1·2d. per unit from 2 to 11 p.m. In the provinces, however, the rate is from 0·9d. to 1·8d. per unit, which is considered to be very expensive. While the use of domestic electric cookers is on the increase, the chief obstacle in the way of development is the cost of electricity. Although this seems strange in view of the fact that a good supply of water power is available, we must bear in mind that in Sweden and other parts of Europe the bakers are accustomed to use ovens which can be heated satisfactorily by means of wood. The design of electric cooking equipment has been largely based on gas-cooker practice. There is no originality in electric cooking. For instance, the old-fashioned hinged type of door is used on electric cookers because it was originally embodied in the gas cooker. The large electric baking oven used exclusively for bread has elements placed in tubes, and these tubes are fitted inside just as in the case of the steam-pipe oven. Although this is orthodox practice, it is nevertheless wrong. For purposes of comparison let us consider three ovens of the same size (4 ft. × 4 ft.), the loading of the first being 10 kW, of the second 8 kW, and of the third 6·9 kW. These ovens will all attain the baking temperature in approximately the same time, and they also take the same time to bake a loaf of bread. The commercial user of baking ovens is solely concerned with the question of cost, and will therefore choose the 6·9-kW oven, which has the smallest consumption of the three. This shows that the loading of an electric oven is an important factor from the point of view of sales. I should be glad if the author would give further information regarding the tubular type of element, which is not placed in close contact with the material to be baked. We badly need some information as to the correct design for electrical equipment, and it seems to me that this question should have been dealt with in the paper. I should also like to know why the use of beads for insulation is not recommended. Turning to the problem of side elements versus top and bottom elements, I am in favour of bottom heat as well as side heat, and, if possible, both top and bottom heat. In connection with the design of hot-plates, would it not be advisable to break away from the orthodox and adopt something after the pattern of Prof. Parker Smith's table-pattern apparatus with plug-in utensils? Hot-plates for scones and similar commodities, of which large numbers are employed in the North of England and in Scotland, are not referred to in the paper. I should be glad of some particulars as to the loading of representative English installations. [Mr. Ellerd-Styles here exhibited some lantern slides showing representative German electric cooking equipments.] In this design of cooking range provision is made for coal heating in the event of a breakdown. All these German ranges have a guard rail round them, a very good practice not generally adopted in this country except for marine work, where it is used on account of the rolling of the ship. I do not advocate a tariff of 1d. per unit for electric baking; it makes a great difference if the price is reduced from 1d. to ¾d. or ½d. per unit. At ½d. per unit electric baking becomes a commercial proposition; at ¾d. per unit the increase in baking cost is 50 per cent, and under certain conditions I recommend electric baking and cooking at this rate, but I always advise consumers not to accept a rate above ¾d. per unit. I do not agree with the author when he states that the abolition of night baking would render electric baking advantageous in comparison with fuel-fired ovens, unless he confines this remark to brick-built thermal-storage ovens. With steel-cased ovens no advantage is secured, seeing that at least 2 hours are required in which to prepare the dough for the oven. Tests on a brick-built steam-pipe fuel-fired oven show that after 12 hours' idleness the oven temperature still remains at 400° F., and without forcing the firing it is possible to raise the temperature again to the 500° F. level required in from 55 to 60 minutes. It would be difficult for the electric oven to improve upon this. Although the author stated in 1928 that he was not in favour of thermostatic control on ovens, the following incident justifies my opinion that such control is desirable. During the Christmas holiday period a member of the staff was instructed to attend and switch on an oven so as to avoid the excessive cooling-off during 4 days' shut-down. The oven in question was fitted with a bank of pilot lights. The individual concerned inadvertently left the building without opening the switches, and 24 hours afterwards the oven had become so overheated as to cause the crown of the baking chambers to sag and touch the oven poles. It was not possible to determine the maximum temperature reached by the oven, but the glass in the light boxes ultimately resembled candle grease. The oven was ruined, the result being a loss of more than £500. Similar trouble occurred in an instance where a time-switch was fitted. Neglect to wind the clock resulted in the oven becoming overheated during a week-end, with much resultant damage. The fitting of a thermostat to limit temperature-rise would prevent such happenings. In conclusion, I should like to state that electric baking is making progress in Italy, a recent installation being an electric brick-built oven in the Vatican at Rome.

Major R. Tandy: I am sorry that the author has not said anything about the mechanical construction of the apparatus, which I consider to be very important from the maintenance point of view and also from that of first cost. The maintenance costs which he gives seem to be rather on the low side, unless they apply only to the heating elements. He does not mention switchgear, which I regard as very important. I should like some information regarding suitable types of boiling-pans for use on hot-plates. Have pans a longer life when used with electricity than when used with gas? I find that some pans take at least 25 per cent longer to boil than

others; this may, of course, be due to bad contact. In one large hotel in the North with gas cooking the maintenance of pans costs over £500 per annum, and if part of this maintenance could be saved by the use of electric hot-plates electric cooking at this hotel might become a commercial proposition. The cost per meal is, I consider, an unsatisfactory basis for comparison; a better one would be units per cost of meal, unless it were stated of what the average meal consists. The installation at Euston Station (rating approximately 200 kW) has a consumption of 1 unit per hot meal, quite a good figure in view of the fact that the apparatus is 18 years old. In all the cases quoted by the author, the number of teas far exceeds the number of lunches. I do not quite understand his remarks about bulk supply. The units used for cooking must be debited to cooking, and 1d. per unit is too high a price for energy for this purpose; something in the neighbourhood of ½d. per unit would pay commercially. The author states that the advantages of using electricity for cooking are cleanliness, speed, and economy. The first cannot be questioned, but the second and third certainly will be. He states that the loss by radiation should be ignored; if this is done, however, the kitchens will have to be heated by some other means, the cost of which must be taken into account. No mention is made of the heat-storage system of cooking on a large scale. This method will probably be strongly advocated by the supply companies of this country, owing to the constant load and low maximum demand involved. With regard to cooking on trains, the London, Midland and Scottish Railway have not yet had any of their trains equipped with electric cookers, owing chiefly to the high first cost and also to the cost of accumulators.

Mr. W. A. Gillott: I am rather disappointed at the small number of technical calculations and figures included in the paper. On page 173 the author states that for the internal wiring of cooking equipment impregnated asbestos-covered wire is used and wires are brought through the lagging: does he recommend this method of wiring? I prefer to see the wiring of cookers rigidly mounted on steatite or porcelain insulators, thus obviating the possibility of the troubles so often met with in connection with asbestos-covered wiring, and I deprecate the practice of passing the wires through the lagging. The wires should be attached to a solid terminal block, thus making a sound engineering job. Regarding the relative merits of top and bottom or side elements for roasting-ovens, the position of the elements must depend upon the shape of the oven. Those types where the width exceeds the height or depth often have the elements fitted on the back; such ovens usually have double doors. Mention is made of the use of monel metal for the oven lining, and I should like to know whether the author has had experience over an extended period of monel-metal interiors? If so, how do they behave under heavy working conditions? He states that the plug-in type of oven element is liable to give trouble under heavy-duty conditions; this, however, is entirely a question of design. I have had experience of the successful use of plug-in elements with large roasting equipment extending over a period of almost 20 years. Provided one houses the terminals in a comparatively cool position no difficulty should arise. I agree with the author as to the difficulty of making allowance for the idiosyncrasies of foreign chefs. With the extended use of large cooking equipment in kitchens this difficulty should, however, to a large extent be overcome, as the results of working under modern conditions will bring out many points of operation that will tend to provide for the personal fancies of the chef. Manufacturers may therefore find that it will not be so necessary to alter their patterns to meet so many small requests. On page 175 it is stated that pastry-ovens usually have a loading of 0·7 watt per cub. inch, but the type of pastry-oven is not mentioned. For many years I have handled and sold pastry-ovens with a maximum loading of 0·5 watt per cub. inch which have given every satisfaction as regards both cooking and maintenance results. These ovens have sheet-steel interiors. The author is probably referring here to ovens with tiled or slab bottoms, necessitating a higher loading to heat up the oven. Turning to the question of grilling, provided suitable drawers are fitted for the collection of fat the saving effected in this direction will be sufficient to pay a large proportion of the total cost of the current consumed by the installation. I have had experience with an installation catering for some 2 000 meals per day, where the value of the fat recovered from the grills was more than the cost of the electricity used per day. I am surprised to find that so little has been said regarding electric cooking on trains, for the introduction of which I was largely responsible. A paper* which I read before the Institution about 15 years ago commenced a discussion on train cooking, and I was subsequently asked to investigate the proposition. I made experiments on the (then) Great Northern Railway, and produced figures that enabled suitable battery and generating plant to be designed. The cooking equipment for some of the restaurant cars on that railway was built up on the information secured. During the tests when the gas-cooking equipment on the train was being worked at its full capacity, the temperature in the kitchen reached a maximum of 111° F. It was necessary to remain in the kitchen the whole period of the journey, as on that day three shifts of meals had to be prepared for lunch and dinner. Observations were taken every 10 minutes over the entire trip of the number of gas-jets burning, and from this the approximate consumption of gas was obtained. From the readings the number of B.Th.U. required was calculated, and this figure was used to give the necessary kW demand. The first kitchen equipment was installed a little over 10 years ago, and as a result of the experience several dining-car electric kitchens were ordered for the trains of the London and North-Eastern Railway.

Mr. J. J. McKenna: I am sorry that the author does not give more detailed information about the cost of running electric cooking equipment, especially with reference to the type of meals being cooked. To give figures of cost per meal is not very informative unless one knows exactly of what the meals consist. In large restaurants it is obvious that the cost per meal will be considerably higher than in hotels and canteens. Moreover, the paper does not deal in a sufficiently detailed way with maintenance costs. Of all electric cooking

* *Journal I.E.E.*, 1918, vol. 56, p. 102.

equipments, none are misused more than those in restaurants; the result is that as a rule the maintenance costs of such installations are fairly high. If purchasers of electric cooking equipment find that they have been misinformed by the manufacturer regarding the running and maintenance costs of the equipment, they soon spread the news to other users of cooking apparatus and in consequence great harm is done to the industry as a whole. I believe the most satisfactory results from the point of view of the customer are obtained in connection with baking ovens, where the costs are competitive and in fact very often less than those of other methods of heating. Here again I should like to see more actual figures of both maintenance (which I know is low) and baking costs. With regard to fish-fryers, while there is a large volume of potential business in this sphere for electrical appliances, considerable difficulty is encountered in the design of fish-fryers to give satisfactory service. There is the question of raising the oil quickly to a high temperature, and the loading has to be high in consequence, and also in order to maintain that temperature when large quantities of fish are put in. As a result there is a danger that in the intervals when cooking is not in progress the oil is liable to get burnt. Can the author recommend any method for overcoming this difficulty whilst still giving quick operation? His figure of 2·5 watts per cub. inch for the loading of pans is not very informative; the loading ought to be given on the basis of the square inch of heating surface because the elements are generally underneath, either clamped to the bottom of the pan or fitted separately. The loading per cubic inch conveys nothing, because the pan may be either shallow or fairly deep. Can the author give a figure for the loading per square inch?

Mr. S. J. Benham: When on a visit to America I was surprised at the small amount of electric cooking apparatus in use in that country. I should say that there is a good deal more heavy-duty electric cooking apparatus in use in London than in New York. In both New York and Chicago I was told that electric cooking, except for baking ovens, is far too expensive, owing to the high cost of current. I am surprised that the author makes such a great point of the saving in the loss of weight of meat involved by electric cooking. There is only a saving if no vent is fitted to the oven, whereas I think that for every large cabinet or other roasting oven a vent is absolutely necessary for satisfactory cooking. Ovens are often filled not only with meat but also with such things as batter puddings and potatoes, which give off a great deal of steam. If no vent is provided or the vent is too small to carry off that steam, the food is partly steamed and partly roasted; it has not the correct colour, and a good chef will not approve it. I agree with the author that where steam is available it should be used for steamers and boiling-pans, and I think it should also be used for tea and coffee apparatus, hot-cupboards, etc. Where 2 000 to 4 000 meals are required daily, it is better and more economical to put in a steam boiler and steam-cooking apparatus than to attempt to do all the cooking by means of electricity. Mr. Hardy referred to the fact that the ranges at the Dorchester Hotel have gas boiling-tops. I think that in a cooking installation for a large hotel or restaurant where many meals are served it is better to have a gas boiling-table than to attempt to use electricity for boiling purposes. This idea has been adopted in many large institutions. For instance, at the head offices of the Midland Bank, where there is a very large staff canteen, the new Princess Beatrice hospital at Fulham, and the new clinic in the Marylebone Road, London, the cabinet roasting-ovens, grillers, and fish-fryers are all electrically heated, the boiling table is gas-heated, and steam is used for other purposes. There is a good deal to be said for combining the three types of fuels in this way. It is interesting to note that in the Princess Beatrice hospital the steam is actually generated by electricity. I do not agree with the author's comparison between the costs of electricity and gas, and I regard as incorrect his statement that electricity at 1d. per unit or under will compare with gas at 8d. per therm. I think the former figure should be ½d. per unit for electric cooking. The future of electric cooking apparatus depends mainly on the cost of current, and I do not think that 1d. per unit is attractive enough. I hope that the supply companies will shortly supply current at ½d. per unit.

Mr. C. M. Flander: The author refers to electrically-operated fish-fryers, and states that, provided the tariff does not exceed 1d. per unit, the overall operating cost is competitive with that of other types of fryers. This type of equipment is in use about 5 hours per day and at a time corresponding to the daily peak of the majority of undertakings, so that from a load-factor point of view it is little better than lighting equipment, and must therefore carry its full proportion of capital charges. As the nature of the load is such that diversity cannot be taken into account, the cost of energy delivered to the low-tension system will not be less than 0·76d. per unit. As a general case it is reasonable to assume that the substation supplying the load is 10 miles from the point at which the bulk supply is received, and that the load has to be transmitted 0·5 mile over the low-tension system. For these conditions the capital charges on the transmission and distribution systems amount to 0·495d. per unit. Thus the cost—excluding management, rates, repairs, and maintenance—amounts to 1·255d. per unit. It is difficult, therefore, to see how undertakings can be expected to cater for this load at 1d. per unit. On page 179 the author states that gas at 8d. per therm is comparable with electricity at 1d. per unit, which would seem to assume (taking the efficiency of electricity to be 100 per cent) that the efficiency of gas-operated apparatus is only 27·5 per cent. It is interesting to compare this result with some recent German figures* which showed that 1 unit of electricity is at least equivalent to 15 cub. ft. of gas having a calorific value of 395 B.Th.U. per cub. ft. On the above basis this gives an efficiency for gas-operated apparatus of 58·4 per cent. These values are confirmed by some other German figures† published in 1928. I should be glad if the author would explain the considerable discrepancies between these test results and the figures he gives on page 179, and also indicate the rate of depreciation which he considers necessary for the types of equipment described in the paper.

* *Electrical Review*, 1930, vol. 106, p. 37.
† *Electrical Times*, 1928, vol. 74, p. 816.

Mr. J. I. Bernard: The author shows that commercial cooking by electricity is now being profitably employed on a considerable scale in this country and abroad. The rapid growth of the heavy cooking load in America is mentioned, but equally impressive figures could no doubt be shown by several British supply undertakings. In one district in London, for instance, there are 6 large commercial cooking installations of which the total consumption is over 1 500 000 units per annum, i.e. an average of 250 000 units each. Similarly, one municipal supply undertaking in the provinces has over 1 820 kW of commercial cooking load connected. Complicated tariffs for this class of load undoubtedly exist, but they need not in themselves prevent us from obtaining the business. The engineers responsible should be able to explain the tariff to prospective users and show what the average cost per unit is likely to be. Further facts and figures demonstrating the superiority of electricity for commercial cooking purposes could easily be given. As an example, the greater cleanliness and improved working conditions brought about by the adoption of electric heating may be illustrated by some comparative tests made in America on gas and electric roasting-ovens. It was shown that with gas firing the amount of heat required to maintain 500° F. was equivalent to 6·5 kW per sq. ft. of oven, as compared with 0·2 kW with electricity. The difference in the heat supplied in the case of an oven of 24 sq. ft. would be sufficient to raise the temperature of a normal-size kitchen (30 ft. × 40 ft. × 10 ft.) by 23 deg. F., even assuming that the air is completely changed every 3 minutes. Figures such as these illustrate in no uncertain way the great advantages which always follow the use of electricity for commercial cooking.

[The author's reply to this discussion will be found on page 188.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 29TH FEBRUARY, 1932.

Mr. R. H. Rawll: By his statement that the heating-up and maintenance of boilers or coal fires take a considerable time, the author infers that electrical equipment is ready for working directly it is switched on. This is obviously not the case so far as boiling-plates are concerned, and it would be interesting to know whether hotel proprietors, caterers, etc., consider this to be an important point, although it is admitted that once a boiling-plate is hot a small current consumption will keep it so for an indefinite period. I agree with the author that no advantage is gained by using plug-in elements, since after about a year's use the contacts often become semi-welded and corroded. I consider it unnecessary for the electrical industry to utilize for propaganda purposes the non-shrinking capabilities of electricity for roasting, since this feature seems already to be well appreciated by the public. As the author points out, the hot-plate represents the weak spot in our armour. I notice that he considers from 28 to 30 watts per sq. inch to be a reasonable loading for hot-plates in this country, and further on in the paper he gives the figure of 19 to 23 watts per sq. inch as the usual loading in the United States. Does this mean that the latter country has the more efficient hot-plate, or does it mean that users over there are content to wait longer than we are for the plate to attain its final temperature from cold? I do not agree that, in practice, current at 1d. per unit will justify electricity for commercial cooking: this figure is a trifle high. It is stated that a works canteen using electricity for cooking purposes would have a maximum load coinciding with the day valley of the supply undertaking's load-curve. Since most works shut down about midday the load drops off at this time, especially in industrial areas, but the cooking of meals to be served at this time would commence perhaps 2 hours beforehand, and it is well known that with electric cooking the greatest load is taken at the commencement of the cooking period. Switches are turned down to "low" and even "off" towards the end of the operation. It seems, therefore, that the maximum cooking load for works canteens would not coincide with the valley of the load curve at midday, but would be superimposed on the day power load a few hours previously. The paper omits to mention the induction type of cooker, where the utensil containing the food acts as the secondary of a transformer, and the induction boiling-plate, where the plate itself forms a low-voltage secondary. A great deal was expected from this type of apparatus when it was first introduced a few years ago, and in view of the ever-increasing adoption of alternating current it would be interesting to know whether the author considers that this design will be developed in the future. Can he explain why it has so far failed to find a market?

Dr. K. R. Sturley: I should be interested to know the voltage used for train cooking equipment. The paper suggests that it is 180 volts. It would appear worth while to increase the number of battery cells from 90 to 100 or 110, thus permitting the use of standard apparatus and a reduction in the current for a given heating effect. The maintenance of cooking equipment is an important factor and I feel that if this were undertaken by supply authorities generally, as in the case quoted in the paper, it would give an impetus to the sale of both large and small cookers. I agree with the author as to the need for suitable tariffs, and it is to be hoped that more supply companies will encourage a cooking load to fill in the valleys in their load curves. Thermal-storage cookers, which can store sufficient heat to allow of their being switched off during the peak-load periods, can be advantageously employed in this connection. I am not aware of the use of such apparatus in England, but it has received encouragement on the Continent. This can be partly explained by the different generating conditions prevailing abroad, where the source of power is generally water; nevertheless, the possibilities of such apparatus should not be ignored.

Mr. K. Pittaway: I should like to refer to the uses of residual heat in ovens, after the current has been switched off. On some of the slides exhibited by the author there appeared a type of roasting-oven the top of which was fitted with a boiling-plate or plates. I particularly refer to plates which are actually parts of the oven tops. If these plates were of the open-bottom

type, when being used in the ordinary way as boilers they would also heat the oven to a medium degree, and the heat so supplied to the oven could be usefully employed for purposes for which residual heat is found sufficient. The boiling-plate would thus serve the dual purpose of boiler and top element of the oven. Referring to fish-fryers, as the essential future of these units is to boil oil, have any of them been fitted with a special type of immersion heater? Is there any good reason for definitely ruling out such a method?

Mr. W. A. Gillott: It would be interesting to have a few more details of the equipments mentioned under the heading " Representative Installations " (page 177), and, if possible, a comparison of the working conditions. Taking as examples the American installation where some 250 kW of plant is installed, and the West End drapery establishment with a total connected load of 244 kW, can the author give a comparison of the maintenance costs under the following headings: boiling-plates, oven elements, grill elements, internal wiring, and switches? It would be interesting to compare the life of British with that of American appliances. If the author is unable to give details of the maintenance costs, could it be expressed as so much per thousand units consumed? Upon this basis one obtains a fair indication of the amount of work done upon the appliances. It is hardly fair to treat the maintenance cost as a percentage of the initial cost, as in some installations the equipment is embellished with nickel plating, vitreous enamelling, illuminated switchboards, and other additions, whereas in installations of exactly similar equipment not having such embellishments the initial cost is considerably lower. I particularly stress this point because when I had control of the design and equipping of national kitchens during the War, I found that the cost of the equipment was not much more than two-thirds of that of similar plant embellished for ordinary use. This also applies to the plant now used in works canteens. The author states that the maximum demand of the American installation is 145 kW with a consumption of 28 000 units per month. This is equal to approximately 2 320 units per kW of demand per annum, whereas the West End drapery kitchen averages 146 000 units per annum with a connected load of 244 kW. Can the author give a few more details of these installations? The West End plant admittedly employs a good deal of steam. Evidently water is boiled by steam, and steam is probably used in other operations. Before, however, a true comparison can be drawn between the two installations it is necessary to balance the work of each. It would be of interest if the author could show the characteristic load curve of each plant. This would not only give the nature of the demands but would also enable one to determine the diversity factors. Turning to the four installations dealt with under the heading of " Energy Consumption," I am surprised to find such a large variation in the figures of units consumed per annum per kW installed, these being 590, 1 125, 303, and 802, for installations Nos. 1, 2, 3, and 4, respectively. Can the author explain this large difference in consumption, and can he state why it is that whereas installation No. 3 records the lowest consumption per kW installed, it shows the highest current consumption per head per meal? Regarding the value of the large-kitchen load to electricity supply authorities, this business is worthy of cultivation. Apart from its revenue production, the advertising value is considerable and assists in encouraging the further use of electricity for domestic purposes. Patrons of restaurants where electricity is used for cooking will realize that it must be a commercial proposition, otherwise a restaurant would not adopt it. I agree with the author that it is desirable for the electricity supply authority to appoint a special representative who has a knowledge of the subject, to discuss kitchen problems with prospective clients. This class of work should be dealt with by men familiar with it, otherwise more harm than good may result. In discussing cooking matters with chefs and hotel or restaurant proprietors, considerable tact is necessary. If the sales representative of a supply company is not well acquainted with large-kitchen work he should confine his activities in the first instance to canteens or works kitchens, where he will discuss the matter with the engineer and thus gain valuable experience. In my opinion the United States cannot teach British engineers much about large cooking equipment; the American policy is largely one of trying a new idea merely because it is new. In the paper* on " Electrical Cooking as Applied to Large Kitchens " which I read before the Institution in 1918 I stated that some 400 kitchens with a connected load of 22 000 kW were operating in this country. Considerable expansion has taken place since then, and I should be surprised if the number of British large-scale kitchens did not now exceed the American total. Whilst I agree with the author that, for domestic cooking, gas at 8d. per therm is equivalent to electricity at 1d. per unit, this comparison is not applicable to commercial kitchens owing to the difficult nature of the work. In domestic work it is usual to carry out a culinary operation and finish it there and then, whereas in a restaurant there is often a considerable waiting-on period for both the actual cooking appliances and the hot-cupboard, urns, etc., in still rooms. In London it is the practice of a gas company to allow to hotels a special discount of approximately 25 per cent off the published charge for gas. A similar allowance is not usually made by electricity supply companies. I consider that under ordinary working conditions 8d. per therm is equivalent to $\frac{3}{4}$d. per unit, disregarding incidental savings effected by the use of electricity. It would be of interest if the author could provide load curves of the installations described in the paper. What percentage of the installed load is the average kW demand of the installations with which he is associated? I have found that where a kitchen is used for the preparation of simple meals at a definite time, e.g. for canteens, schools, etc., the kW demand averages 60 to 65 per cent of the total load installed. In kitchens catering for a varied menu such as that of a restaurant or hotel, the demand is much lower—35 to 45 per cent. This is due to the employment of special appliances for dishes that are only occasionally called for. The normal plant cannot be used for these dishes as it is usually kept running to continue the cooking of the ordinary meals.

[The author's reply to this discussion will be found on page 188.]

* *Journal I.E.E.*, 1918, vol. 56, p. 102.

SCOTTISH CENTRE, AT EDINBURGH, 22ND MARCH, 1932.

Mr. E. Seddon: I am inclined to doubt the figure of 10 per cent for the saving due to reduced shrinkage of electrically-cooked meat. I understand that the latest type of gas oven is heated externally, and I should like to know whether the results of shrinkage tests on such ovens have been compared with those on electric ovens. As regards the steam-tightness of ovens, I understand that the author has introduced a ventilator at the back of the oven instead of in the door. It is well known that steam confined in an oven which is being used for roasting spoils the condition of the food. The steam must be eliminated to permit of the food being dry-heated. Several large catering establishments in Edinburgh which use electric cooking ovens for general purposes have gas-operated boiling pans, because the electric hot-plate is found to be too slow. I therefore consider that the hot-plate should be redesigned. We have heard a great deal in recent years about machined-bottom saucepans: these are satisfactory for a time, but they gradually deteriorate. Even if their flat surfaces could be maintained in perfect condition there would remain the difficulty that the hot-plates themselves become distorted by use. The air space between the saucepan and hot-plate greatly delays the process of boiling. I believe the well type of heater with bottom and side elements will eventually prevail, and even this arrangement would be improved by a hinged, domed cover-plate to retain the heat. I agree with the author (page 172) that chefs are reluctant to alter their established practice, and I am convinced that the more general use of electric cooking is being retarded by their conservative attitude. With regard to the replacement of cooker hot-plate elements, we have changed over from the wired type to the plug-in type with complete success. When maintenance men have to use pliers and other tools for replacing elements the householder gets the impression that a big job is being undertaken, whereas a plug-in element can be dropped into position without effort and in a minimum of time. With regard to baking, 2 years ago we offered the low rate of 0·3d. per unit for this purpose between the hours of 10 p.m. and 7 a.m., but as Edinburgh bakers cannot be induced to work at night no business has resulted.

Mr. A. Mears: The question of the efficiency and adaptability of the electric hot-plate as compared with the gas-ring seems to me to be one of further research, not of combining gas and electricity in one piece of apparatus. I recently made some comparative tests of the speed and economy of a gas-ring used with an ordinary kettle, and an electric kettle loaded to 1 kW. The results indicated that for the same amount of water the cost of using the electric kettle—at the domestic heating rate applicable in Edinburgh—was a trifle less than the cost of using the gas-ring, and the two systems were equally quick. Experience of the usual type of gas-ring, placed in apparently the most suitable position for the disposal of the products of combustion, shows that the fumes of burnt gas quickly pervade the kitchen where it is in use. Has the author investigated the question of the grinding of the surfaces of hot-plates and the bottoms of kettles or cooking utensils? Unless perfect contact is made between the surface of the hot-plate and the bottom surface of the cooking utensil great difficulty is experienced in connection with the speed and reliability of the cooking operations. Referring to the question of the combined gas and electric cooker, it seems to me that a considerable fire risk is taken when such a combination is used, as a leakage to earth may readily melt the gas pipe and ignite the gas. I feel that the insurance companies would not look favourably upon this combination. According to the author electric cooking is quite economical at 1d. per unit or less; in this connection I should like to state that in Edinburgh the price averages $\frac{3}{4}$d. per unit for commercial and $\frac{5}{8}$d. for domestic cooking.

Mr. H. C. Babb: I deplore the remarks of previous speakers about the heating of water by electricity, and I support Mr. Mears's view that if electric water-heating apparatus is inefficient we ought to try to improve it by carrying out suitable research work. With regard to the cost of electric cooking, the tenants of Council houses in my area are taking up electric cooking very strongly. The cost of using a small electric cooker which we can let out on hire for 2s. 6d. per quarter, and which is capable for cooking for 3 or 4 persons, is less than that of using a gas stove in a similar house. There may be some difficulty in comparing figures obtained in this area with those of other areas, owing to the fact that a large number of the people who occupy these houses are miners and can buy coal at a cheap rate: the electric cooker is therefore probably not used quite as often as it would be in most other districts.

Mr. W. Duncan: The electrical industry is passing through a phase of development analogous to that which the gas industry experienced in its earlier days when competing with coal. The use of electricity for cooking purposes is being hindered by lack of knowledge of the apparatus, and I think it would be a good piece of propaganda for manufacturers to provide free demonstration cookers to all schools and colleges where domestic science is taught. This would enable such schools to educate the younger generation in the use of domestic electrical appliances. I am glad to know that the author approves of the embedded type of boiling plate, the introduction of which has made a great difference to progress in the use of electric cookers. I should be glad if he could indicate what the future changes in boiling-plate design are likely to be. I do not agree with the policy of certain manufacturers who make statements as to the time taken to boil specific quantities of water, as I find that the figures given are often inaccurate. For instance, these figures usually assume the initial temperature of the water to be 60° F., whereas in actual practice it averages 50° F.; this lower temperature makes a considerable difference to the boiling time. I should like to mention the case of an electrical cooking equipment in Edinburgh where all the elements

are loaded to 1·5 kW and are of the plug-in type: boiling-plate, grill, and oven elements are all interchangeable, and can be replaced in a few minutes without skilled attention. This feature should, I think, be extended and developed. The mention by the author of the case where a concrete oven base was insisted upon suggests that there might be an additional advantage in electric cooking if insurance companies could be induced to lower their tariffs to premises where cooking is done electrically. Has the author had any experience of the thermostatic control of ovens? This idea has been adopted in America even for domestic equipments. In this country we have been rather slow to introduce such refinements. The author showed a slide illustrating a battery of large electric boilers; I should like to know how the heat is applied to these.

Mr. G. Gunn: Have any tests been made of electrode boilers of the type in which the electrode can be raised out of, and lowered into, the water? Also, have any experiments been made on the high-frequency boiler?

Mr. J. Eccles: We all hear from time to time of the difficulty of regulating the boiling appliances of electric cookers; I suggest that where an a.c. supply is available this difficulty could be overcome by providing an auto-transformer with a series of tappings up and down (mostly down), so as to give a wide range of graduation on each of the three heats. If auto-transformers are as cheap as power transformers are just now, the additional cost of such a device should not be serious. At the festive seasons, when many meals are being cooked simultaneously and supply mains are being severely taxed, the auto-transformer could be used to step up the voltage slightly and thus overcome the difficulty of insufficient heat being available to cook large roasts in a reasonable time. I should be glad to have the author's views on this suggestion.

The Author's Reply to the Discussions at London, Birmingham, and Edinburgh.

Dr. T. Settle (*in reply*): Before answering in detail the various points raised in the discussions, I should like to express my thanks to the speakers for the interest shown and for their valuable contributions.

A considerable volume of criticism was directed by various speakers against the alleged failure to give details of technical and mechanical construction of heavy cooking apparatus. I can appreciate the desire of manufacturers to obtain as much information as possible with regard to details of construction used by other manufacturers. It is well known, however, that I am connected with the manufacturing side of this industry, and any particulars I might have given would naturally, in the first instance, have been particulars of the products for which I am responsible. The publication of such details might have provoked criticisms from other manufacturers, and I think it will be admitted that a discussion of this kind is entirely outside the scope of an Institution paper.

Every manufacturer has his own ideas and methods of construction. There are a few general principles which have been referred to as far as possible, but as the design and construction of heavy cooking apparatus are still in a state of continuous development I considered it advisable to refrain from dealing with matters which, in the eyes of competing manufacturers, might have been largely controversial.

Another general criticism referred to the insufficiency of information with regard to actual figures, and the particulars given were evidently not as complete as some of the speakers might have wished. It will be appreciated that I was able only to give such figures as were obtainable, and I could only give them in the form in which they were obtained, because in every single case some link would be missing which would prevent the reduction of available figures to a common comparative basis.

I welcome Mr. Downe's remark with regard to the hire of heavy cooking apparatus by supply authorities, and the necessity of having properly trained assistants in this branch of the business. Wherever such assistants are available, good progress is being made. Every manufacturer standardizes his own equipment, and under present conditions general standardization is out of the question, not only from the point of view of the manufacturer, but also from that of the user, who very often has special views and wishes.

Mr. Hardy's statement on the great success of the electric kitchen in the Dorchester Hotel is very interesting and very good news. I am glad to hear Mr. Hardy's confirmation from practical experience of my opinion of the average chef, and his suggestion as to how to deal with chefs who are averse to electric cooking is to be heartily welcomed and recommended. I fully agree with Mr. Hardy's recommendations, but there is one point on which I cannot follow him. I cannot agree with the use of gas for boiling in connection with electric roasting ovens and forming part and parcel of the complete apparatus. Modern boiling-plates are very little slower than gas boiling-rings if proper utensils are being used, and with carefully constructed apparatus damage to the hot-plates by boiling over can be practically eliminated. The speed of boiling can also be improved by the use of hot water to be made available from a storage water-heater. By introducing gas into the electric kitchen, many of the advantages of a complete electric kitchen are done away with. Apart from the vitiation of the atmosphere, the introduction of gas always brings with it the risk of explosion and fire, particularly when electricity is used on the same apparatus, and in case of any accident electricity would probably always get the blame.

I am afraid that the greater part of Mr. Ellerd-Styles's contribution to the discussion is not quite within the scope of the paper. Most of his remarks refer to my contribution to the discussion on his paper on electric baking ovens read before the Institution in 1928. The 10 per cent saving in shrinkage is an all-round figure obtainable by the average cook in an average kitchen equipment, and is not based on the results of tests carried out by experts for this particular purpose. To get absolutely comparative figures with regard to

shrinkage, tests would have to be carried out with the same kind of joint taken from the same kind of animal and roasted in electric and gas ovens of exactly the same oven capacity. It is almost impossible to obtain these conditions. Mr. Ellerd-Styles makes some very sweeping statements, which are highly controversial and very much of a commercial nature, and they ought not to remain uncontradicted. The placing of elements in tubes in baking ovens is declared to be entirely wrong. Why this should be so is not stated, but elements enclosed in tubes do not only give a longer life than other types of elements, but they also ensure better heat distribution. Comparison is made between three ovens of the same size with three different loadings (10 kW, 8 kW, and 6·9 kW), which are all supposed to attain baking temperature in the same time. This statement, if correct, means that the general construction of the ovens must of necessity be different. If the sole of an oven is brick, and in some cases the sides and back are also brick, it stands to reason that a much higher loading is necessary to attain the same temperature in a given time, than in the case of an oven having fewer or thinner tiles or none at all, but of purely metallic construction. The heat-retaining properties of ovens with thicker tiles and higher loading are superior to those of lighter construction. Once an oven has attained baking temperature it is only a matter of using the lower controls to keep the temperature at a baking level. It is, therefore, the consumption of current required for baking over a period only that counts, and whilst Mr. Ellerd-Styles mentions that a lower-rated oven may appeal more to the layman and appear to him to be a better commercial proposition, he omits to mention that in most cases heat control is available for providing full, half, and quarter heat, or full, two-thirds, and one-third heat. The all-important point for the baker is current consumption in relation to his output. If he is satisfied with this—and there may be very little difference between the various types of ovens—it is only the construction of the oven, its life, and the ease of handling which count. As mentioned above, I do not propose to deal with questions referring to details of construction.

I think that no chef would welcome the introduction of Prof. Parker Smith's table pattern apparatus in his kitchen. This type of apparatus may be useful in a private house, but it would not last long in a large all-electric kitchen.

The incident quoted by Mr. Ellerd-Styles with reference to thermostatic control has no bearing, in my opinion, on this question. Apparently through carelessness an oven was left on over the week-end. Surely thermostatic control is not intended to take care of isolated cases of this kind, but is usually meant to control the temperature when the appliance is in regular use. I still maintain that for ordinary baking operations thermostatic control is not necessary and is not used to any extent. However, in order to follow Mr. Ellerd-Styles on his own ground, I can refer to a case where an oven was inadvertently left on from Saturday evening until Monday morning, the front of the oven being then nearly white-hot. No damage was done, except to the thermometer, and the oven has since been in daily operation. This only shows that the method of construction is an important point, and isolated cases like the one quoted do not justify the extra cost of thermostats to counteract gross carelessness in working.

Major Tandy raises the question of maintenance of electric kitchen equipment. This depends very much on the method of handling. The figures given in the paper referred to heating elements and any other replacements which may become necessary. Good-class aluminium pans with bases ground dead flat are found to be quite satisfactory for use on hot-plates. Many chefs, however, prefer copper pans, but the continual cost of having these re-tinned is bound to be taken into consideration. Boiling time depends, of course, on the quality of contact between utensil and hot-plate. The expenditure of £500 per annum for utensils in a large hotel in the north with gas cooking seems extraordinarily high, and would certainly be very much lower with electric cooking. The figure of 1d. per unit for electric cooking was only given as the basis of a comparison against gas at 8d. per therm, but I quite agree with Major Tandy that ½d. per unit would put electricity for cooking on an unassailable basis. The heat-storage system for cooking on a large scale has not been developed, and I do not think it will ever be a commercial proposition unless some entirely new method can be devised. If based on constant load it would certainly be too expensive. With regard to the cost per meal, the class of meal is generally indicated by reference to the type of installation. A meal served in a canteen consists usually of a plate of meat with vegetables and a sweet. To give particulars of the class of meal as served in restaurants and hotels would be an impossible proposition.

In reply to Mr. Gillott, I certainly do not recommend that wires should be brought through the lagging, but in some cases this cannot be avoided and possible attack by the lagging material on the insulation of the wire must then be guarded against. The figures which I have given for the loading of pastry ovens refer to ovens with tiled soles. I agree with Mr. Gillott that more details of equipments and comparisons of working conditions would be valuable, but, as pointed out, this information can only be given as obtainable, and particulars of the cost of maintenance of American installations are not easily obtainable. The present method of calculating the maintenance cost by basing this on the original purchase price of the equipment is the only one which interests the consumer. The figures given are usually maximum figures, and it would be impossible to give an estimate based on a consumption of 1 000 units. It would be interesting to know this figure, but it would probably be so small as to lose all importance. A large number of the kitchens referred to by Mr. Gillott as working in 1918 were war establishments, and their use was discontinued when peace conditions returned. I cannot agree with Mr. Gillott that the number of British large-scale kitchens might exceed the American total.

I can assure Mr. McKenna that baking costs for bread and pastry are very reasonable and show considerable advantage to the baker if all the advantages of electric baking are taken into consideration. The maintenance of electric baking ovens varies considerably according

to the treatment they receive, but the replacement of elements in a well-known type of baking oven is practically nil, and other replacements are very few and then not of an expensive nature. It is difficult to see how detailed information about running cost can be given. Figures can only be given when they become available, and it is a very difficult matter either to persuade users of electric kitchens to keep proper records or, if they keep them, to disclose them. All that a manufacturer can say about maintenance cost is what spares he has to supply to each particular customer. The cost of spares plus the cost of necessary labour to carry out repairs constitute the cost of maintenance, and the percentages given in the paper are based on records of this kind. To give the loading of fish fryers per cubic inch has been considered the most satisfactory way.

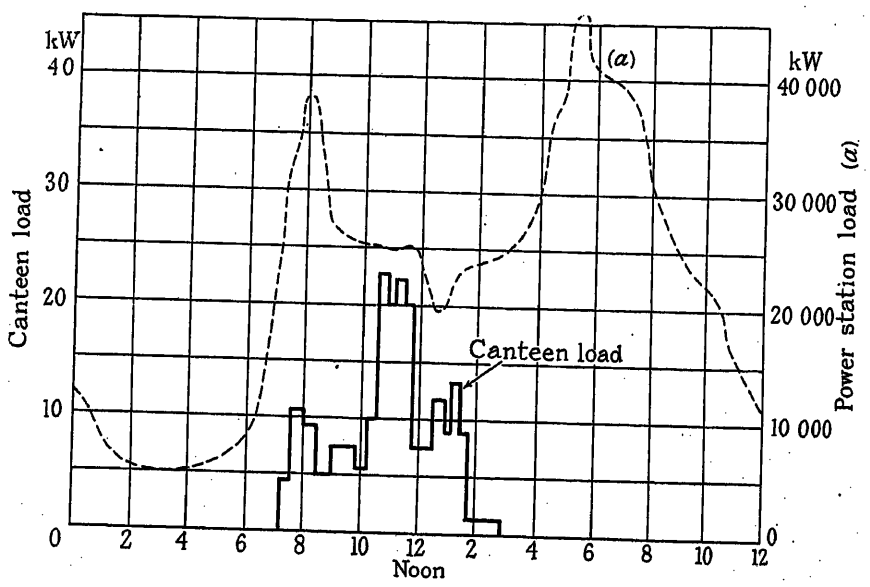

FIG. A.

A loading of 22 to 25 watts per square inch is considered satisfactory.

Whilst I agree with Mr. Benham that there is a good deal more heavy-duty electric cooking apparatus in use in London than in New York, I cannot accept his general statement that a very small amount of electric cooking is used in the United States. Both in New York and Chicago the electric supply is controlled by the gas interests. In Chicago, however, some of the very largest electric cooking installations in existence can be found. Where the gas interests are entirely separate, electric cooking has made great headway, and very important complete or partial electric equipments are continually being laid down in all parts of the United States. I am afraid I cannot consider Mr. Benham as an unbiased judge with regard to the merits of electric cooking. He is a manufacturer of cooking equipment of all types, and I am not surprised that he prefers other types of cooking equipment. This is one of the difficulties that the electrical industry has to deal with; it is responsible to a large extent for the general impression that electric cooking equipment is merely electrified fuel-fired equipment. The suggestion that gas at 8d. per therm is equivalent to electricity at $\frac{1}{2}$d. per unit is quite incorrect. I cannot do better than quote the figures obtained from an actual installation. In an important installation in the Midlands which was run entirely on gas, some time ago part of the gas equipment was replaced by electrical equipment. All roasting, grilling, and fish frying are now done electrically, whilst for all boiling, steaming, etc., gas is still being used. For six months weekly records were taken. The number of people supplied and the type of meals were practically identical. The total consumption of electricity for the purposes mentioned above for six months was 13 129 units. In the corresponding period of the previous year when gas was exclusively used, the total consumption was 452 300 cub. ft. The consumption of gas for boiling, etc., during the recent period was 99 300 cub. ft., so that 353 000 cubic feet of gas had been replaced by 13 129 units. At 1d. per unit the cost of electricity amounted to approximately £54. At 3s. 6d. per 1 000 cub. ft., or approximately 8d. per therm, the cost of gas was £62. These figures prove that the usual comparison between 1d. per unit for electricity and 8d. per therm for gas is a correct basis. There is no doubt that even if boiling also were done electrically the basis of comparison would not have to be altered. At $\frac{3}{4}$d. per unit, of course, the saving due to the introduction of electricity would be beyond any question. The figures published by Sir Dugald Clerk some years ago, which are based on a very doubtful calculation, give a comparison between efficiencies of gas and electricity as 42 per cent for gas and 59 per cent for electricity. These figures were very severely criticized by Mr. Highfield at a joint meeting of the Institution of Gas Engineers and the Institution of Electrical Engineers in 1920, and it will be admitted to-day, I believe, that these figures are not correct. I would put the efficiency of an average commercial gas equipment at about

40 per cent, whilst the average efficiency of electric apparatus could be taken as 80 per cent. These figures vary, of course, with the nature and type of apparatus. It is a very widespread practice of the gas interests to make the basis of comparison between gas and electricity the cost of coal at the gas works and at the generating station. We are only concerned with the efficiencies of gas and electricity as delivered to the consumer.

In reply to Mr. Fiander, I do not think that the figure of 58·4 per cent efficiency for gas apparatus is even claimed by gas authorities in this country. As far as charges for current are concerned, Mr. Fiander's statement is not borne out by the prices for current freely offered by supply authorities. A number are offering ½d. per unit and many ¾d. per unit. Unfortunately, there are no particulars available in this country as to the relation of a canteen load to the central station load, but I have been able to find a reference to this in *Elektrizitätswirtschaft Mitteilungen der V.D.E.W.*, No. 499, and Fig. A shows that the peak of the canteen load comes well within the valley of the central station load. Of course, this refers to a small installation catering for about 300 people.

In reply to Mr. Rawll, I do not infer that electrical equipment is ready for working directly it is switched on, but as far as boiling-plates are concerned, to which Mr. Rawll specially refers, they are ready much more quickly for boiling than an oven is ready for roasting. The reason for the lower loading for hot-plates customary in the United States is evidently that people there are less impatient with regard to boiling time than in this country. An induction type of cooker has not been referred to, because at the present time it cannot be considered either a sound technical or commercial proposition.

In reply to Dr. Sturley, apparatus for cooking on trains is usually designed to operate on any voltage between 180 and 220 volts. This wide range is necessary on account of supply being taken when the train is at a standstill, either from supply mains at the station or from the battery. Thermal-storage cookers are beginning to make headway for domestic purposes, but for industrial purposes they cannot be considered either a technical or commercial proposition. With the exception of baking ovens, which are of course an entirely different class of apparatus, I am not aware of any thermal-storage cooking on the Continent.

I think that Mr. Pittaway, who refers to a roasting oven fitted with a boiling plate or plates on the top, must have obtained a wrong impression of the slide shown. The slide in question referred to a method of removing the hot-plate for the purpose of cleaning or exchanging, but the hot-plate certainly did not form part of the oven top. The use of immersion heaters in fish fryers would not prove satisfactory; in fact there would be danger of the fat burning due to direct contact with the heaters. Immersion heaters would also take up valuable space in the frying pan.

Mr. Seddon must, I think, have misunderstood me when he refers to my introduction of a special type of oven ventilator. Opinions differ as to the necessity of eliminating steam in roasting ovens. Quite a considerable body of opinion attributes the better results of electric cooking to the presence of steam. I have not yet come across an industrial type of gas cooker which is heated externally.

I fully agree with Mr. Mears's remarks with regard to the efficiency and adaptability of the electric hot-plate as compared with gas rings. I agree that perfect contact between the surface of the hot-plate and the bottom surface of the cooking utensil is essential.

I can assure Mr. Gunn that electrode boilers of the type in which the electrode can be raised out of and lowered into the water would not be satisfactory in practice, and the use of high frequency for boiling purposes has so far only been dealt with experimentally.

Mr. Eccles's suggestion that boiling appliances on a.c. supply might be regulated by means of auto-transformers with a series of tappings is worth consideration, and experiments carried out in this direction may bring useful results.

DISCUSSION ON

"THE ELECTRICAL HEATING OF BUILDINGS."

North-Eastern Centre, at Newcastle, 9th November, 1931.

Mr. S. S. Jewsbury: Has the author found that a thermostat gives satisfaction in controlling the temperature of a room heated by means of a radiant panel? I suggest that an ordinary thermostat, which is operated by the air temperature, should not be used in rooms heated entirely by radiant panels, since it is admitted that the air temperature in such rooms is not a correct criterion of conditions of comfort. I also question the figures for the hot-water panel system given in Appendix X, page 1089 (vol. 69). The capital cost of both the plant and the structural work appears to me to be too high; also the depreciation cost has been based on the structural work in addition to the plant. I suggest that the annual cost of maintenance, etc., given as £200, should be reduced to £50. Even this is a higher figure than has been found necessary in connection with a much larger apparatus at Carliol House.

Mr. H. W. Clothier: A matter of vital interest to the whole electrical industry is the demand for storage load to keep generating plant working during off-peak periods. Apparently the average load factor at present is about 30 per cent, in which case an off-peak load of, say, 2 000 000 kW would be of immense service in flattening the load curve on the "grid" system. As an example of the extent of the water-heating load obtained for this purpose elsewhere, it is interesting to note that in Canada one maker alone has made 83 electric steam-generators with a total capacity of 850 000 kW. This great demand is due to the necessity of utilizing surplus power from hydro-electric stations where fuel costs do not enter into consideration; but assuming that our average fuel costs are of the order of one-quarter to one-third of our total works costs, the off-peak load becomes with us also an essential for maximum economy in the production and transmission of electrical power. It seems to me that the total average works cost of units generated could be nearly halved if a level load curve were possible. The late Dr. Ferranti told us in Newcastle a few years ago that water heating was the key to the problem of energy storage. The last time he spoke in London he said: "If I talked for the rest of my life I should feel I had not talked enough to emphasize the importance to the electrical industry of this question of storing the electricity produced." Having a strong faith in his prophecies, I think it behoves us to make a combined effort in all sections of the electrical industry to bring about this general economy. At present the heating of buildings and the demand for domestic hot water afford the main openings. The author's Appendices V and VI, valuable as they are in their present form as a statement of actual experience, would be improved if he brought them to a common basic denominator. In the discussion† before the Institution on the paper by Messrs. Monkhouse and Grant, it was suggested that a basis was necessary on which comparative calculations for different buildings and different purposes could be made. Could this not be called the "average heating factor," and signify the average watt-hours per hour required, over a day of 24 hours, per cubic foot of building capacity per deg. F. temperature-rise? As examples from published figures, this works out to 0·162 Wh in the case of Carliol House, which is an office building of 1 800 000 cub. ft. capacity, and at 0·38 Wh for a private house of 56 200 cub. ft. If the experience of several classes of buildings and methods of construction could be expressed in some such standard, it would be easier than it is at present to make a comparison with a table such as Appendix VI, where the number of days, hours per day, and average temperature-rise are left to the imagination. Further, if this standard were adopted such widely different figures as 0·060 and 1·23 kWh per cub. ft. per annum would be avoided. The attractiveness to the average user of the author's system of panel heating will depend upon its value as a storage system, and upon whether it will be accepted as such by the supply undertakings in determining the rates to be charged for the power used during off-peak periods. The author states that the Electricity Commissioners' Regulations for the Safety of the Public are contravened when electrode boilers are installed with the neutral point earthed through the resistance of the water. This type of boiler has been fitted in London, Glasgow, Manchester, and Newcastle, with the approval of the supply authorities, and the following remarks may help to clear away any formal difficulties in the path of electrode-boiler progress. The regulations applicable are: (*a*) Electricity Commissioners' Regulations El. C. 12a, Clause 3 (Insulation Test). This regulation says that the insulation of every circuit shall be so maintained that the leakage current shall not exceed one-thousandth part of the maximum current. (*b*) Regulation El. C. 12a, Clause 44 [Connection of Circuits with Earth (a.c. circuits)]. This regulation says that if an a.c. circuit is connected to earth, connection shall only be made at the place where energy is delivered to the circuit, and that this connection shall be made at the neutral point on the star winding. It also contains similar provisions to that set out in (*a*) above. A high-voltage electrode water-heater or steam-raiser is usually star-connected, and the whole of the water and metal work outside the controlling tubes is at the potential of the star point, which is definitely connected to earth through the shell (or through the neutral electrode, if one is fitted). This arrangement is shown diagrammatically in Fig. D.

* Paper by Mr. R. Grierson (see vol. 69, p. 1045).

† *Journal I.E.E.*, 1930, vol. 68, p. 676.

In another type of electrode water-heater or steam-raiser, the arrangement of electrodes is such that the load is delta-star, the star point being the neutral electrode. The shell is earthed, and the star point is connected to earth through the resistance of the belt of water between the neutral electrode and the shell. This is shown diagrammatically in Fig. E. Both these types of apparatus, whether for high voltage or for low voltage, contravene the existing British regulations for earthing. Moreover when earthing at more than one point is permitted, it may still be difficult to keep the out-of-balance current strictly within the limits required to conform with the specified permissible leakage current. The possible introduction of resonance due to multiple earthing must also be taken into account. But earthing the neutral at additional points through the resistance of the water should not disturb the operation of suitable protective systems. Leakage protection is unsuitable for parallel feeders and ring mains because the out-of-balance current due to an earth fault on one feeder would tend to trip out others on the same system.

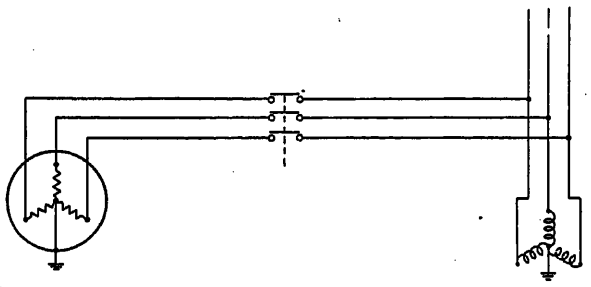

FIG. D.

This would occur with either single or multiple earthing of the system. The degree of trouble may be more severe when multiple earths are scattered over the system, but the inadvertent tripping is then attributable to the protective system, and not to multiple earthing. Leakage protection is intended for normal "tail-end" feeders, and is applicable, therefore, to electrode heating circuits earthed at the neutral; but it must be set heavily enough to prevent inadvertent operation due to the current through its earth path occasioned momentarily by an earth fault occurring on a feeder in the same vicinity. The minimum value of this setting would be $\sqrt{3}$ times the maximum load current. With the development of electrode water-heating on a large scale, it seems to me that we may require a revision of the practice of earthing, and that it may be helpful to earth the neutral at consumers' premises instead of at the source of supply. Given the necessary attention to this question of the earthing of the neutral, the electrode method possesses many advantages.

Mr. T. H. Carr: There is no question but that electricity is seriously handicapped, bearing in mind that the most efficient steam-driven turbo-alternator power station in this country at the present time has an overall thermal efficiency of not more than 24·5 per cent. It must be remembered that the commercial success of any power supply undertaking is absolutely dependent upon the cheapness and reliability of supply. Reliability must, however, take precedence over everything else, even over economy of production. With the introduction of the grid system interconnection will tend to promote security of supply and at the same time reduce the cost of reliability, but whether the cost of electricity to the consumer will be reduced to any great extent (as imagined by many) remains to be seen. On the other hand, the advantages of electrical heating are many, and its final cost to the consumer may in some cases be much smaller than that of other forms of heating. On pages 1058 and 1059 the author gives particulars of rooms, offices, etc., with normal window area. I should like to know what in his opinion is the normal window area of a control room for a power station. From information relating to the control rooms of 12 of the principal power stations in this country I find that the ratio of glass area to floor area varies from 15 to 100 per cent. This ratio affects the size of heating apparatus to be installed. Some authorities

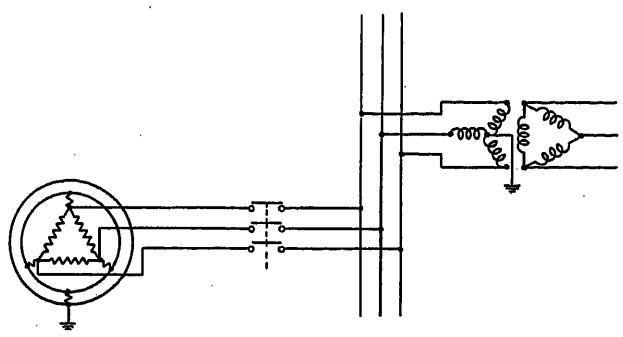

FIG. E.

state that this ratio should be not less than 20 per cent for workshops, etc., while others consider that the normal window area should be 20 sq. ft. per 1 000 cub. ft. of space in the room. Has the author had any experience of the application of thermostatically-controlled electrical heating apparatus to switch-houses and similar buildings, and, if so, could he give any reliable figures regarding the necessary number of air changes per hour and the allowable temperature-rise? I give below five methods of determining the size of thermostatically-controlled heating apparatus for a certain building, and I should be glad of the author's comments on them. Approximate capacity = 98 000 cub. ft.; area of glass = 4 300 sq. ft.; area of exposed wall = 1 000 sq. ft.; area of interior wall = 2 000 sq. ft.; area of floor = 2 800 sq. ft.; area of ceiling = 2 800 sq. ft. One complete change of air per hour. Temperature-rise = 23 deg. F. Sheltered on the north side, otherwise exposed.

Method (1).

No. of B.Th.U. per min. $= w\theta k_p$

where w = weight of air per min. $= \dfrac{98\,000 \times 1}{60 \times 12{\cdot}4}$ lb.

θ = temperature-rise = 23 deg. F.

$k_p = 0{\cdot}24$

Therefore

$$\text{No. of B.Th.U. per min.} = \frac{98\,000 \times 1}{60 \times 12{\cdot}4} \times 23 \times 0{\cdot}24$$
$$= 730 \text{ (approx.)}$$

Now

$$\frac{\text{kW} \times 1\,000 \times 33\,000}{746 \times 778} = \text{No. of B.Th.U. per min.}$$

Therefore

$$\text{kW} = \frac{730 \times 746 \times 778}{1\,000 \times 33\,000}$$
$$= 13 \text{ (approx.)}$$

B.Th.U. per deg. F. temperature-rise of glass, walls, etc., to allow for radiation losses (only approx.) $\frac{1{\cdot}0}{0{\cdot}3} = 3{\cdot}5$ approx.

Approx. kW capacity of heating apparatus

$$= 13 \times 3{\cdot}5$$
$$= 45 \text{ kW}$$

Method (2). *Wilmshurst's Formula.*

$$\text{kW capacity} = \frac{20{\cdot}4(30a + 8b + nc)\theta}{36 \times 10^5}$$

where

a = area (in sq. ft.) of window surface = 4 300
b = area (in sq. ft.) of wall, floor, and ceiling = 6 600
c = volume (in cub. ft.) of air in room = 98 000
n = number of complete air-changes per hour = 1
θ = temperature-rise of air (in deg. F.) = 23.

Therefore

$$\text{kW} = \frac{(30 \times 4\,300 + 8 \times 6\,600 + 1 \times 98\,000) \times 20{\cdot}4 \times 23}{36 \times 10^5}$$
$$= 37 \text{ (approx.)}$$

Method (3). *Young, Osmond, and Young's Formula.*

$$\text{kW} = \frac{AU\theta}{1\,000}$$

where

A = floor area (sq. ft.) = 2 800
U = 595 (for 36-ft. high room)
θ = temp. difference = 23 deg. F.

Therefore

$$\text{Capacity of heating plant} = \frac{2\,800 \times 595 \times 23}{1\,000}$$
$$= 38 \text{ kW}$$

If this formula is applied the normal glass area should not exceed 20 sq. ft. of glass per 1 000 cub. ft. of space. The formula therefore does not strictly apply in this case.

Method (4). *Grierson's Method.*

Section	Area	B.Th.U. per deg. rise*	Heat loss per degree	Temperature difference	Total B.Th.U.	Equivalent watts
	sq. ft.			deg. F.		
Glass	4 300	1·1	4 300	23	98 900	28 800
Exposed wall	1 000	0·3	300	23	6 900	2 000
Interior wall	2 000	0·3	—	—	—	—
Floor	2 800	0·4	1 120	23	25 800	7 500
Ceiling	2 800	0·4	1 120	23	25 800	7 500
Air (cubic feet) ..	98 000	0·02	1 960	23	45 000	13 000
Totals					202 400	58 800

* Taken from the author's table (see vol. 69, p. 1088).

Approx. capacity of heating plant = 60 kW

Method (5).

A figure of 0·8 to 1 watt per cub. ft. of building is sometimes used by architects.

Adopting the lower figure of 0·8,

$$\text{kW capacity of heating plant} = \frac{98\,000 \times 1 \times 0{\cdot}8}{1\,000}$$
$$= 78$$

Mr. W. Richardson: While I agree that the author's new system approaches the ideal form of heating, I think we have to admit that it cannot compete with other forms of heating on a purely commercial basis, when energy is charged at a rate which is profitable to the supply undertaking. There will, however, be a large field for this type of heating in small buildings and suites of offices where it is desired to avoid the complication of a central-heating plant and where satisfactory heating is important. So far as larger buildings are concerned, the author's system will be in competition with central-heating installations; throughout the paper he avoids any detailed comparisons between the two, confining his remarks to a general statement of overall efficiency. Table 16 shows the various losses which may occur on fuel-fired installations, and the author finally arrives at a figure of 15 per

cent for the overall efficiency of such systems. This value appears to me to be too low. Some inquiries which I have made regarding various local buildings show that the figure should be at least 30 per cent, assuming that 0·72 kWh per cub. ft. is the minimum amount of energy required during the heating season. The paper is unfair to thermal-storage equipments, which are stated on page 1080 to have a working efficiency of only 30 per cent. From this statement the author proceeds to make out his case for low-temperature panel heating, instead of thermal-storage heating. He gives a figure of 0·72 kWh per cub. ft. per annum for the consumption of the low-temperature panel system; a similar figure has been obtained with thermal-storage heating for large office-block buildings, and for a medium-size block of office buildings situated in an exposed position the figure during the second heating season was 1 kWh per cub. ft. Apparently there is not a great difference between the consumptions of direct and thermal-storage heating systems, but as a much lower rate for energy can be obtained for thermal-storage heating it naturally follows that the running costs of the latter are the lower. In Appendix X the author gives the energy consumptions for thermal-storage and direct heating as 562 000 and 441 000 units per annum respectively, which is contrary to the statement he makes earlier in the paper. The capital cost of the thermal-storage system is given as £10 300 for an installation of 368 kW, or approximately £28 per kW. An installation carried out in this city was completed for slightly over £9 per kW, and although this does not include thermostats and solenoid valves in each room, this omission would not account for the whole of the difference. If the capital cost of the installation were corrected, and a more reasonable figure given for attendance and maintenance, there would be an ample credit on the side of thermal storage. If electric heating is to be satisfactory, it is essential that installations should as far as possible be under automatic control. Whilst this is an essential feature of the low-temperature panel system, it can also be incorporated in thermal-storage heating. In the second case to which I have referred a thermostat situated in a central room is arranged to control the heating of the whole building. A time clock is also provided, so that heating can be started in the early hours of the morning to ensure that the offices are at the required temperature by 9 o'clock.

Mr. T. Carter: The Satchwell thermostat is an interesting device. It seems to depend for its much more successful working with alternating than with direct current on the fact that a short, not necessarily quick, break is perfectly satisfactory for the interruption of an alternating current, but not so for a direct current. Tests with much cruder apparatus, namely ordinary British Standard protected-type plugs and sockets (B.S.S. No. 196), have shown that, however slowly the plug is pulled out of the socket, a very small gap between the brass pins and brass contact-tubes is sufficient to open an a.c. circuit; and a series of tests at the National Physical Laboratory a few years ago proved the excellence of the operation of such plugs and sockets in a.c. circuits, even under abnormally severe conditions. Perhaps the metal of the contacts has to be carefully selected in an accurate controlling device like the Satchwell thermostat; but for mere circuit-breaking purposes the ordinary material of plugs and sockets is amply good. The point of importance is that the principle of circuit-breaking embodied in a refined way in the Satchwell thermostat can be applied widely in a.c. circuits generally, and its fullest use in suitably-designed apparatus would lead to much simpler switching than is usual to-day for alternating currents up to, say, 15 amperes at 250 volts. Incidentally, the word "freeze" is used in what seems to me a rather unusual sense in the tenth line from the foot of the left-hand column of page 1067. It is more commonly applied, I think, to the welding-together of contacts in a circuit breaker than to the mere solidifying of molten metal, strictly accurate as the latter meaning is.

[The author's reply to this discussion will be found on page 211.]

North Midland Centre, at Leeds, 10th November, 1931.

Mr. W. R. T. Skinner: The author is to be congratulated on co-ordinating in one paper so much scattered information and so many individual opinions on all aspects of this problem. I gather that he is in favour of low-temperature panel heating in preference to the many other possible systems, although he mentions (page 1055) that in his dining-room he has found a temperature of 55° F. with a 2-kW radiator to be "very comfortable indeed." On the ground of comfort I prefer the last-mentioned arrangement to the low-temperature panel system which aims at maintaining the relatively high and uniform air temperatures set out in Table 5. If we put aside for the moment all questions of artificial heating and consider what are the ideal natural circumstances of comfortable warmth, I think that most normally active individuals would agree that the best and most invigorating conditions obtain on those bright days in spring when the air temperature is comparatively low and the sun sufficiently high to be perceptibly hot. I suggest that the conditions most conducive to activity and work are a comparatively low ambient temperature with some form of high-temperature radiation, rather than uniformity of temperature of air and surroundings. Table 5 is in my opinion calculated to give rise to a large number of common colds. Living for a number of hours a day in uniformly warm surroundings seems to me to lower one's vitality and one's resistance to cold and colds. I would much prefer an ambient temperature of 50 to 55° F. supplemented by a high-temperature radiator rather than do without the radiator and have a uniform temperature of 65° F. A close approximation to what I suggest are the ideal outdoor conditions, demands the use of high-temperature rather than low-temperature radiators with possibly (at some future date) the addition of a small amount of ultra-violet radiation. I think that the radiators should be fixed to the ceiling or high up on the walls where they would be out of the way

and, beyond question, safe. For this purpose the bowl fire is eminently suitable as regards design, although it is not always large enough for heating large rooms. It is, however, well adapted to the heating of small rooms, especially the heating of bathrooms where the fact of the radiator being out of reach is of paramount importance. For the past 3 years I have heated a bathroom and a small bedroom in this way, the bowl fire in each case being fixed to the wall just below the ceiling. The author mentions consumptions per head for domestic use of 30 units per annum, with a possibility of 300 in the future. As the result of running a practically all-electric house for 5 years I find that the consumption per head has never fallen below 2 000 units per annum, of which rather over 40 per cent are absorbed by appliances for heating the house. In addition, two coal fires are in use during the winter. Only high-temperature radiators are used, the installed capacity being as follows:—

	Maximum loading of radiators	Net cubic content of room	Watts per cub. ft.
	kW	cub. ft.	
Dining-room ..	2·25	1 050	2·14
Sitting-room ..	3·2	1 460	2·19
Small bedroom ..	0·6	640	0·94
Nursery	1·0	1 040	0·96
Bathroom	0·6	400	1·5

A coal fire is used in the nursery in cold weather, the radiator capacity of 0·96 watt per cub. ft. being insufficient to deal with low-temperature conditions. I should say, however, that a radiator capacity of 2 watts per cub. ft. is sufficient to produce comfortable conditions within 10 minutes of switching on. As regards casual heat due to lighting, I find that the loading in the sitting-room amounts to 370 watts, or 2·4 watts per sq. ft. of floor area, this figure being equivalent to 11·5 per cent of the capacity of the radiator. I should like to know whether the author's figures in Appendices V and VI are based on the gross cubic capacity of the buildings or merely on the net cubic capacity of rooms, etc., heated. My own figures for 52 weeks ending 25th October, 1931, amount to 5 273 units used principally for heating (a small part of this consumption is due to kettles, an iron, and a vacuum cleaner, which are not separately metered), equivalent to 0·421 kWh per annum per cub. ft. based on the gross cubic capacity of the house and 1·148 based on the net cubic capacity of rooms heated wholly or in part by electricity. I estimate that the annual load factor is approximately 12 per cent. In Appendices V and VI the author distinguishes between the annual consumption of various thermal-storage and direct heating installations respectively. I have averaged those figures which are complete and find 1·69 kWh per cub. ft. per annum for thermal-storage systems as against an average of 0·517 for direct heating. If these are representative averages, the thermal-storage system uses something like 3¼ times as much energy as the direct system. Or, put another way, if one can afford to run thermal-storage systems at 0·25d. per kWh, one can afford to pay something like 0·8d. per kWh for direct heating. It is stated that low-temperature embedded panels produce no pattern staining on walls or ceilings due to deposition of dust. For what periods have these panels been in use without causing selective discoloration of the plaster or its decoration? The Department of Scientific and Industrial Research have recently investigated this state of affairs, and they attribute selective deposition of dust to the slight variation of temperature of the plaster surface resulting from the different thermal conductivities of lath and plaster. Variation of surface temperature must be much more marked where heating panels are embedded in the plaster, and it seems to me that pattern staining would be correspondingly accentuated.

Mr. G. Wilkinson: With reference to the low-temperature panel system, I installed one of the earliest water-heated panels (8 ft. long by 2 ft. 6 in. wide) opposite an alcove in my house some years ago, and in order to give a cheerful effect a rectangular recess was formed in the panel and fitted with a polished copper reflector and a lamp-holder, into which a 250-watt radiator lamp was inserted. As an illustration of the comfort and economy of radiant heat, I would state that whereas a temperature of 60 to 62° F. is required for comfort in a sitting-room heated in the ordinary manner, the alcove is quite comfortable with the thermometer reading 3 or 4 deg. F. lower. Table 1 mentions iron, oil, and water as three practicable heat-storage media. Three or four years ago in visiting a church heated electrically by the well-known tubular system, I found that the alarmingly high maximum load of 230 kW was taken by the installation. This figure indicates at once that success from the economic standpoint for electric heating does not lie in the direction of hand-to-mouth methods of that type, but that some kind of thermal-storage system must be adopted. The author deals in detail with hot-water storage and non-storage methods of electric space heating only: I wish to speak of the use of cast iron, as I have recently had some surprising experience of its heat-storage properties. Although Table 1 gives the maximum working temperature of iron as 700° F., it is futile to expect iron to emit much heat at so low a maximum temperature. By way of illustration of this point, if a poker is put into the fire and withdrawn when it is red hot, say at 1 200 to 1 500° F., it will lose its glow very quickly, i.e. the emission of heat to the atmosphere will be rapid, but after it has cooled to a black heat the emission becomes less and it is a long time before it becomes cold enough to be handled at the heated end. Again, castings and steel ingots soon lose their glow on emerging into the open, but as they cool the heat emission becomes slower and is extremely sluggish at the lower temperatures. I have in my house a space heater in which cast iron is the heat-storage medium, the temperature of which rises to about 1 400° F.—a dull cherry red. The heat emitted from this glowing mass is transferred to a low-temperature surface, the working temperature of which is taken care of by a room thermostat operating upon a heat-emission valve placed between the heated mass of iron and the outer casing. In this manner the heat emission to the

apartment is automatically regulated independently of the temperature of the heated mass of iron, the maximum temperature of which is also controlled automatically by a simple device. Table 1 gives the minimum working temperature of iron as 200° F.; this again is a practically useless figure, as one cannot profitably employ cast iron at temperatures lower than 300 to 350° F. Below this figure the rate of heat emission is too slow for most practical purposes. If good results are to be obtained, the working range should not be less than 1 500–350° F. This gives the high heat-storage figure of 150 B.Th.U. per lb. of iron and changes the whole aspect of the problem of successful thermal-storage heating. Instead of storing 29 800 B.Th.U. in a cubic foot of iron—at a capital cost of 18s. 8d., as set out in Table 1 (some of this being practically useless, due to its low temperature)—we get 67 500 B.Th.U. per cub. ft. at a capital cost of something like 6s. only per 10 000 useful B.Th.U. stored. If the heat-insulation sleeve and valve be lifted off the glowing mass of iron the room temperature goes up quickly to a point which is distinctly uncomfortable; this, however, is a valuable characteristic, showing as it does the extreme flexibility of heat storage at high temperatures in cast iron. It also has a high economic value, as a heater of given rating can be called upon to perform the double duty of continuous heating and the quick heating of a cold apartment, the maximum demand for a given building being halved thereby. This should have the good effect of enabling considerably lower tariffs to be offered for such supplies without in any way decreasing profits. Many designs embodying the distinctive features of this type of heater may be made. The non-storage heating panel mentioned at the outset is built of 30-in. by 16-in. sections each of which weighs 35 lb. and emits 2 760 B.Th.U. per hour. In its simplest form the heat-storage apparatus consists of an outer vertical cylinder of planished sheet steel with a centre core of cast iron in the form of a column of square section. This is surrounded by a sleeve of sheet metal sliding over the column and furnished with insulating flanges at each end, the upper flange carrying a valve which controls the heat emission to the outer casing which may in turn be controlled by a room thermostat, as already described. The casing between its upper and lower flanges is wound with thin crinkled aluminium foil in 4 to 6 layers, which constitutes a surprisingly good heat insulation, the whole being covered on the outside by an enveloping cylinder of sheet tin. This concentric casing can readily be lifted in and out of the heater; it is arranged with a clearance below so that air from the outer casing can circulate between the heated iron and the outer heat-emission cylinder. The necessary ducts in the hot chamber are provided by the passages on the four sides of the heat block formed by its flat sides and the curved surface of the enveloping sleeve of sheet metal. Referring to Appendix X, the estimated capital costs given are £10 300 for the hot-water storage system and £5 300 for the panel system. With cast-iron heaters of the type already described one can get the same number of heat units and an equivalent distribution of heat for a capital outlay estimated at £2 500 to £3 000. The annual costs are given as £1 974 and £1 630 respectively. With cast-iron storage each heater is self-contained and there are therefore no heat losses due to radiation from pipes or tanks, and there are no circulating pumps to run; therefore the 25 per cent extra kWh allowed in the hot-water system to meet these losses must be deducted, and the annual energy consumption becomes the same as for panel heating, viz. 441 000 kWh per annum. The iron storage-heaters take their current during off-peak hours and the units consumed are therefore chargeable at the storage rate of 0·3d. per unit quoted by the author, instead of the 0·594d. per unit for the non-storage panel system. Allowing the same percentage for interest and depreciation as is set down for the panel system, and adding the £10 per annum for attendance, the annual cost comes out at only £761, or over 100 per cent less than for the non-storage panel system. In this figure no allowance is made in respect of the substantially-decreased maximum demand required due to the extreme flexibility in the output of this class of heater.

Mr. H. G. Fraser: I think that we ought to be very cautious in preparing estimates for electric heating on a fairly big scale, otherwise we are likely to do the industry a great deal of harm at the outset. If, on the other hand, electric heating is carefully tackled, it will lead to opportunities of greatly helping the industry. I have a few figures for tubular heating that may prove interesting. They represent an elementary-school installation which has been in service for a little over two years, thermostatically-controlled tubular heaters being employed throughout. The total installed capacity is some 140 kW and the maximum demand rarely, if ever, exceeds 130 kW, this load invariably coming on between 8 and 10 a.m. Usually the full load is on at 8 a.m., and the load gradually decreases as the thermostats come into operation. Towards 10 a.m. the load is probably 100 kW. In the afternoon the load comes on again for a short time just after lunch when the school opens, but not to the same extent. It never exceeds 100 kW in the afternoon, and it gradually falls at about 3 p.m., when there is probably less than half load on, given a reasonably cold day. At 3.30 p.m. 20 or 30 kW are being taken, and the whole load is off at 4 p.m. Although it does not affect the power-station peak, the load is not a cheap one to supply. The flat rate at which we give this supply at present is 0·55d. per unit. The consumptions for the last two years have been 86 000 and 96 460 units respectively, which work out at roughly £196 and £216 per annum. If it is true that the installation enables the school authorities to dispense with the caretaker's labour, etc., the proposition is a good one from their point of view. If it is not true, however, the price will have to be reduced, assuming that no great value is set on the superior convenience and cleanliness of electric heating. I think that in an industrial district, certainly in the West Riding of Yorkshire, the convenience, etc., of the electrical installation is not assessed at so high a value as it is in other parts of the country. We have established that this type of load is a distinctly "off-peak" one so far as the power station is concerned, but it is only on for the winter months and is not used in June, July, August, and September, except occasionally. The supply always

has to be available, however, because with electric heating the necessity for shutting down the school heating system for a fixed period during the summer regardless of temperature, does not arise. The electric heating system is always available and is used accordingly.

Mr. E. A. Logan: I worked for a considerable period in a large building equipped with a thermal-storage heating system with embedded panels, and one of the features which impressed me most was the enormous effect of air humidity on the feeling of warmth experienced. I found that when working at a temperature of 63° F. on a dry day quite a number of people complained of being too hot, whilst on a foggy day they complained that they felt cold at the same room temperature. I think that not only will the embedded-panel system suffer from this variation of sensation with humidity, but so also will the thermostatically-controlled system. In time engineers will no doubt evolve a new thermostatic system which will take account of the humidity. I found that if a wet overcoat was hung up to dry in the building to which I have referred, it was just as wet a few hours later, because in the highly saturated atmosphere the moisture percolated through the coat without drying out. The garment thus became practically useless for the time being. In some of the first buildings to be heated electrically the ventilation problem was rather neglected. I think that the engineers responsible for the designs were rather concerned at the amount of heat they would lose if the ventilation were adequate. The problem has been dealt with better in later installations and in at least one case a rather elaborate air-conditioning plant, involving a certain amount of regeneration, has been installed. The author may be able to give us some details of this system. The paper reveals that new kinds of fixtures and a new electrical heating technique are being developed. Materials are being used which do not belong properly either to the electrical or to the building trade, but partly to both. I should like to know how the labour question is dealt with on these heating installations. In London, in particular, there are at present very great difficulties in this connection. For example, if an electrician requires a hole through a wall he has to have a bricklayer's labourer to make it. One great advantage inherent in an electrically-heated building with embedded heaters is worthy of comment. Sometimes in the spring there is a rapid rise of air temperature coupled with a high degree of humidity. Under this condition in a building with cold walls and floors, particularly with marble panels or painted surfaces, a distressing weeping effect is created by water running down the walls. This does not occur in an electrically-heated building, due to the walls being warmer than the surrounding air. I am interested in the easily-applied heating method which the author has evolved, but I should like to know whether the material used is non-inflammable. I have recently had an unfortunate experience with a low-temperature heater made of an inflammable material. The latter being in a dry state, when slight arcing occurred it began to smoulder. With regard to the question of high-temperature versus low-temperature ceiling radiators, can the author give any information as to the possible physiological effect of high temperatures overhead? I have heard it suggested that high-temperature heating placed overhead is liable to set up a condition closely approximating to sunstroke. Fig. 15 gives the results obtained with a thermostatically-controlled non-thermal-storage system, a system which the supply engineer is rather inclined to disparage from a load-factor point of view, fearing that the incidence of the heating load will add to his normal load peak. It will be seen that the curve is almost the obverse of a normal load curve, with the exception of a period about 9 a.m. I think Fig. 15 is worthy of study by the supply engineer from the point of view of levelling the load on his mains.

Mr. R. M. Longman: Mr. Wilkinson has, I think, gone a long way towards saving the situation for the supply undertakings, by a system of heating iron up to a temperature of about 1 700° F., which reduces the cost and completely alters the figures for Appendix X. His method is rather similar to that adopted in the thermal-storage systems used in Norway and Sweden with great effect and satisfaction. If we can develop on those lines, there is great hope for industrial electric heating. I should like to ask Mr. Wilkinson the weight of the heater which he has in use at his own house. Before coming to this meeting I felt that we ought to pay special attention to thermal-storage systems to assist in filling up the night valleys in the load curves. The ideal load would come on any time after 9 p.m. and go off at 9 a.m., with a refresher between 12 noon and 2 p.m., and partial load after 5 p.m. In a certain town they were recently considering heating the schools and public buildings electrically, and the engineer was very sceptical as to whether this would give such an increased demand in the morning that the peak would occur in the morning due to this industrial heating. I trust that he has carefully studied the paper and consequently feels reassured on this point. Domestic heating is quite a different proposition from industrial heating. As a substitute for a coal fire one must provide something that is pleasant, attractive, bright, and cheerful. My home installation, which heats an 8-room house occupied by 6 persons, has a consumption of 9 000 units per annum for all purposes, but coal fires are used in the kitchen and dining-room during the winter. All the cooking and about 75 per cent of the water heating is done electrically. What is wanted is an increase of the domestic load, which is always with us, both in good times and in bad.

Mr. W. Dundas: The supply engineer must spread the author's enthusiasm for electric heating if progress is to be made. The task is by no means easy, the load being entirely seasonal, thus adding to the demand on the station at times of heavy loads and thereby mitigating against the requirements of a low tariff, upon which the success of electric heating from the point of view of the supplier is primarily dependent. Winter-evening peak-load hours must be ruled out entirely, which indicates that electric heating will certainly have to rely on heat storage on the consumer's system. Again, the load curves shown in Fig. 15 indicate a decided peak at 9 a.m., and it is quite conceivable that that peak may rise considerably with the development

of the heating load unless some restriction be made to cover the period in question. From experience of steam heating, I am convinced that it will be necessary to get down to a low figure in the region of 0·2d. per unit to attract custom, but this figure is permissible only during off-peak hours. The more efficient application of electric heating compared with the other systems mentioned by the author, together with other advantages, will assist, no doubt, in obtaining a more economical overall price per kWh. The heating load is attractive inasmuch as it will help to fill the early-morning gap in the load curve, about which all supply undertakings are much concerned, and whether the advantage thus obtained will enable an attractive day-load tariff to be secured calls for careful investigation.

Mr. G. W. Jenkins: I should like to add a word to Mr. Logan's remarks about humidity in connection with electrical heating. I believe that a lot of the smell, or the "stuffy" feeling, that has been mentioned in the paper and by other speakers is due to the excess of humidity set up by fairly high-temperature heating. A radiant-heat system enables one to get a degree of comfort by maintaining a very much lower temperature of the room, and the thermometer is therefore not necessarily a guide to the state of comfort of the individual. I believe that a lower temperature gives rise to a lower degree of humidity and therefore tends to eliminate "stuffiness" and smells while still maintaining the state of comfort of the individual. Perhaps the author could enlarge upon this particular feature. Mr. Longman has mentioned that the conservative ideas of electrical heating held by some people in this country make them insist upon seeing the source of heat, i.e. some sort of glow. I think that this is a matter on which electrical supply engineers should educate the public. In travelling America from one end to another one never comes across an open fire. Evidently the Americans have been educated up to the degree where they can feel comfortable and warm without seeing the source of heat, or any kind of glow.

Mr. C. F. Wells (*communicated*): Whilst I agree that thermostatic control is generally desirable, I think there may be a danger of the electric system losing some of its advantages if rooms in occasional use only, such as bathrooms, are continuously maintained at a temperature of, say, 60° F. In a 6-room all-electric house I carried out the whole of the heating with electric fires for a consumption of 6 800 units per annum, which worked out at 1·1 units per cub. ft. per annum. On the same basis I estimate that there is a potential market for 200 to 300 million units per annum for the heating of houses in the United Kingdom. One of the installations for which my company has been responsible is a Roman Catholic church where 40 kW of tubular heaters are installed. In this case the consumption is 9 800 units per annum, which works out at 0·1 unit per cub. ft. per annum.

[The author's reply to this discussion will be found on page 211.]

SOUTH MIDLAND CENTRE, AT BIRMINGHAM, 7TH DECEMBER, 1931.

Mr. E. A. Reynolds: It is now recognized that electric heating has entered into competition with other methods of heating buildings and that as regards cleanliness, adaptability, ease of control, and variety of application, it has advantages over those. There are, however, two other considerations—comfort and economy—to be taken into account. The sense of comfort of the human body as far as warmth is concerned depends much more on the heat received by radiation than on that received by convection. A much greater sense of comfort is experienced in a room where the air is moderately cool and radiant heat is acting on the body, than in one where the air is heated to a higher temperature without any radiant heat. A low air-temperature is also an advantage from the point of view of health. Radiant heat makes it possible to have better ventilation and even open windows without feeling that heat units are being extravagantly wasted by driving the heated air out of the room. We have all experienced the feeling of healthy comfort given by bright sunshine in a still atmosphere that is well below freezing-point, and this is a good object lesson to guide us in our efforts to give comfortable and healthy heating of buildings, and more particularly of the living-rooms in our own houses. This end can be more satisfactorily attained by electric heating than by any of the other systems. Probably the most economical and healthy way to heat a living-room would be to install some form of low-temperature heating such as electric panels or tubes, so as to maintain a moderate temperature, and to augment this by an electric radiator of the reflecting type. This would provide a definite source of radiant heat which can be moved to any part of the room, and which in addition to its heating effect would introduce a centre of interest which is absent in uniformly heated rooms. The question of the general use of electricity for heating depends entirely on the relative cost of electrical and other systems, bearing in mind the advantages peculiar to electric heating. The fact that the unit of electrical energy represents 3 415 B.Th.U. has been extensively used as an argument against the use of electric heating, by comparing this quantity of heat with the very much larger amount of heat energy represented by the amount of coal necessary to produce that electricity. This is, however, quite beside the point, as the important question is the actual cost of obtaining heat at the particular position in the form required for comfort. This figure is best settled in actual practice, and it does not depend entirely on the fundamental facts of the theory of heat and calculations of heat losses in various forms. The essential factor in the general use of electric heating is, therefore:—What is the lowest price at which the supply authority can afford to distribute this energy, and at that price is it economical for the consumer to use that energy for electric heating? The author states that it is more economical to maintain the temperature of a building constant throughout the day and night, than to allow it to fall during the night and be raised again the next morning, and also that under many conditions the load is a minimum during the late after-

noon. If this is the case, such a heating load would be an ideal one from the point of view of the supply authority, and it should be charged for at the lowest possible rate. In some areas current for this purpose is now being sold at ½d. per unit, and in other areas this price is charged for domestic water heating and for heating loads in factories. Thus there is apparently no reason why the continuous heating load for private houses and public buildings should not be charged at the same rate. If supply authorities were to adopt this rate for such purposes, the probability is that they would soon have to increase the size of the distribution mains in the centres of large towns to deal with the increase of continuous output that would have to be met.

Mr. F. C. Platt: Although, as the author remarks in his Introduction, the seeds sown by the Electrical Development Association are bearing fruit, a good deal remains to be done in the way of education, and the amount of money spent on advertising in the lay Press should be tremendously increased. Regarding his statement that more attention is being given to electrical matters by the lay Press, I am of opinion that public services have no news value unless they go wrong; thus a tube failure at the rush hour, a black-out in the West End of London in the evening, the fume question, etc., all constitute news, whereas the application of electricity does not. The germ of the whole paper lies in the comment (on page 1080) regarding pollution of the atmosphere. The public does not realize the extent of the injury to health and fabric caused by smoke, and a determined effort to suppress this nuisance would direct the public mind towards the desirability of using electricity generated in power stations where fumes can be rendered innocuous before being discharged to the atmosphere. We are practically no further advanced than in mediæval times as far as domestic space heating is concerned, and in this connection I would deprecate excessive emphasis on the financial aspect. Surely the virtues of electrical space heating are worth the slight extra cost. At the risk of seeming inconsistent, I submit the following figures for comparison with those given in Appendix VIII.

Type of Building. Single-story mills; north-light roof.
Heating Season. 30 weeks.

Type of Heating.
Works A. Steam 185 lb. per sq. in., superheated 100 deg. F., reduced to 60/90 lb. per sq. in., and circulated through pipes suspended at 9 ft. above floor-level.
Works B. Steam generated at 40/60 lb. per sq. in., saturated, circulated through pipes as in "A."

Volume of Building.
Works A. $12{\cdot}1 \times 10^6$ cub. ft.
Works B. $1{\cdot}16 \times 10^6$ cub. ft.

Total Slack Burnt.
Works A. 2 422 tons.
Works B. 392 tons.

Total Steam Supplied.
Works A. $33{\cdot}67 \times 10^6$ lb.
Works B. Not recorded.

Slack per cub. ft.
Works A. 0·45 lb.
Works B. 0·756 lb.

Steam per cub. ft.
Works A. 2·78 lb.
Works B. Not recorded.

The whole of the figures are for 30 weeks.

Fuel Used. Slack, about 9 500 B.Th.U. per lb. as fired.

Mr. J. Anderson: It is a great pity that so much endeavour should have been expended in so poor a cause as the one championed by the author. He himself appreciates that it is a bad cause, for in the Introduction he states:—"Very many technically-trained men at present hold the opinion . . . that electricity is hopelessly handicapped." If he had substituted "all technically trained men know" he would have been nearer the truth, because to heat buildings economically by electricity is impossible. It is only when economy becomes less and less important, and convenience—whether of use or of installation—becomes more and more essential, that a case can be made for electrical heating. In the heating of a workshop the problem is presented in its simplest and crudest form, for there economy is imperative. I have worked out the following costs for two workshops. The first is a large workshop covering nearly 3 acres, with a total cubic content of approximately 1½ million cub. ft. The plenum system is used; low-pressure steam raised in a boiler passes through pipes to nests of tubes over which air is blown by electrically-driven fans into large ducts carried the length of the buildings. The condensed water is pumped back into the boiler, and only a very little make-up water is needed from time to time. The shops are usually very comfortable to work in, although on very cold mornings when the stoker has not kept the fires up the temperature has on some occasions been rather low for the first hour or two. The system was started 14 years ago, and was extended as the works grew. With coal at 20s. per ton, stoking at £4 14s. 6d. per week, and electricity at 0·96d. per unit, the cost works out at 0·000021d. per cub. ft. per hour over the whole 12 months, i.e. 8 700 hours. Assuming 14 000 B.Th.U. per lb. of coal, there are 1·48 B.Th.U. per cub. ft. of air space per hour at the coal heap. Taking October to April (5 100 hours), the corresponding figures are 0·0000345d. and 2·43 B.Th.U. Turning to the author's figures for a London office, although he buys electricity at 0·675d. per unit as against the 0·96d. which a large consumer has to pay in Birmingham, his cost is 0·000095d. per cub. ft. per hour over 5 100 hours, and there are only 0·485 B.Th.U. in the air. Assuming the efficiency of the steam plant to be only 50 per cent, the electrical cost at 0·675d. per unit would be 6·9 times the present cost, and at 0·96d. it would be 9·8 times. The second case is that of a small workshop 60 ft. × 20 ft., the volume being 11 700 cub. ft. It is partitioned into three parts, 40, 10, and 10 ft. long. The

40-ft. part is heated by a specially designed gas heater located towards the partitioned end; the flue is carried along the centre of the shop and passes out through the end gable. The temperature of the discharge gases is about 112° F. The other two parts are heated by eight resistances, two under each window, and they are run either at a dull red heat or just below it. A comparative test was made on a mild day with no sun, no fog, no rain, and very little wind, when the outside temperature was constant at 42° F. throughout the duration of the test. The temperature at 5 ft. from floor-level in the gas-heated part was 57° F. at the coldest spot and 63° F. at the bench nearest the stove. Similar figures for the electrically-heated part were 59° F. at the coldest and 61° at the warmest, so that the mean temperature was the same in both cases. The price of gas is 7·79d. less 5 per cent per therm (3s. 1d. per 1 000 cub. ft., less 5 per cent), and of electricity 1½d. per unit. The results were 0·000336d. per cub. ft. per hour for gas, and 0·0018d. per cub. ft. per hour for electricity, or electrical heating was 5·35 times as costly as heating by gas. The largest consumers in Birmingham buy gas and electricity at about 62 per cent of the price I pay, so that the ratio would remain unaltered in their case. Taking the efficiency of the electric heaters as 100 per cent, the B.Th.U. supplied to the air per cub. ft. per hour are 4·05, and taking the official figure of 475 B.Th.U. per therm for the calorific value of the gas the corresponding figure is 4·55 B.Th.U. per cub. ft. per hour. This makes the efficiency of the gas heater 89 per cent, which is quite a likely figure in the circumstances. That there is not much wrong with my figures for electricity is shown by the fact that if one reduces 0·0018 in the ratio of the price per unit and the B.Th.U. in the air, one gets 0·000097 as against the author's 0·000095. Coming higher up the scale to small houses of £50 to £80 rateable value, the position is a little more favourable. I have lived in and fitted out six houses in the past 25 years; the first two were completely gas-heated, except for the water heating, the next was equally completely electric, the next two were gas, and the last has a mixed system—coke, coal, gas, and electricity—which I am satisfied is the only one giving the maximum of comfort and convenience at a reasonable price. Continuous heating, advocated by the author, is not attempted and it would not be of much use since the whole house is thrown open to the four winds of heaven from 9 a.m. to 12 noon, and some of the windows are practically never closed. Only the fixed charge plus ¾d. per unit makes the limited use of electricity for heating at all possible; the overall charge works out at 0·985d. per unit for all purposes in my case.

Prof. W. Cramp: The author omits all reference to the physiological aspect of electric heating, although this appears to me to be the factor which, in the future, will control the type of radiator. The recent experiments of Prof. Leonard Hill lead one to believe that low-temperature radiation should not be encouraged, and my own experience is in exactly the same direction. Children are very good and unprejudiced judges of what is comfortable. I had a nursery and for some years it was heated by means of an anthracite stove, which maintained an even temperature of about 60 to 65° F., day and night in the room, yet the children constantly complained of feeling cold. I substituted a radiator of the lamp variety, which was switched on about half an hour before the room was used, but in a very short time after entering the room and remaining in the direct radiation the children asked that the radiator should be switched off, although the temperature was only 50° F. This occurred repeatedly, and an analysis seemed to show that the effect of the radiation was to stimulate the action of the skin, so that the natural circulation materially improved, and the effect of warmth was produced without that dryness of the air and excessive evaporation from the skin which accompany all systems that give a uniform air-temperature. I believe that direct high-temperature radiation is much more akin to the effect produced by summer sunlight than any kind of low-temperature radiation or convection heating, and in addition the cost of heating electrically by such means is very much lower. The transfer of heat also is quite different, when such radiation is employed. Dark objects, including practically all furniture, absorb the radiation and rise to a temperature higher than that of the surrounding air, which is in accordance with what takes place under pleasant conditions in nature. As a result, no feeling of cold is experienced in touching such objects, whereas if the heat be transferred to the air first and to the furniture through the air, the opposite effect is produced. It may be useful to add a comment upon the calculations which are usually made in connection with coke stoves. The conditions which obtain in practice are not at all the best for producing that high efficiency which is often quoted. In most offices and houses the coke stove runs for many hours with bright burning fuel at the bottom and cold coke at the top. In consequence, it acts as a producer, turning out large quantities of carbon monoxide, which pass away up the flue. When the bulk of the fuel becomes red hot, this gas can be seen burning with its characteristic blue flame in the upper portion of the stove, and only then is the stove efficient; for the quantity of heat given out by the change from coke to carbon monoxide is far smaller than in the change from the monoxide to the dioxide.

Dr. L. G. A. Sims: I should like to comment upon Section 11 (page 1050) of the paper, which is apparently based upon information given in the recent paper on "The Heating of Buildings Electrically by means of Thermal Storage"* and perpetuates what seemed to me a somewhat serious omission from that paper. I refer to the omission of information relating to the unit type of thermal-storage heater employing as the storage medium blocks of suitable stone or of iron, instead of water or oil. Circulatory liquid storage systems are not the only ones worthy of consideration by the heating engineer. In my opinion both the floor-heating system used abroad and the unit-type heater should have been mentioned by the author, particularly as he criticizes the hot-water system rather severely. Information relating to the floor-heating system of thermal storage will be found in the contribution which I made to the discussion† on the paper by Messrs. Monkhouse and

* S. E. Monkhouse and L. C. Grant: *Journal I.E.E.*, 1930, vol. 68, p. 657.
† *Ibid.*, vol. 68, p. 698.

Grant, and I propose on this occasion to confine my remarks entirely to the unit type of heater. This consists of an accumulation core of blocks of cast iron or suitable stone enclosed in a heat-insulated casing. While an iron core is very convenient for manufacturing reasons, its weight is a slight disadvantage. A stone core is very much lighter, but as it has rather less storage capacity per unit weight it must, in general, be run at a somewhat higher temperature than one of iron. Furthermore, many forms of stone are unsuitable on account of their poor thermal and mechanical properties. In a heater of the unit type developed at the University of Birmingham from a rather crude and inefficient model to an efficient and practical heating device, cast iron was used.* For a model rated at 2 kW (8-hour charging period), the overall dimensions are approximately 20 in. × 20 in. cross-section by 33 in. height. The heater, even in this small size, has an efficiency of approximately 90 per cent. With this form of heater storage takes place, in the room to be heated, so that no boiler room is necessary and therefore much of the

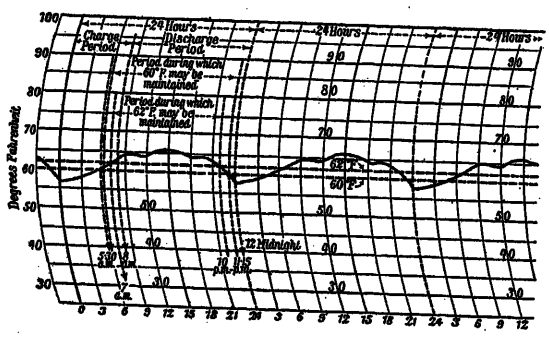

FIG. F.

author's criticism of the thermal-storage system using water does not apply to this system. There is even a case for claiming 100 per cent efficiency for it rather than the 90 per cent quoted above, as all the heat developed is liberated in the room. As the author points out, the room-temperature characteristic is an important matter with any form of heater, and the unit-type solid-core heater requires careful design in this respect. Though early models were not entirely satisfactory, the heater in its latest form meets all reasonable demands. A room temperature constant within less than 5 deg. F. during 15 hours may be obtained by means of it. Fig. F shows a thermogram taken with one of these heaters in a room with closed windows over a period of 3 days. It will be seen that during 11 hours of the working day the temperature was maintained at 65° F. constant to about 2 deg. F., and that over 15 hours the temperature did not fall below 62° F. or rise above 66° F. It has to be remembered that this performance was given by a heater which can be erected by any contractor in a few hours in an existing room, no alterations to the structure nor additions of any kind other than the usual wiring being necessary. Moreover, the heater is in circuit only during the night (in the case described above the charging period was 8 hours) and so qualifies for the maximum "off-peak" rebate. No difficulty is encountered in meeting the requirements of supply authorities for different "off-peak" periods. For example, a satisfactory design was recently evolved for a case in which the heater could be allowed to remain in circuit all day except between 10.45 a.m. and 12.45 p.m. and between 2.45 p.m. and 5 p.m.—a very long charging period. The heater is even more suitable if only a short charging period is available, provided that this occurs after midnight. I am very sanguine that unit-type thermal-storage heaters will meet a need in such service as, for example, office heating, where 20 to 30 kWh per day are sufficient, provided that a small amount of floor space can be spared. They ought to be better known, for I believe they will do the work required of them more economically than other methods.

Mr. H. Hooper: The subject of electrical heating opens up such a wide field that practical figures are of interest at this juncture. It is my opinion that future electrical development in this country will be along the lines of the paper, including further domestic electrification. The following are the details of an actual installation of tubular heating for a block of large offices consisting of 20 rooms and 4 garages. Connected load = 84 kW; number of units consumed in one year = 83 000; 1 201 ft. of tubing and 31 thermal switches were installed. The value of such a system in any area would depend entirely upon the price per unit obtained, but tubular heating is not in my opinion a practical proposition at a tariff exceeding ½d. per unit. I should like to refer to an attempt to put in a thermal-storage system in a building of 30 000 sq. ft. floor area; schemes were obtained for an 850-kW installation to give a temperature of 55° F. The capital cost was found to be from £4 000 to £5 000. For a temperature of 45° to 50° F. alternative schemes were put forward of approximately 450-kW loading, at a capital cost of £3 000. Even if this difficulty of high capital cost had been got over it would have been impossible to obtain a satisfactory price per unit, 1d. being the lowest figure available. In this case it was found that electricity could not be used, and an oil-fed steam system was put in at a cost of approximately £900. It is my opinion that for the heating of large works, warehouses, etc., by thermal-storage off-peak supply, the price per unit will have to be a small percentage on the supply station's coal costs.

Dr. R. D. Gifford: I was surprised to see amongst the illustrations a view of the office in which I work. I refer to the lower figure on Plate IV. This shows one floor of a 4-story block of offices heated on the tubular system, the total load being about 120 kW. It will be seen that the tubes are placed within 6 in. of the window-sill level, and not on the skirting board as depicted in Fig. 1. There are three reasons for this. First, to combat most effectively, by convection, the down-draughts from the windows; second, to increase the effective radiating arc, which becomes about 85°, as against the 60° mentioned by the author on page 1048; and third, because these tubes are not intended to be stood upon, and the easiest way of preventing this is to place them where it is not likely to be attempted. It

* L. G. A. SIMS and K. R. STURLEY: "Solid-Core Thermal-Storage Heating Units," *Engineering*, 1931, vol. 131, pp. 561, 664.

may be argued that in this position there is a likelihood of people getting burned, but in three years this has not happened. The heating is controlled thermostatically. When first installed, in 1928, there was only one thermostat per floor, but this was not a success, as the temperature at the thermostat did not necessarily represent that elsewhere, for example near a door or open window. These thermostats were therefore replaced by the type mentioned by the author, each controlling about 30 ft. of tube—some 2 kW. In Table 4 the author places this type of heating in class C owing to its effect on decorations. From my experience I should place it in class B. I do not find myself in agreement with the author when he advocates continuous heating throughout the season from October until May. I have tried it and have found the cost to be very much higher than with intermittent heating, without any advantage from the point of view of comfort. I use a time switch arranged to cut off the heat about 6 p.m. and to switch it on again in the early hours of the morning. At the week-end the switch comes out at mid-day on Saturday and comes in again early on Monday morning, the temperature of the offices being about 60° or 61° at 9 a.m. Under the author's suggestion there would be about 37 hours of heat losses to be made good, without useful effect. The author has referred to the disability under which the engineer labours when asked to guarantee the temperature of buildings which are only in the paper stage. I agree with this and have sometimes found it necessary to make corrections of as much as 10 per cent. The only other type of electric heating of which I have had experience is the high-temperature panel system, but I find the panels rather fragile, which is not surprising when one remembers that they are slabs of fireclay about 25 in. × 15 in. × $\frac{3}{4}$ in. It would be interesting to know whether the manufacturers have tried to reinforce the panels with embedded steel strips.

Mr. A. G. Engholm: Electric heating of buildings has many advantages, especially as regards installation and manipulation. Unfortunately the price of the electricity required to give the necessary number of B.Th.U. over the normal heating period in a building increases the cost far beyond that of a steam or hot-water system. I am of opinion that the running cost of heating by electricity is about 17 times the cost of steam or hot-water heating. Gas, even if gas-fired boilers are used, is about 5 times as costly. I therefore think that at present there is a comparatively small field for large-scale heating by electricity. The author has brought one good feature—the use of electric thermostats—into prominence. These enable a mean temperature to be maintained in any part of a building, notwithstanding variations in the outside temperature. As we only require heat for our own personal comfort, it is necessary, when we set a thermostat to govern the temperature, to take into consideration the question whether manual work is being done or not. For manual work we only require a temperature of 55 to 60° F., whereas for sedentary work we require 60 to 70° F. There are many ways, however, in which electricity can be used to great advantage by heating engineers. For instance, electrically-driven pumps are now on the market which will automatically return condensed water to the boiler or hot well, so that even if the steam pressure from the boiler dies down and the steam pumps therefore fail to operate, the electrically-driven pumps can be relied upon to do their work. The same applies to electrically-driven wet vacuum pumps, which are now able to reduce the steam pressure to as low as 26 in. of vacuum, giving a temperature of 133° F. This system of steam heating can be so easily governed by electrical control, that not only can a good mean temperature be maintained in a building notwithstanding the variation of outside temperatures, but a long temperature range can be given, say 133° to 227° F., which is equal to 5 lb. per sq. in. of steam pressure. This means a big saving in fuel consumption, as on mild days it is not necessary to generate so much steam. Such a system, electrically driven and controlled, saves at least 25 per cent in fuel consumption over even the ordinary vacuum system of 10 or 12 in. Electric indicators can be installed in the engineer's office so that it is possible to see at once whether the temperatures are being maintained on any particular floor or part of a building. Unit heaters are now being largely used which consist of steam or hot-water heated gilled copper tubes, properly encased, over which air is circulated by means of a small electric motor, using only about $\frac{1}{6}$ or $\frac{1}{8}$ h.p. On the discharge side of the unit heaters deflectors are fitted one above the other; these deflect the heated air down to the floor. These unit heaters give quite a large number of B.Th.U. per hour, for a very small cost of first installation. If electric tubular heaters could be employed in place of the gilled tubes, it would probably be very advantageous, but apparently the running costs of the former are too heavy. Perhaps the author could give us some information on this point.

[The author's reply to this discussion will be found on page 211.]

Scottish Centre, at Glasgow, 8th December, 1931.

Prof. S. Parker Smith: It is a remarkably good paper. I am principally interested in the author's panel heating system. Shortly after it was first introduced I recommended it for the heating of a hospital. It was ultimately adopted, but the panels were heated by water. I should like to have seen an example of an all-electric system in use in a hospital; and if the energy rates had been a little more favourable, electricity might have been used as the heating medium. It is interesting to consider how a room can be heated by low-temperature panels in the ceiling. The only ways in which heat can be got rid of are conduction, convection, and radiation. In the case of ceiling panels one prevents the heat from being conducted away by the use of suitable insulation. Heat can therefore escape only by convection and radiation. Consider a flat plate heated on one side and suspended in air. The relative amounts of convection and radiation will depend upon the position of the plate. If the plate is so placed that convection is prevented, radiation will take place and the

temperature will rise until the rate of dissipation is equal to the heat supplied. In the case of ceiling panels convection is prevented, consequently most of the heat is dissipated by radiation. In the panel-heated room we have seen that the temperature is practically the same from ceiling to floor. Panel heating thus removes the big objection that many people have to convection heating or air-warming. Though the room should not be chilly or cold, it is unpleasant to sit in "stuffy," heated air. One objection to panel heating is the fact that the heating goes on whether the room is used or not. One does not want to push this point too far, but one of the arguments in favour of electricity for heating is the economy resulting from the fact that it can be switched off when not required. Even with panels controlled by a thermostat, and heating going on night and day for 24 hours, may not the panel system become rather expensive with the price of energy as low as ½d. per unit? For many months in the year in Glasgow heating is needed in the house in the morning and evening, but not in the middle of the day or during the night. Panel heating, however, has a big time-lag. In London and Birmingham, cities where there is an immense amount of female labour in the factories, the domestic labour question is becoming very acute and is changing current ideas. The domestic servant is vanishing, and help in the home is being given by charwomen or day girls. This fact is rapidly solving the coal problem. However charming a coal fire may be, it is a very difficult matter to keep it going without the labour necessary to look after it. From this point of view in future the competition will be not so much between coal and electricity, as between the general systems which the author has described.

Mr. D. M. Macleod: In Lanarkshire a somewhat peculiar problem is facing us at the present time. Throughout the Clyde valley there has of recent years been a complete failure of the strawberry crop, due to plant disease, with the result that the growers have been compelled to turn their attention to other sources of livelihood. A great many of them have solved the problem by going in for the culture of tomatoes. All the way up the Clyde-side one can see on every hand large areas being covered with glass-houses, a fact which indicates that a very big load will some day be offered to the supply authorities. I understand that about 60 000 tons of coal are used annually in heating these tomato houses, which present a complicated problem so far as heating is concerned. Could the author suggest any way in which the panel system might be applied to this case? Clearly the panels could not be fixed to the roofs of the glass-houses, as they would interfere with the natural lighting and heating during the day-time, and the heat losses from the panels would become excessive.

Mr. E. Seddon: I am interested in all the author says about the panel method of heating, and the few persons I have met who have actual experience of it are delighted with the results. We must not, of course, lose sight of the fact that the public will not readily accept any proposal for electric heating which involves the cutting of walls or damage to decorations, and for this reason the tubular method is the most popular of the low-temperature systems. The one drawback of low-temperature heating is the want of glow in a room. My house is fitted with tubular heating, and I have got over this difficulty of glow in my drawing-room by fitting a painted glass panel across the fireplace representing a river scene, which is well illuminated from behind and is pleasant to look upon. The tiled hearth in front is fitted with imitation grass, and flowers are arranged on this in suitable bowls. Referring generally to the subject of tubular heating, I estimate that in Edinburgh no less than 35 000 ft. of tubing has been installed for various purposes during the past few years. We have the following numbers of buildings heated by this method: 8 churches, 8 church halls, 11 large offices, 6 dance halls, and 1 cinema. I notice on page 1047 the remark that it would appear that some form of interlocking switch is required in controlling resistance-wire convectors. Reference is made in a footnote to a maid throwing bedclothes over a glowing electric fire. I do not follow the connection between these two statements, and perhaps the author will explain more fully. On page 1048 he gives the surface temperatures of tubular heaters; I find that these figures only hold good for dull tubes, and that for chromium-plated or other brightly polished surfaces the temperature would be increased by about 25 per cent. For instance, the 60-watt heater with a polished surface has a temperature of about 250° F., so that one should be careful in selecting the positions where such tubes are fitted.

Mr. S. J. Conner: I should like to ask the author how he gets over the relative-expansion difficulties associated with the paper-embedded wires.

Mr. A. W. Johnston: Is any provision made for ventilation in the ceiling-panel system? Also, what would happen if the ceiling became water-logged? Is there any danger attached to placing electrical elements in a ceiling?

Mr. R. A. Ure: With regard to electrical heating and panel heating systems, in my view a great amount of educational work is called for among architects and others. Electrical heating received a set-back a number of years ago. When the coal strike was on a number of people adopted electrical heating, but shortly after the strike was settled these people gradually went back to the older methods on account of the smaller expense of the latter. Electrical heating presents certain difficulties for the engineer contractor, as new ideas are always being put on the market and finality never seems to be reached. This means that the electrical engineer has to change his methods every five or six years, and he is therefore rather handicapped in competition with hot-water systems.

Mr. W. D. Brassington: While I think we all agree with the author that a very low unit charge must be obtained if electric heating is to be a success, I suggest that most of the electrical schemes which are considered in the first instance are turned down on the grounds of high cost of apparatus and of installation. A second point which I should like to bring to the notice of the author is that in my area the housewife is able to have a ton of coal delivered to her coal-cellar for 18s. What can the author put forward to meet this competition? In the West of Scotland area and, in fact, all over Scotland the tariffs are comparable with any in Great

Britain. We have some very low tariffs, but they are not low enough. The manufacturer should support us by providing lower-priced apparatus. Although I have installed tubular heating in a number of halls, churches, and local housing schemes (as part of the equipment provided by the town council), the apparatus is dear.

Prof. G. W. O. Howe: I feel that the main stumbling-block in the way of the adoption of the ceiling-panel scheme outlined in the paper, is its novelty. The idea of putting heating elements in the ceiling is so revolutionary that it is bound to take a long time to become familiar to people, even when we electrical engineers are convinced that it is the right thing to do. A striking example of this inherent dislike of novelty is disclosed by Mr. Seddon's description of the way in which he has tried to replace to some extent the brightness of the coal fire, by miniature gardens and sun-lit seascapes. I suppose it is the result of an inherited craving for something visibly glowing. Certainly nothing looks more cheerless and unsatisfying than an empty fire-place, however warm the room may be. One speaker has referred to architects, and they have to be reckoned with in every scientific advance that applies in any way to buildings. It has needed propaganda to educate architects in modern lighting, and at the present time they are going through a strenuous training in the application of the recent advances in our knowledge of acoustics. The paper foreshadows the possibility of revolutionary changes in the methods of heating buildings, and architects will be faced with many new problems in this connection.

Mr. D. W. Low: I am in agreement with the author that the tubular heater transmits the largest portion of its heat to the occupants of the room in the form of convection, and I do not regard his figure of 16·6 per cent radiant heat as too low. Tubular heaters well distributed round the room provide a more uniform temperature and a more economical form of heating than individual radiators or convectors, but if short lengths of tubular heaters are arranged in groups to form radiators all the advantage of tubular heaters is lost. Tubular heaters are very suitable for buildings used for certain purposes, but their use in dwelling-houses is limited owing to their unsightliness. I would not care to have my sitting-room surrounded with 2-in. pipes, and I think that the ordinary householder would have the same objection to the tubular system as he has to the exposed pipes in a hot-water central heating system. Where the panel system of heating has a great advantage over any other system is that no pipes are exposed and the architect has all the surfaces of the room at his disposal for decoration; it is not necessary to place an iron pipe or cast-iron radiator in the centre of his most cherished piece of decorative art. In a Glasgow hospital where the new wards are heated by panels in the ceiling, and the old wards by ordinary hot-water radiators, it has been found that the temperature shown by an ordinary thermometer can be at least 5 deg. F. less in the former than in the latter, with the same degree of comfort; or rather, with more comfort in the panel-heated wards, in which there is not that feeling of stuffiness often associated with rooms centrally-heated by radiators. As with tubular heating, if the panels are concentrated in a few high-temperature groups the advantages of panel heating are to a large extent lost, and the arrangement then becomes the equivalent of a high-temperature-radiator system. I think that in the future the heating of large buildings will be done by low-temperature ceiling panels with thermostatic control. Whether it will be done by electric panels or by pipes fitted in the ceiling through which water is circulated from thermal-storage tanks, will depend upon the electricity supply authorities, as the rates must be such as to give the heating engineer a chance of having his scheme considered. Realizing that the heat equivalents of coal and electricity do not constitute the only factor in the case, but that other important points have to be taken into account, we must regard electric heating as an alternative to the more common methods of heating by coal, gas, or oil. In view of the large amount of money a fog in a city like Glasgow costs the community, even after allowing for the extra lighting load obtained by the electricity department, I think that there is a large balance which should go to give reasonably low tariffs for electric heating. The question of tariffs for electric heating should be given immediate and careful consideration by all supply authorities, so that heating engineers may be in a position to know what the heating tariffs are and be ready with their schemes at the right time. Otherwise, they may find that, owing to delay in arranging tariffs, more chimneys will be erected, thus making the smoke problem even graver than it is at present. Have the fire-insurance companies approved low-temperature electric panels in the form of bare wires between what appear to be two sheets of press-spahn pressed together and fixed to the ceiling like a ceiling paper?

[The author's reply to this discussion will be found on page 211.]

Western Centre, at Bristol, 14th December, 1931.

Mr. W. A. H. Parker: The author's figure of 2 000 units per annum to cover the average consumption of electricity for the heating of a room in a house seems to me to be on the high side. I am interested in a house where most of the heating is done by tubular heaters and a certain amount of radiant heat is also employed; last year the total consumption of this installation worked out at just over 1 000 units per room. The author makes a very important point when he mentions that thermostatic control of these systems is essential. I believe it would pay to install a thermostat in each room of the house or office. Under ordinary circumstances 55° F. is sufficient in the average home, but in offices it may be necessary to keep the temperature higher because of the lack of movement of the occupants when working. I was sorry to hear previous speakers decrying the use of electricity for heating, as I believe that there is quite a lot of business obtainable in this direction with the price of electricity at about ½d. per unit. We ourselves have experience of a large office

panels being reflected to the floor. This has been refuted in a previous discussion*, and it would therefore appear that the saving in current compared with, say, tubular heaters under windows, must be at the expense of cold draughts at these points. In Appendices III and IV the actual consumption of a given installation is shown as being only one-third of the estimated consumption. While this discrepancy may to some extent be accounted for by casual heat, it suggests that the calculations may also be faulty. Mr. A. H. Barker's recent paper† stated that the art of radiant heating was to-day in the same state as convection heating was 30 or 40 years ago, and while appreciating the endeavours of the author and Mr. Barker to put the subject on a scientific basis, we are at liberty to feel that at present the claims made must be accepted with some reserve. It seems to me that a combination of heating methods will be found to be most effective in the long run. With regard to the author's advocacy of continuous heating, this question surely depends on the use to which the building is put. Presumably he would not advocate the continuous heating of churches, and as schools are used only for 40 hours a week, why heat them for 168? The temperature of the rooms can be raised to the required value in two or three hours at most, and even if the running hours are thereby increased by 50 per cent they are still only 40 per cent of the possible number. At the discussion before the Institution‡ Dr. Ekstrom confirmed this by giving figures from tests in which a 40 per cent saving in consumption was obtained by switching off from 5 p.m. to 7 a.m. Provided that the supply authorities do not insist on a 24-hour load for a heating rate of 1d. or less per unit, there appears to be no reason for the additional consumption. I fully endorse the claim made by the author that electric heating is usually in every way an economical proposition, and is undoubtedly the most efficient. But, I agree, thermostatic control is essential.

Mr. W. Moffat: I should be glad if the author would state at what surface temperature the low-temperature radiant panels would work when embedded in plaster. In view of the fact that they are embedded behind plaster and any renewals would mean cutting away a portion of the ceiling, it would be interesting to know the life of the panels. As regards floor heating, Liverpool Cathedral is heated in this way by an installation designed by the firm with which I am connected. The temperature a few inches from the floor is 60° F. and 100 ft. above the floor-level it is 58½° F.; the temperature at the floor itself does not exceed 72° F. The uniformity displayed by these figures appears to be an argument for floor as opposed to ceiling radiant heating.

Mr. W. Hill: With regard to ripple control, is the author of the opinion that this system will operate satisfactorily when all the supply authorities are connected to the "grid"? It seems to me that we might easily get our mains overcrowded with ripples in the same way as the atmosphere has become overcrowded with wireless waves. I should be glad of some further particulars of the ceiling-paper panel, as it seems to be a very cheap and simple form with which the uninitiated may make experiments.

[The author's reply to this discussion will be found on page 211.]

Mr. F. S. Grogan: In my opinion the author is not entirely impartial when comparing the merits of the various systems of electrical heating. He is certainly unjust to the heating of buildings by electric fires and tubular heating systems, and he rather overstates the case for low-temperature panel systems. I have summarized Table 4, taking the higher value where two are given, and have allocated to the A, B, C, and D classifications marks of 4, 3, 2, and 1 respectively. The results are: low-temperature embedded ceiling panels 41 marks; radiant lamp heaters 36; and electric fires, tubular heaters, and high-temperature panels all equal at 33. The author awards too many "A's" to low-temperature panel heating. His results are quite wrong for radiant lamp heaters, which are now almost entirely superseded by electric fires and tubular heating. There are many thousands of electric-fire and tubular-heating installations operating to-day to the entire satisfaction of the user from every aspect. Their capital and maintenance costs are small, and running charges are low where the electricity supply tariff is favourable. Flexible cords should not fail at the point of entry if suitable terminals are arranged. For such connections I have recently employed enamelled wire suitably insulated with braided and impregnated asbestos. Reference is made to the possibility of the heating coils in tubular heaters making contact with the metal wall of the tube. My comment upon this is that if proper methods of construction are adopted it is impossible for the heating element to burn out under any practical conditions. I have here a section cut from a 10-ft. length of tubular heater; the resistance wire is of the same composition as that used in an electric fire operating at 1 800° F., and normally when loaded to 66 watts per foot run the resistance wire is only at a black heat. I cannot see how such a construction could deteriorate even after 50 years' service, and in any case every tubular heater throughout the system should be efficiently earthed. Referring to Fig. 2, I must take exception to the statement that the inverse-square law only applies to radiant emissions from a point source. As the panels cover a comparatively small area compared with the total floor area, the intensity of the radiant energy must decrease approximately as the square of the distance from the source. The early experiments of Tyndall showed that the most intense heat is not found in the most luminous portion of the spectrum. A body at low temperature, say less than the boiling point of water, emits non-luminous radiation. This emission of dark heat increases very rapidly with small rises in the temperature of the heated body. For instance, if the heated body is made of iron, upon reaching a full red heat it will throw out 27 times the radiant heat emitted at a low temperature,

* See Mr. HALLETT's remarks on page 1099 (vol. 69).
† "The Principles of Calculation of Low Temperature Radiant Heating," *Heating and Ventilating Engineer*, 1932, vol. 5, p. 246.
‡ *Journal I.E.E.*, 1931, vol. 69, p. 1096.

and when approaching an orange temperature 60 times. The majority of this heat radiation is beyond the range of the visible spectrum. In other words, the higher the temperature of the heating source the greater is the proportion of radiant energy emitted compared with the heat conducted away. In all conversions of electrical energy to heat energy the efficiency is 100 per cent, but a very marked difference is obtainable according to the design of the heating apparatus and the resulting surface temperatures which heat the building. The author makes a great claim, especially in Fig. 19, for panel heating by radiant heat, and I should like to know how he can justify this claim in the face of scientific records which show that only a small percentage of the total energy can be emitted as radiant heat. Some years ago I proved in practice that the substitution of a $2\frac{1}{2}$-kW fire having a 70 per cent output of radiant heat saved for the electricity supply undertaking a heating consumer who would otherwise have ceased to take electricity for heating purposes through an older type of electric fire consuming 3 kW. Later experience has proved to me that the loading with a tubular heating system can be some 25 per cent lower than would be installed for electric fires in the same room. The chief difference is that in cold weather at least an hour must be allowed for the tubular heating system to bring the temperature of the room to a satisfactory figure, whereas in the case of electric fires the sensation of warmth experienced when switching on is almost instantaneous because of the amount of heat thrown off as radiant energy. It is well known that glass will absorb heat radiated from low-temperature bodies and will transmit some of the radiant energy emitted from heating sources at luminous temperature, but this cannot altogether account for the extravagant claims in favour of panel heating, because it is not necessarily only high-temperature radiation which is associated with the electric fire. While a very small proportion direct from the source may radiate through the glass, the majority strikes the walls, furniture, and people in the room, and is then converted into heat and radiated away from these bodies at low temperature. This picture of the distribution of heat from an electric fire explains why in large buildings where numbers of people congregate another system of heating is necessary. For such buildings I have found the tubular heating system effective and economical, provided thermostatic control is employed. Under ordinary conditions a fair estimate of the annual consumption is provided by taking one-third of the working hours during the heating season operating at full load.

Source	Temperature of source	Watts per sq. ft. of heating surface	Number of sq. ft. of heating surface per kW	Capital cost per kW
	°F.			shillings
Electric fire	1 800	5 500	0·18	10 to 70 (approx.)
High-temperature non-embedded panels	500 to 550	550	1·8	65
Tubular heaters	200 to 250	115 to 200	5 to 9	44
Low-temperature non-embedded panel..	100 to 150	80	12·5	200
Low-temperature embedded panel ..	80 to 85 (nominal), and up to 120	25 to 30	40	—

I maintain—in spite of the author's recommendation of continuous heating over the 24 hours—that this is the more economical procedure, because it eliminates the heat losses during the night, which obviously are higher than during the day. Such an estimate of the loading of the tubular heating system should be based strictly on the heat losses of the building in question, and not upon the rule-of-thumb process of allowing a fixed number of watts per cub. ft. As the author shows in some cases, the watts per cub. ft. may be quite a small fraction of unity, whereas in other cases, such as an up-to-date school with ample glass area on both sides, the watts per cub. ft. often amount to as high a figure as 1·6. For such a school the consumption should probably be based on from 50 to 55 per cent of the working hours operating at full load. For large buildings equipped with ceiling-panel heating systems the author claims a very low figure of watts per cub. ft., if thermostatically-controlled continuous heating night and day over the heating season is adopted. Much greater loadings on other systems will produce almost a 50 per cent saving in annual running cost, however, as I hope to show later. Over the last 18 weeks two similar sets of rooms in a school of the type to which I have referred have been tested for consumption figures as between the high-temperature panel and the tubular heating systems. Over part of the period there was little difference in the units consumed, but up to date there is a slight difference in favour of high-temperature panel heating. Referring to Table 7, I do not think that even for the purpose of calculation the author should deliberately reduce his loading for the room in question by taking only 25 per cent of the full air losses. If the room is to be properly heated and ventilated the air losses must be identical in the two cases. If he can establish his facts, however, the economy in loading should be taken as a percentage off the total heat losses. I have no experience of the radiation thermostat, but for general purposes I should prefer the ordinary thermostat operated by the temperature of the room. Turning to Appendix II, the fact that the maximum load is only 8 kW for a connected load of 20 kW suggests that a loading of about 15 kW would be ample, and for such a block of offices full load for one-third of the working hours (i.e. 10 hours per day for 212 days) would give a consumption of 10 600 units, which is $33\frac{1}{3}$ per cent less than the units shown for the 24-hour method. Referring to Appendix VI, the figures given in the last column are very much open to question; the variation being so vast, they can serve no useful purpose. If the operating costs shown in Appendix VII

represent continuous heating over the 24 hours, it helps me to prove that in spite of the low figure of watts installed the consumption is excessive. If tubular heaters loaded to 1 800 watts had been installed, the daily consumption for a 30-deg. rise—even if we allow 14 hours per day for a dining-room, which is on the high side—would be $(1{\cdot}8 \text{ kW} \times 14) \div 3 = 8{\cdot}4$ units per day, against the author's average figure of 15·9. The approximate figures given in the table on page 1062 show that the capital cost per kW installed must grow to a very high figure if excessively low temperatures are to be employed at the heating source. According to Appendix IX, the fixing of panels in the ceiling costs £18 per kW, as against which figure the installation of tubular heating costs only about £4 per kW, including the wiring and switchgear. I think the author has failed to establish his point that low-temperature panel heating is much more economical than tubular heating. Tests made by the late Mr. Dowsing 20 years ago showed that whilst non-luminous heaters gave a normal temperature up to 5 or 6 ft. from the ground-level, temperatures of the order of 70° F. were obtained at the ceiling-level. Why, therefore, go to the expense of ceiling-panel heating when by the installation of tubular heaters at correct surface temperatures and suitably placed we can get the whole of the ceiling to operate as a low-temperature panel heater at a greatly reduced cost?

Mr. W. L. Webb: I am glad to find that the author favours luminous radiators. In my own house I have a luminous lamp radiator with three lamps and a 3-kW heater, which I find very satisfactory; in the summer the luminous lamp radiators are used alone, and in the winter months additional heat is obtained from the radiator bars. As regards thermostatic heating of rooms, one maker advocates putting the thermostat near the door, and another putting it where the heat is emitted. I noticed recently that thermostats were placed at the entrance of a picture gallery and there was a great variation of temperature in the building. It would be interesting to know the number of thermostats one should use for a room of large cubic content, and also the correct position for these. Regarding radiant heat, in the arboretum at Derby there is an open-air aviary in which the mortality of the birds was very high due to the cold nights. We fixed at the back of the perches a luminous heating panel the dimensions of which were about 3 ft. × 1 ft., and since this was done none of the birds has died.

Mr. W. F. Furse: So far the paper has been criticized from the point of view of men interested in different systems of heating, rather than from that of the question whether there is a big field for electrical heating. The advocate of thermal storage says that, irrespective of the inefficiency resulting from the loss of heat in the pipes, he can heat a building cheaper because he can take the current at off-peak load prices. The tubular-heating and radiator enthusiast says that the author must have an insulated house for the panel-heating system before if it is to be at all efficient. The supply engineer maintains that if he has to buy electricity from the "grid" at £3 10s. to £4 per kW and 0·25d. per unit, he is bound to lose money on a building which is heated by panels. Undoubtedly low-temperature embedded-panel heating from hot-water installations fired by oil fuel has made great strides, and must therefore have considerable merit. Has the author any comparative costs of heating a building with low-temperature panel heating by hot water, and low-temperature panel heating by electricity? He points out the well-known fact that the thermostat which he is using is suitable only for a.c. circuits, but I should be glad to know what alternative he would put forward in the case of a d.c. supply.

Mr. J. F. Driver: Some years ago tubular heating was installed in eight classrooms at the College, Loughborough, and the installation has been a great success. We are now equipping a hall of residence for 90 students as an all-electric building. All the rooms of this building are electrically heated, and cooking and water heating will be done by electricity. The total load will be of the order of 400 kW. I am particularly interested, therefore, in the "electric ceiling paper" described by the author. If low-temperature panels are used, is it necessary to switch on a long time before the room is occupied? I have at home a room which is heated by tubular heaters, with a radiant fire for boosting; even when the outside temperature is very low the room becomes comfortably warm within 10 minutes of switching on. While I appreciate that gradual heating is satisfactory where rooms are used every day, in the average house there are "casual" rooms where heat is only required at week-ends or at irregular intervals. In such rooms it is desirable to be able to produce comfortable conditions quickly. From long personal experience I can say that in clean houses where a vacuum cleaner is regularly employed, tubular heaters do not blacken the walls with dust. The author appears to get a good efficiency with his panel heating by stuffing up all the cracks in the room and reducing the number of air changes. I cannot agree to this. A great advantage of ceiling heating is undoubtedly the fact that it does not interfere with furniture and involves no danger of scorching fabrics. Will the author give his views regarding the suggestion to fix tubular heaters at picture-rail height? By fitting "dummies" it should be possible to make the tubes harmonize with the general scheme of decoration.

Mr. L. M. Jockel: I strongly support the author on the question of tariffs (page 1046, vol. 69). Forty years ago the late Dr. Hopkinson showed that electricity should be charged for on a 2-part tariff, but possibly, like the late Dr. Ferranti, Hopkinson was about forty years in advance of his time. Engineers have in the interval developed complicated scientific methods of charging, whereas if development is to proceed rapidly it is essential that simple and easily-understood 2-part tariffs should be adopted. Recently I had to install an electrical heating system in two offices heated by coal fires but having electric fires for occasional use. I decided to install tubular convection heaters with a loading of 60 watts per ft., and with the existing electric fires a total loading of 1·40 watts per cub. ft. of space was obtained. This figure seems to be rather high, but it has given satisfaction, and I should like to ask whether the figure of ½ watt per cub. ft. of space which the author quotes is not too low in general practice with

thermostatic control. I suggest that about 1 watt per cub. ft. of space is safer, although I know how difficult it is in heating work to decide on a definite figure applicable to all cases. The author mentions the triple-tariff meter of the Compagnie Parisienne de Distribution d'Électricité, and I should welcome further information regarding triple tariffs, as they might be useful as a temporary measure until British supply engineers are able to agree on some simpler form of tariff.

Mr. B. Gill: I should like to support the author's claims regarding the superiority of the low-temperature ceiling-panel system of electrical heating. A good electrical heating installation offers a much higher standard of comfort than that provided by other types of heating systems, due to the even temperature control which it provides. At ½d. per unit the cost of heating a house in this way is not more than £3 to £4 greater than that of heating by coal. After my experience of low-temperature electrical heating I would never go back to coal-heated rooms if cheap electricity were available.

Mr. D. M. Duncan: I disagree with the author regarding the relative merits of continuous and intermittent heating (page 1059, vol. 69). He infers that once the building has been heated up only a few units per day are required to maintain the desired temperature. In his analogy of the loaded truck he loses sight of the fact that more energy is required to push the truck up a hill than along the level; in the case of the heating installation this means that the system must be capable of heating the building on a sudden cold day, when more heat units than usual would necessarily be required. The heat losses through walls, glass, etc., vary with changes in the outside temperature. Although the weekly consumption varies owing to outside temperature changes, the author's theory does not apply in one single instance to the guaranteed figures for the running costs of tubular and other systems of electrical heating to which I have access. In his analogy he may be referring to buildings specially insulated with a 3-in. layer of cork, but such buildings are very hard to find. If I informed a prospective consumer that after first heating up the building only a few units per day would be required to keep the cold away, after a year's working of the installation I should probably have to meet a very enraged consumer. In many cases it is impossible to use panel heating with success. For instance, where one requires heat for the total volume of a building with guaranteed variations of ± 1 deg. F. at 70° F. to enable expensive machinery to operate with success, the radiant method would be useless owing to the fact that it would give rise to "hot spots." I have experienced inferior heating with ceiling panels owing to a restricted area only being heated; outside that area conditions are very uncomfortable in such cases. My experience of many forms of heating inclines me to the view that a high efficiency is obtained with the tubular system combined with a modified form of panel heating. A system which is satisfactory when applied to one particular building may be a failure when installed in another. The capital cost of panel heating is 3 to 4 times that of tubular heating, but when combined the two systems give good results.

THE AUTHOR'S REPLY TO THE DISCUSSIONS AT NEWCASTLE, LEEDS, BIRMINGHAM, GLASGOW, BRISTOL, AND LOUGHBOROUGH.

NEWCASTLE.

Mr. R. Grierson (*in reply*): In reply to Mr. Jewsbury, we have obtained very satisfactory results with the "Satchwell" thermostat in rooms warmed by the low-temperature ceiling-panel system. In actual practice a room "constant" is obtained which connects the condition of comfort with a definite setting of the thermostat. It is possible that the eupatheostat type of thermostat may maintain conditions slightly more perfect than those obtained with the Satchwell thermostat, but they introduce the complication of relays and additional wiring, they are more costly to install, and their ability to maintain a condition of comfort remains to be proved. Regarding the figures given in Appendix X, I note that Mr. Jewsbury questions the costs of the hot-water panel thermal-storage system, but he does not put forward alternative figures.

I think it will be generally agreed that Mr. Clothier's contribution to the discussion is a most valuable and helpful one. The collection and publication of really reliable data relating to consumption and cost are of vital importance to the industry, and I am hopeful that either the Institution, the Electricity Commission, or the British Electrical Development Association will take this task in hand immediately. Architects and consumers all appreciate the advantage of "doing it electrically," and fear of the cost is the obstacle to be removed before marked progress can be made with domestic electric heating work. In regard to the value of the heating load, I would refer Mr. Clothier to Figs. G, H, and J in my reply. Mr. Clothier examines the multiple-earthing problem at some length, and then arrives at the conclusion mentioned by me on page 1051 (vol. 69). Regulations are only made to prevent abuse and danger, and I feel that the time is ripe for the Electricity Commission to review the Regulations concerned. If they are satisfied that the risk of danger is negligible, then these restrictions should be removed forthwith.

I cannot understand Mr. Carr's reason for opening his remarks on the pessimistic note, and reminding us that the efficiency of the turbo-alternator is 24·5 per cent. The other aspect of the situation is equally true and very much more to the point, i.e. that the cost of good house coal is 48s. per ton in the London suburbs, that space is required to house it, and that labour is required to transport it from the coal store to the coal scuttle and eventually to the fire. Ashes require to be removed, grates to be cleaned, chimneys to be swept, and rooms to be dusted. Has not Dr. Margaret Fishenden shown* that the radiant efficiency of the coal fire is from 17·5 to 25 per cent, that direct convection heating accounts for less than 5 per cent, and that these values indicate

* See Bibliography (3).

an aggregate efficiency of from 22·5 to 30 per cent? On the other side of the picture, I am informed that a reasonable price for the coal burnt by the average power station is approximately 17s. per ton delivered in the furnaces. It should be unnecessary for me to labour the point further in order to indicate the possibilities of electric heating under thermostatic control. In requesting me to give values for the normal window area for the control room of a power station, I think Mr. Carr has overlooked the fact that the paper purports to deal with the electrical heating of buildings and not with the architectural design of power houses. Regarding the method of calculating the heat losses for any given building, I was hopeful that I had indicated my views on this aspect of the subject in paragraph 8 of Section (2), in Tables 7 and 8, and in Appendices VIII, IX, and XI of the paper. If I were calculating the heat loss of the building in question, I should figure the heat losses on the basis of an air change equal to 50 per cent of the cubic content for a low-temperature ceiling-panel system, and for an air change equal to twice the cubic content for a convection system. It should be clearly noted that whichever system is adopted, *the natural air change would be in no way interfered with*, and entirely depends on the method of construction, aspect, workmanship, etc. Unfortunately Mr. Carr has omitted to state the thickness of the exposed wall, the temperature maintained on the other side of the interior wall, the

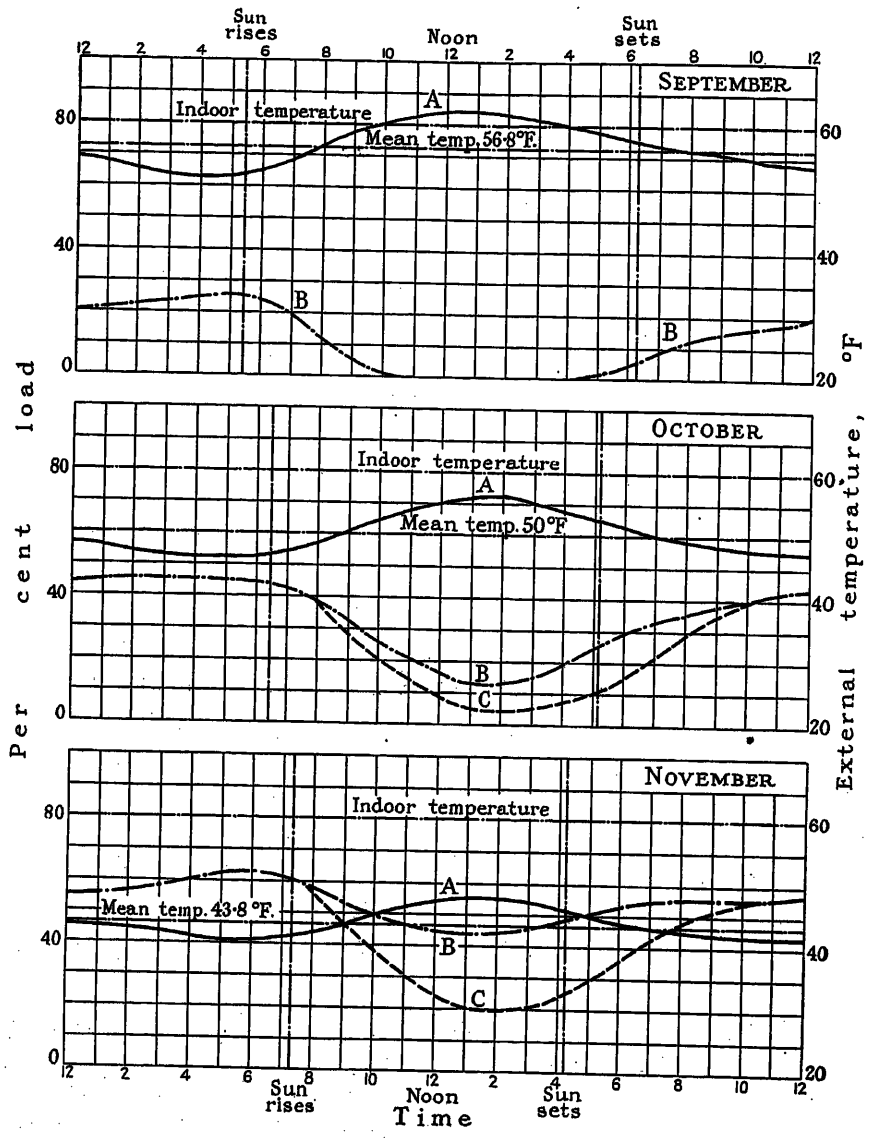

FIG. G.—Graphs showing hourly variation of the outdoor temperature and the corresponding heating load. (See also pages 1069, 1070, and 1071, and Figs. 15 and 17, for the effect of casual heat in flattening the total-load curve.)

Curve A:—Mean outdoor temperature. Curve B:—Theoretical load (as percentage of kW) to maintain 60° F. indoors. Curve C:—Estimated load (as percentage of kW) allowing for casual heat, but excluding the effect of thermal storage of the structure. (See also page 216, col. 2, for method of construction.)

type of floor construction, and whether it is on the earth or if there is a warm or cold basement below it, details of the ceiling construction, and whether there is a warm or cold room over or whether it has a flat roof, and if the latter, whether it is insulated. Mr. Carr states that he has obtained the loading of 58·8 kW by employing the constants given on page 1088 (vol. 69). Had Mr. Carr studied the details of construction of the room in question (given on page 1087, vol. 69) he would have seen that the exterior walls are 9 in. brick, the interior walls are 4½ in. brick, the floor is 1 in. boards on joists, the ceiling is lath and plaster on wood joists, and the total content is 1 536 cub. ft. Such construction would scarcely be suitable for the volume of 98 000 cub. ft. mentioned by Mr. Carr, and the constants naturally vary. If he will forward me a plan of the building I will have the heat losses communicated to him.

Mr. Richardson is also in pessimistic mood without disclosing any good cause or reason. He complains that I have avoided any detailed comparisons, but I feel that my reply to Mr. Carr justifies the course I have adopted. As I stated in my reply to Mr. Skinner, my object in writing the paper was to indicate the very large market available for the sale of current, and in my reply to Mr. Fraser I have stated that my object was to induce all electrical engineers to try out for themselves the modern types of thermostatically controlled equipment. I cannot but feel that it is early days to

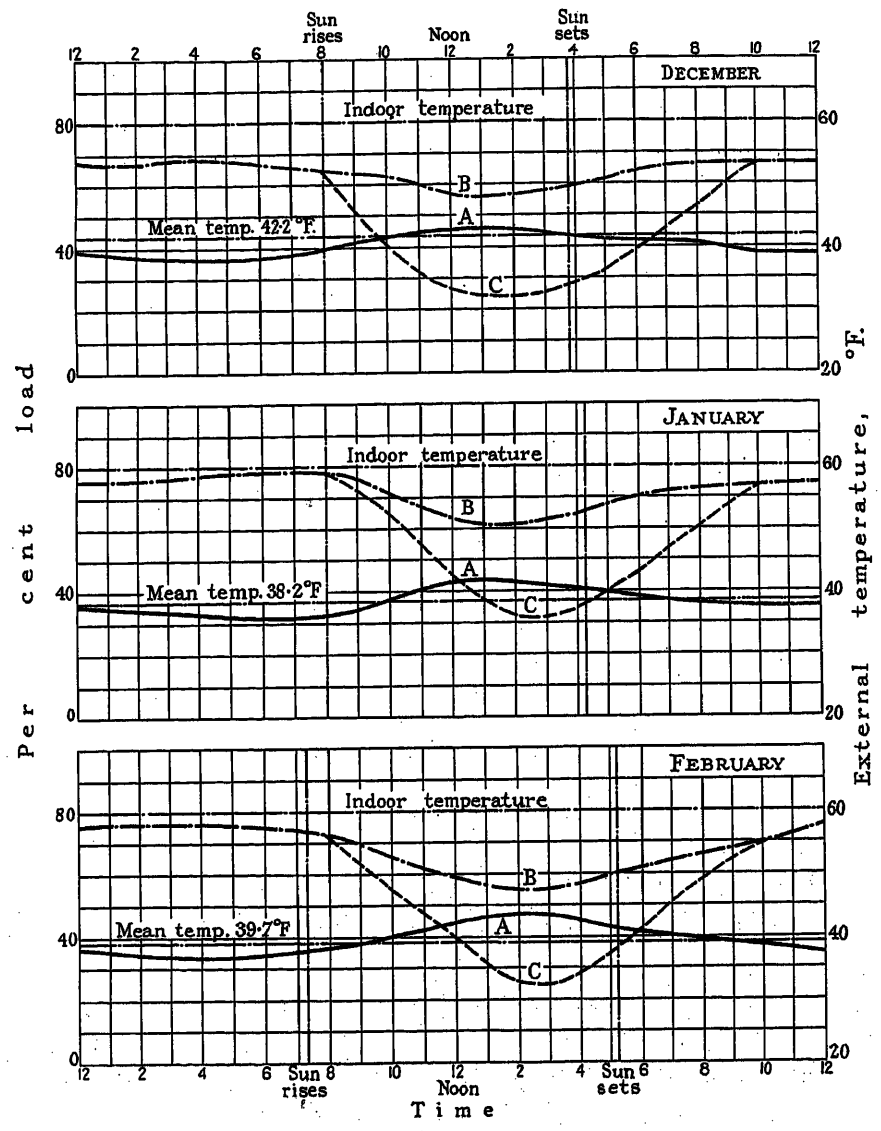

FIG. H.—Graphs showing hourly variation of the outdoor temperature and the corresponding heating load. (See also pages 1069, 1070, and 1071, and Figs. 15 and 17, for the effect of casual heat in flattening the total-load curve.)

Curve A:—Mean outdoor temperature. Curve B:—Theoretical load (as percentage of kW) to maintain 60°F. indoors. Curve C:—Estimated load (as percentage of kW) allowing for casual heat, but excluding the effect of thermal storage of the structure.
(See also page 216, col. 2, for method of construction.)

endeavour to decide the argument of the thermal storage versus the direct system, because the former is most definitely in the experimental stage, and I am informed that one firm lost several thousand pounds on one installation alone. Clearly the cost of such an installation is not the contract price but the actual cost to the contractor, for repeat orders would not be taken at the same price. On the other hand, if experience shows that mass production of the boilers and all the automatic gear can be proceeded with, then the cost of the thermal-storage system may fall considerably. Mr. Richardson also mentions the possibility of controlling the temperature of the whole building from one room which can be regarded as an index room. From my fairly extensive experience of this aspect of the problem, I have no hesitation in stating that there is no index room in any building, and I would point out, once again, that each degree Fahrenheit maintained in excess of the desired temperature represents an addition of 5 per cent to the cost of energy, for so long as it is maintained. I would also refer Mr. Richardson to Table 10 (page 1068) to indicate the difficulties experienced in finding the " central room " to which he refers.

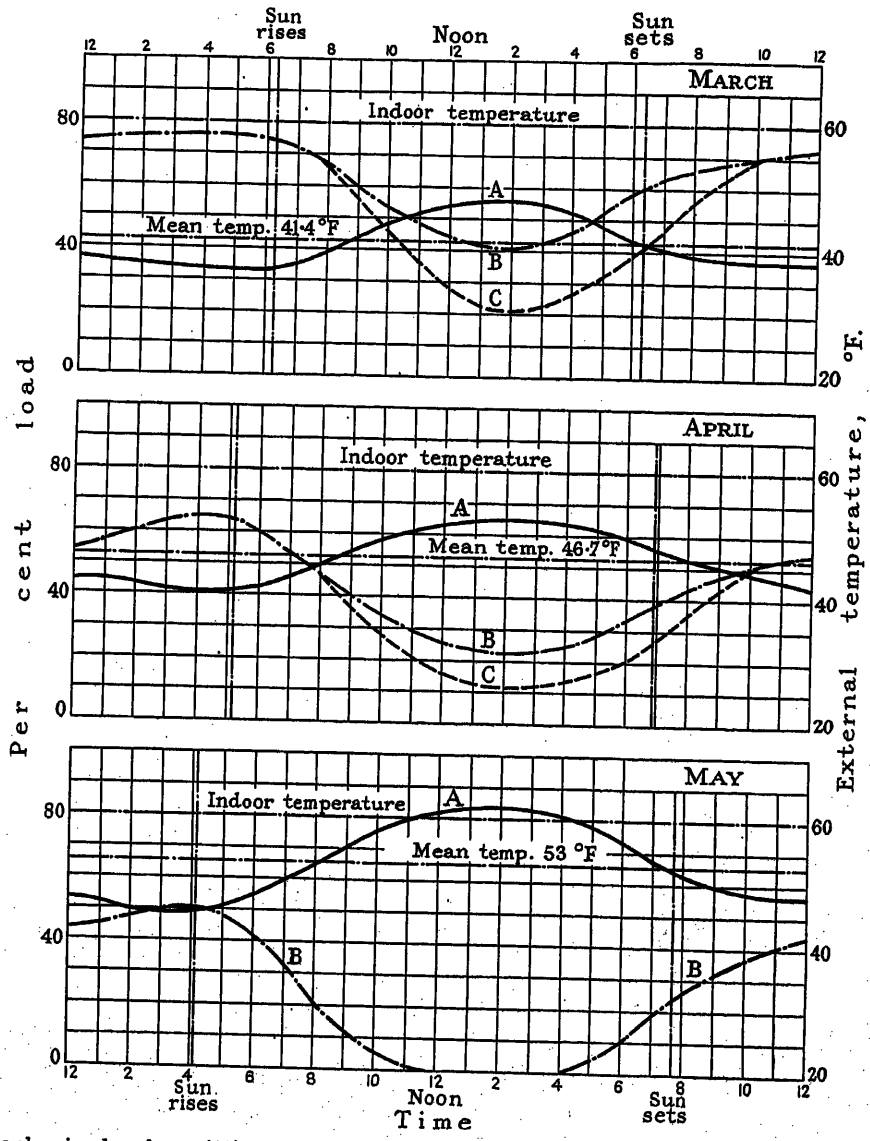

FIG. J.—Graphs showing hourly variation of the outdoor temperature and the corresponding heating load. (See also pages 1069, 1070, and 1071, and Figs. 15 and 17, for the effect of casual heat in flattening the total-load curve.)

Curve A:—Mean outdoor temperature. Curve B:—Theoretical load (as percentage of kW) to maintain 60° F. indoors. Curve C:—Estimated load (as percentage of kW) allowing for casual heat, but excluding the effect of thermal storage of the structure.
(See also page 216, col. 2, for method of construction.)

Mr. Carter has analysed the operating principle of the Satchwell thermostat on a.c. circuits. The important principle is that the contact lever is practically in an unstable state of equilibrium and merely has to topple over to make and to break alternating currents of the

order of 10 to 15 amperes at 230 volts, so that the operating force required is exceedingly small, and the accuracy is relatively high. The small travel necessary to effect the "make" and break is also an immense advantage in securing close differentials.

LEEDS.

I would agree with Mr. Skinner when he expresses his preference for high radiant temperatures and low air temperatures, if such a condition could be proved to be practicable. The only method whereby such a condition can be provided is to remove the whole of the convected heat that is produced, and, as Dr. Parker Smith has shown,* the radiant efficiency of the electric fire averages 65 per cent. The other objection is the difficulty experienced in efficiently warming the *entire* floor area by means of high-temperature radiant sources. Heat shadows are formed, and the inverse-square law is effective to a very marked extent, with the result that the only comfortable area of the room is that included in what I have termed the "magic circle." In other words, it is necessary to "sit round the fire." If Mr. Skinner proceeds with his experiments with the bowl fires fixed near the ceiling, he will observe the formation of the well-known convection dust patches—inseparable from all forms of convection warming—on the ceiling, and he will find that the cost of maintaining a white ceiling is excessive. Again, if in the larger rooms several fires are distributed about the room, in order to eliminate the heat shadows, and so to secure a moderately even distribution of the radiant warmth, it will be found that the loading is out of all proportion to the cubic content. One further objection is the feeling of nausea produced when high-temperature radiant-heat rays are allowed to play on the back of the body. The rays penetrate the clothing quite readily, and experience has proved that it is not possible to sit, with any degree of comfort and for any length of time, within a distance of 6 ft. of a wall panel operating at a temperature even as low as 100° F. The figures given in Appendices V and VI are for net cubic content, i.e. the net internal dimensions of the warmed space. Those who have had experience of intermittent and of thermostatically-controlled continuously-warmed rooms will agree that the former method merely mitigates the sense of discomfort, while the latter, if the installation is skilfully planned and controlled, provides a sense of comfort that must be experienced to be appreciated. Mr. Skinner attempts to compare the cost of energy for an intermittent type of heating installation with the cost of energy for a continuous, thermostatically-controlled type of installation, to the detriment of the latter. In doing so he has overlooked the fundamental law of experimental work, which is to remove all but one variable quantity. The parallel case is the comparison of the cost of living of the poverty-stricken man and of the man in receipt of a comfortable income. The former may regard an annual food bill of from £25 to £50 as being satisfactory, while the latter would maintain that he could not exist on anything under £250 to £500, yet they may both be of the same weight and height. Both men would be right, they merely differ in their point of view regarding cost, quantity, and quality of food. Mr. Skinner has employed the figures contained in Appendices V and VI in a way that I did not intend them to be employed. My object in publishing these figures was to indicate the very large market available for the sale of current and, moreover, the sale of current in comparatively large blocks. His conclusions, however, coincide with the views that are beginning to form in my own mind, i.e. that, to be comparable, all items being taken into account, the restricted-hour rate for thermal-storage systems must be of the order of 25 to 33 per cent of the "on tap" rate.

The experimental results obtained by Mr. Wilkinson regarding air and radiant room temperatures for an equal degree of comfort coincide with the views now very generally accepted. Mr. A. H. Barker* has attempted to tabulate these values in the following way:—

RADIANT AND AIR TEMPERATURES.

Radiant temperature, ° F.	52	54	56	58	60	62	64	66	68	70	72	74	76	78	80
Air temperature, ° F.	72	70	67	65	62	60	58	55	53	51	46	45	43	40	38

I think that Mr. Wilkinson has drawn the wrong conclusion when he refers to a loading of 230 kW in a church. Such a case is exceptional and is solely due to the intermittent form of heating that has been adopted for the building in question. The parallel case is the very large water tank that is only used occasionally. The tariff offered induces the consumer to fill it in the minimum of time, just before it is required for use, so that very large pipes are necessary. If the tank is reasonably free from leakage, the time of filling could conveniently be arranged to occupy a much longer period, and the leakage to be made good would call for a much smaller pipe. Mr. Wilkinson describes experiments with cast iron as a medium for thermal storage, but the heat emitted must be almost entirely of the convected type, and the equipment must be bulky and of considerable weight, so that its application must be restricted to a marked extent. Similar appliances based on the use of (I think) soapstone and similar minerals have also been described.

Mr. Fraser is on very sound ground when he advises progress with caution. My object has been to induce all electrical engineers to abandon the old and entirely incorrect ideas regarding the relative costs of heating by coal, coke, gas, oil, and electricity—based solely on

* "The Radiant Efficiency and Heat Distribution of Electric Fires," *Journal I.E.E.*, 1930, vol. 68, p. 1211.

* "The Principles of Calculation of Low-Temperature Radiant Heating," *Transactions of the Institution of Heating and Ventilating Engineers*, 1931, vol. 30.

the calorific values and on the costs of the raw materials —and to try out for themselves the modern types of thermostatically controlled electrical heating equipment. If we can only convince ourselves first, we shall experience very little trouble in convincing the general public regarding the commercial practicability of electrical heating. They appreciate the advantages, and the fear of the operating cost is the only obstacle that remains to be surmounted. The heavy loadings of the type of installation to which Mr. Fraser refers will prove difficult to handle in many areas of supply where good progress has been made with electric cooking, as the first cooking peak occurs between 7 a.m. and 9 a.m. There is no question at all that tens of millions of units could be sold for the purpose of warming elementary schools, and there is no question that this is an attractive load, as the thermal-storage capacity of the structure and the contents, and the casual heat of the occupants, permit the current to be switched off 1 to 2 hours before the school closing time. When travelling down from Scotland recently the steam-heating pipe coupling between the second and third coaches blew out just after leaving Carlisle. Although the outdoor temperature was 38° F. the temperature in the train was well maintained until we reached Crewe 3 hours later. This is an interesting and unexpected proof of the thermal-storage capacity of a structure, and the effect of casual heat and insulation, in maintaining the desired temperature.

I am not convinced that humidity has the effect on comfort that Mr. Logan suggests, and unfortunately he has not included figures either for the relative humidity or for the wet-bulb readings, taken during the periods to which he refers. Personal observation indicates that the relative humidity indoors is remarkably constant in continuously warmed and adequately ventilated buildings, notwithstanding considerable variations in the outdoor conditions. I am inclined to question the temperature actually maintained in the room referred to by Mr. Logan, or possibly the location of the panel surface in relation to the exposed surfaces of the structure—in other words, whether the radiant "coldth" was adequately negatived or compensated for. In the event of Mr. Logan's contention being proved to be correct, with a thermostatically controlled system it is a simple matter to set the room thermostat up 2 or 3 degrees during the prevalence of the unusual conditions. Mr. Logan's reference to the coat-drying—or rather, the non-drying—episode is interesting. If he observes a pavement on a damp day he will note that it remains damp so long as the sun is obscured by clouds. Immediately the first ray of sunshine breaks through the clouds, the pavement dries as though by magic—owing to the radiant heat of the sun. Mains engineers have also for many years been acquainted with the effect of fault currents and of the resultant soil heating on pavement drying, but have probably not realized the fact that the phenomenon is simply one aspect of low-temperature panel heating. So far, no labour difficulties have been experienced in connection with the new forms of heating equipment, and none is contemplated. The erection of a lift is an example of work by a composite tradesman. He fixes the steel guides, puts the car together, lifts the engine into position, and wires up the controller. The new thin "Dulrae" is ignitable when it is isolated in air, but when it is fixed to a plaster ceiling or to a cement-asbestos board it can be regarded as non-ignitable, because the access of air, which is required for ready combustion, is restricted. The application of a blow-lamp to the finished ceiling will char a hole in the material but general ignition will not ensue. I have no information which would indicate that exposure to high-temperature ceiling panels may cause a condition approximating to sunstroke, but from experiments that I have carried out with both types I find the low-temperature type preferable (see also my reply to Mr. Skinner). Following Mr. Fraser's reference to Fig. 15, and in order to explore further the inversion of the ordinary load curve, I have prepared the graphs shown in Figs. G, H, and J from the data given in Table 5 (page 1061, vol. 69), for the months of September to May, inclusive. Graph A shows the hourly variation in the outdoor temperature from midnight to midnight, while graph B represents the *theoretical* heating load curve of a dark and empty shed constructed of thin sheet metal (i.e. a structure having no casual heat, no thermal-storage capacity, and maximum heat transmission through the walls). The data for the graph have been calculated by ascertaining the difference between the outdoor temperature (at the various hours) and the assumed indoor temperature of 60° F., this being a mean of 63° or 65° F. for sitting-rooms, offices, etc., and 55° F. for corridors, bedrooms, etc. It has then been assumed that the average heating installation will be designed for a 30-deg. F. rise of temperature (30° to 60° F.), and the *difference* between the assumed indoor temperature and the actual outdoor temperature has been plotted as a percentage of 30° F. Thus, from Table 5, the outdoor temperature on September 1st, between the hours of midnight and 1 a.m., is 54° F., or 6 deg. F. below the desired indoor temperature of 60° F., so that the *theoretical* heating load is 6/30ths or 20 per cent of the maximum. This value of 20 per cent is therefore plotted on the midnight ordinate. In the graphs for October to April inclusive I have introduced a third curve (C), which is an attempt—and only an attempt—to indicate the effect of casual heat introduced by the occupants of the rooms, artificial lighting, the radiant heat of the sun, cooking, hot water, etc. In other words, graph C purports to show the probable shape of the heating load of the individual building, allowing for casual heat, but there still remains to be considered the effect of the thermal-storage capacity of the structure and the contents, and also the diversity created by the operation of thousands of thermostats controlling loads of the order of from 1 to 3 kW.

I note that Mr. Longman is intrigued with the possibilities of thermal storage, but I would impress upon him the necessity of studying the actual loadings as well as the shape of the load curves.

A study of the curves in Figs. G, H, and J may enable Mr. Dundas to take a more optimistic view of the "on tap" heating load under thermostatic control. Experience indicates that millions of units could be sold each year if rates of the order of 24 units per shilling could be quoted for the day load, and from 30 to 36 units per shilling for the night load, for thermostatically

controlled heating loads on tap 24 hours per day throughout the year. At rates of the order of 16 and 24 units per shilling respectively, the load can be developed, but progress will not be rapid.

Mr. Jenkins expresses the opinion that the smell and stuffy feeling associated with central-heating systems are due to the excess of humidity set up by a high-temperature installation. Several speakers at the E.D.A. Conference, which I addressed on the 24th March, mentioned that they considered that the tubular heaters operated at an excessive temperature, and stated that when switched on, after standing for a day or so, smoke could be observed ascending from the tubes, due to the decomposition of the dust that had settled upon them. These statements confirm the views of several investigators regarding the objections to high temperature surfaces that I reprinted on pages 1056 and 1057 (vol. 69). Regarding the question of humidity, the capacity of air to absorb moisture increases with increasing temperature, as shown in Table A.

per day, are a few of the necessary "luxuries" of modern life. The potential market for the sale of electric heating units is very much larger than Mr. Wells mentions. There are at present some 650 authorized distributors of electrical energy. If only 500 will decide each to obtain 500 electrically heated rooms in their respective areas—500 buildings of one room each, or 250 buildings of 2 rooms each, or 100 buildings of 5 rooms each—the total will be 250 000 rooms. The consumption will probably average 2 000 units per room, and the total is 500 000 000 units per annum. This would be merely the test—and the real development would follow.

BIRMINGHAM.

I am inclined to agree with Mr. Reynolds that there is a very large future for domestic electric heating of the combined form, and I think it is possible that considerable economies can be effected by this method. I refer to the combination of the low-temperature type for

TABLE A.

Grains of Water which Air is Capable of Absorbing to the Point of Maximum Saturation, in Grains per Cubic Foot, for Various Temperatures.

Deg. F.	25	30	35	40	45	50	55	60	65	70
Grains per cub. ft.	1·85	2·19	2·59	3·06	3·61	4·24	4·97	5·02	6·81	7·94

Relative humidity is defined as the ratio of the weight of water vapour in a given space as compared with the weight which the same space is capable of containing when fully saturated at the same temperature. For example, if on a dry frosty day the dry bulb or ordinary air thermometer reads 30° F. and the relative humidity is 56 per cent, the amount of water vapour contained in each cubic foot of air will be 1·08 grains. If the air be now warmed up to 65° F., without the addition of moisture, 6·78 grains would be required to saturate (100 per cent relative humidity), but as there are only 1·08 grains present the *relative* humidity is only 16 per cent, *which is comparable for dryness with the Sahara desert.* Values quoted by various authorities for the weight of water vapour exhaled per hour are the following:—Man at work 0·267 lb., man at rest 0·155 lb., youth 0·088 lb., infant 0·029 lb. Mr. Jenkins mentions that many people insist upon seeing a glowing source of heat. It is merely the association of the idea of comfort with the glowing fire, just as the cow associates the idea of the process of milking with the byre, and the horse associates the idea of a feed with the appearance of his nose-bag.

In reply to Mr. Wells I have tried the intermittent heating method, by means of electric and also gas fires in my own house, and it was the entire failure of the experiment to provide a sense of *real* comfort, as differentiated from *make-believe* comfort, that caused me to change over to continuous heating under thermostatic control. Dry towels and steamless mirrors in a warm bathroom, at every hour of the day and for a few pence maintaining a temperature of 56° F. throughout the house, with the possible exception of the bathroom—which would be at 65° F.—and the use of 1 000-watt fires as boosters in the rooms when they are occupied. The figures given by Mr. Platt for the annual heating of two factories are extraordinarily low, but he does not state the temperature maintained within the buildings, and he does not give the figures for the correlated expenses. In any case, I have not advocated the employment of electricity for heating factories, but I do maintain that there is a vast field on the domestic side where labour is difficult.

Prof. Cramp touches on an interesting and debatable point when he mentions his preference for the visible type of radiant heater. The difficulty we experience is in the practical application of the principle. Invisible radiation is simple to apply and to control and maintains a condition of comfort *throughout* the room, and it is an easy matter to supplement it with a visible type of radiant heater when desired.

Dr. Sims enlarges on the merits of the unit type of thermal-storage heater. While we shall all welcome the addition of this weapon to our electrical armoury, to enable us to wage an even more vigorous offensive during the coming campaign, I feel that it has very marked limitations. I should like to hear further details regarding the weight, the operating temperature, the views of the insurance companies, and the atmospheric condition produced—particularly as regards the characteristic smell invariably associated with high-temperature convection-type heaters. Another point

for consideration is the duplicate wiring systems involved in the larger buildings, and this at the time when the Commissioners are pressing forward the ideal of the two-part tariff with a flat rate for all current metered.

The figures given by Mr. Hooper are interesting and more or less endorse the views regarding thermal storage that I expressed in the paper, although the installation was only designed for a temperature-rise of 25 deg. F. The price of 1d. quoted was, of course, quite unreasonable, and indicated that the supply authority did not desire the load.

I note that Dr. Gifford favours intermittent rather than continuous heating, but I hope that he will see his way to operate the installation continuously next winter, and that he will publish his views regarding comfort and also the costs of operation, after negotiating with the supply authority for a specially low night rate. I feel confident that the results will be to his satisfaction.

I am sorry to see that Mr. Engholm still considers that the cost of heating by electricity is about 17 times the cost of heating by hot water or by steam. If this is actually a fact, then the cost of heating my own dining-room (see Appendix IX, pages 1087 and 1088) would have been somewhere about 7s. for the season, which is rather remarkable, and exceeds the most optimistic statements of the manufacturers of hot-water boilers and radiators. Similarly, the cost of heating the suite of offices detailed in Appendix II would have been £2 10s., which is the price of about 1¼ tons of coke—again a surprising result. Labour and other correlated costs are neglected in these figures, but if they were taken into account the fuel consumption would be reduced to a value approximating to zero and might even be a minus quantity! Up to the time of writing I have had no experience with the unit heaters fitted with electric tubular heaters, and I have no data regarding costs.

Glasgow.

Dr. Parker Smith expresses fears regarding the cost of continuous heating by the ceiling-panel system, but reference to Appendix II should assist in reassuring him. The total cost of nine rooms was £42 4s. 2d., thus giving an average price of approximately £4 15s. per room for the season, and an average cost per room per day of 5¼d. This was obtained with current at 0·675d. per unit, and I consider that there are good prospects of securing even better rates than this in the near future.

I regret that I cannot give Mr. Macleod any assistance in regard to the problem of heating glass-houses, but I think that the operating costs have been very much over-estimated and that investigation will show that there are distinct possibilities, when all the correlated items are taken into account, e.g. equally good results are obtainable with lower temperatures than the gardener demands, when thermostatic control is employed and an even temperature is maintained; the effect of the sun on the glass is much greater than the average engineer allows for (Carrier places it at 150 B.Th.U. per sq. ft. per hour); the efficiency of utilization is much higher with electricity than with coke-fired boilers; and no labour is involved in the distribution of electricity to the various houses, and none in stoking or in regulating the temperature on those days when we get rapid alternations of sunlight and cloud. I am told that this last-mentioned item is a very important one.

Mr. Seddon is to be congratulated on the results that he has achieved in Edinburgh with the tubular form of electric heating; evidently the users are satisfied as I understand the mileage is rapidly increasing, at the rate of 316 kW per mile. This is a strange phenomenon, occurring as it does in Scotland, if we are to credit the views expressed by Mr. Engholm ("electricity is 17 times more costly than hot water"), of Mr. Anderson ("that so much endeavour should have been expended in so poor a cause"), and of Mr. Kilburn Scott ("the idea of using it . . . appears to me to be nonsensical"). My references to the desirability of the interlocking switch on the convector, and to the fact that the maid threw the bedclothes over a glowing electric fire, were intended to indicate that people do the most unexpected things, so that they might even attempt to clean the convector when it was switched on. Only last week it was reported that a lady used an electric hair dryer while she was in her bath—with fatal results. A friend of mine, desiring a hot bath, immersed the electric kettle in the bath after filling the bath with cold water. I was called on to explain why he received a severe shock when he tested the temperature of the water by immersing his elbow in the bath. Mr. Seddon refers to the higher operating temperature of tubular heaters of the chromium-plated type. I stressed this aspect of the subject on page 1076 (vol. 69), and gave the results of a test on various surfaces in Fig. 20.

In reply to Mr. Connor, owing to the very low operating temperature of the thin Dulrae panel no difficulties are experienced by reason of unequal expansion.

Mr. Johnston asks for information concerning the ventilation of rooms equipped with the ceiling-panel system and I would refer him to paragraph 4 in Section (2) of the paper. I consider that all rooms should be provided with means of ventilation for use if and when required. Regarding the effect of a waterlogged ceiling on the ceiling-panel system, we inadvertently made this experiment at the office during a recent week-end. On arriving on Monday morning we found two ceilings, the carpet, and the floor below soaked. The ceiling-panel material was still adhering to the ceiling, the fuses had blown, and there was only a scorch mark half an inch long to indicate where the element wire had burned through. The lighting installation was out of action, the circuit had to be re-wired, and the room had to be re-decorated, so that the cost of renewing the ceiling panel was a minor one.

Mr. Ure appears to complain that the times are moving too fast for him, but surely this is an advantage rather than a handicap, because it means that every six years he can inform his friends that their equipment is out of date, and that he would like to quote them for modernizing their installations.

I agree with Mr. Brassington that a large number of proposals for electric heating are rejected on the score of operating cost, and that was one of my reasons for writing the paper. The discussion at 16 meetings has afforded me an unique opportunity of conferring with electrical engineers all over the country and of discussing

the pros and cons of the subject. With coal at 18s. per ton the electrical heating proposition is somewhat difficult for the larger installations, but even at that price there is a large domestic field, as Mr. Seddon has indicated. I do not agree that the apparatus is dear, for investigation will show that it compares most favourably with the cost of good-class hot-water boilers, pipes, and radiators, and with electricity there is no labour, dirt, or trouble, and no boiler house, fuel store, chimney stack, or ash pit.

While the general public is notoriously conservative, I feel that Prof. Howe has struck an unduly pessimistic note regarding the difficulty of educating it to new methods. I have personal knowledge of one thermostatically controlled tubular installation where the lady of the house invites her friends to tea in order to display her latest triumph. On each occasion the operation of the thermostat is described in detail, and the comfort provided by the installation is eulogistically explained. The invitations are invariably accepted, as I am informed that it is one of the few houses in the district that are *really* warm and comfortable.

I am glad to have Mr. Low's confirmation of the lower temperature found desirable in the panel-heated sections of the hospital to which he refers, and it will be recalled that I have already mentioned that a rise of 5 deg. F. represents an increase of 25 per cent in the fuel bill. I should also like to point out that, during the prevalence of the fogs to which Mr. Low refers, the lighting load (and therefore the casual heat from this source) is at a maximum, so that the thermostatically controlled heating load will be at a minimum. It is also a fact that periods of intense cold do not coincide with dense fogs, because wind is entirely absent, and the radiation from earth to space is restricted by the blanket of fog. The intensely cold weather invariably coincides with the clear, starry nights when the radiation from earth to space is at a maximum. The low-temperature electric panel system has been approved not only by the leading insurance companies, but also by the Board of Trade, and Lloyd's for installation on the C.P.R. boat "The Duchess of Richmond," and is now being considered with a view to use on railway rolling-stock and also on tramcars.

BRISTOL.

I note that Mr. Parker considers the figure of 2 000 units per annum per room to be on the high side, and that he refers to a house where the consumption averaged just over 1 000 units per room. At the same time he mentions a temperature of 55° F. as being adequate for the average home. I think that it will be generally agreed that 63° F. is the minimum temperature for comfort in any occupied room that is warmed by a convection system, and that 65° F. is very generally demanded. The lower figure of 55° F. provides a fair degree of comfort in bedrooms, corridors, and similar rooms, provided that the temperature is boosted up to 63° F. or 65° F. when the dining-room, lounge, etc., are occupied. I am entirely in agreement with Mr. Parker when he expresses regret that other speakers considered it necessary to decry the use of electricity for heating, particularly as their remarks generally indicated that they were not speaking from actual personal experience of thermostatically controlled installations but merely as the results of calculations made on entirely incorrect assumptions.

In reply to Mr. Smith, I feel that heat insulation will play a very much larger part in the design and construction of buildings than it has done hitherto, and here I would sound a note of warning regarding the use of the ordinary cavity wall for this purpose. Tests have shown that the air circulates in the cavity, is cooled by contact with the outer wall and thereby lowers the insulation efficiency. A considerable loss also takes place by reason of radiation from the outer surface of the inner wall to the inner surface of the outer wall. Effective means should be employed to prevent the circulation of the air, e.g. by the use of special bricks. Fig. 7 was included in the paper for the purpose of indicating the unsatisfactory results obtained when the intermittent system of operation was adopted, the current being switched on at 4 a.m. and off at 4 p.m. daily, with the exception of Saturday when it was switched off at 12 noon. The curve from 12 noon Saturday to 4 a.m. Monday shows the rate of cooling and also the effect of the normal rise and fall of the outdoor temperature on the indoor temperature. Fig. 12 is the corresponding curve for the room with continuous heating.

In reply to Mr. Bowman, the temperatures shown in Fig. 4 on page 1057 (vol. 69) were obtained during the evening, in the ordinary way, the windows being closed. I think that Mr. Bowman is unduly pessimistic regarding the unit charge of the bulk supply. Figures have been mentioned to me of the order of 0·18d. and 0·2d. per unit. Time alone can provide the complete answer to his question.

I am sorry that I cannot inform Mr. Bache how long the ripple system of control of the 2- and 3-rate meters has been in operation, but I hope to publish some further information on this subject shortly. In a wood-joist floor, heat insulation such as 2 in. thick cork slab or magnesia powder is fixed over the ceiling panels to prevent loss of heat into the floor above. In a concrete or tile floor, the ratio of thickness of the material above and below the Dulrae is so large that approximately 95 per cent of the heat is emitted in the downward direction. As a matter of fact, the insulation of the floor of the heated room is frequently of more importance than the insulation of the ceiling, because the heat is radiated from the ceiling to the floor and is absorbed by the floor. If there is a substantial emission of the heat from the floor in a downward direction (conducted to the earth or radiated to the concrete slab), the temperature of the floor cannot build up to the desired degree, and complaints of cold may result. (See also my reply to Mr. Gamage containing further information on this point.) In convection-warmed rooms, high ceiling temperatures are encountered over the whole area and the transmission of heat through the ceiling also involves loss in efficiency. Wherever convection is allowed to occur, dusting is inevitable, and for this reason, among others, panels should always be located in the ceiling. Even the dials of my synchronous clocks are showing signs of dusting over the holes through which the spindles pass, due to the heat

generated by the driving motors. When the heating element is pasted to the flat ceiling, convection currents are eliminated and dusting does not occur.

I regret that Mr. Bowden was not more definite regarding the vital point of operating temperature when he commented adversely on his experience of the ceiling-panel system of heating. In certain cases, to reduce installation costs, it is possible that the surface has been reduced and the operating temperature is therefore necessarily high. Experience indicates that such a course is highly undesirable, not only on account of the discomfort produced, but also on account of the increased operating cost. Temperatures should not exceed 110° F. as a maximum in severe weather and in new buildings. Immediately the building has thoroughly dried out and the steady state has been attained, the area of surface should be such that the desired condition of comfort can be maintained in the room with a panel temperature of the order of from 90 to 95° F. I would refer Mr. Bowden to the remarks made by Mr. Low at Glasgow, regarding the hospital which he mentioned. It is also interesting to note that an Italian deputation, after touring Europe, has recommended the hot-water ceiling-panel system of heating for the new 2 500-bed "Benito Mussolini" hospital in Rome. I feel that I must register a protest regarding the repetition by Mr. Bowden and other contributors to the discussion who call for "the education or conversion of the architect." I should like to assure all these gentlemen, from personal knowledge, that the architects and the consumers are fully alive to the benefits of "doing it electrically," and desire to adopt electrical heating wherever possible. Their apparent apathy is the result of years of experience of the sales methods and tariffs adopted by the electrical industry. Let us advertise in a popular manner low rates for the thermostatically controlled continuous heating load, adopt modern methods of salesmanship, and eliminate from our minds the idea of "educating" the architect.

The point raised by Prof. Robertson regarding the use of thicker window glass in order to reduce the heat loss is an interesting one and one that merits further study. The well-known authority Prof. R. C. Carpenter of Cornell University,* quoting from a lengthy translation of "Traité de la Chaleur" (Péclet, 7th edn., p. 75), states . . . "the heat transmitted through glass is independent both of the thickness and the coefficient of conductivity." I would refer Prof. Robertson to one of the books mentioned for the full mathematical investigation that led Péclet to arrive at this conclusion.

When Mr. Gamage criticized Table 4 (page 1054, vol. 69) and referred to the difference in grading between thermal-storage and low-temperature embedded ceiling panels, I think that he overlooked the space required by the storage cylinders and connecting pipes and valves; the loss of heat from the pipes and the cylinders and energy required for the circulating pumps; the chases and trenches and special provision required in the floors to take the panel pipes; the attendance required on pumps, motors, valve glands, feed tanks, relays, thermostats, automatic gear, and electrodes or immersion heaters. It is also a fact that where large quantities of water are contained in a heating installation that is located below sewer-level, the question of flooding and drainage cannot be entirely ignored. I think that the figures given in Appendix X have served the purpose that I intended, which was to draw attention to the fact that a low unit price was not the sole factor and that there were many other correlated items to be taken into account before a correct conclusion could be drawn. As a matter of fact, the figures quoted for both systems are now out of date. The figures given in Appendices V and VI were never intended to be comparable, but were merely intended to indicate the progress that had been made to date and that energy was being sold in large blocks, despite the theoretical disadvantages of electrical heating. (See footnotes to Appendix VI in confirmation of this statement.) Mr. Gamage cannot have it both ways. If, with the thermal-storage system, thermostatic control to the individual rooms is not provided, then there is a very substantial waste of energy. If the rooms are provided with thermostatic control, then the capital cost is substantially increased. The loss of heat from the circulating pipes is again taken exception to, but I have already dealt with this. In domestic supplies, in the pipe-runs actually obtainable in practice, it is usually found that the loss of heat from the pipes equals or exceeds the heat required to heat the water actually drawn from the taps. In other words, in an actual installation, if the actual water used requires a daily expenditure of 500 kWh, then another 500 kWh would be required to make good the heat loss from the circulating pipes, and the total consumption would be 1 000 kWh per day. This is one of the reasons why electrical water-heating is making such rapid progress. Heat energy can be more efficiently distributed throughout a large building by electricity than by hot water. This statement also reveals another reason why electrical heating is economically possible. In one building, investigated only this week, that required 1 000 000 B.Th.U. for heating, the estimate of the heat loss from the domestic hot-water supply pipes of 100 000 B.Th.U. per hour was criticized as being inadequate. It will be agreed that such values are a substantial contribution to the casual heat that the thermostat takes full advantage of. In regard to the heat loss through the back of ceiling panels, it is now standard practice, in wood-joist floors, to employ heat insulation comprising 2 in. thick compressed cork or one of the insulating powders. It may be of interest to note that the insulation of the wood-joist floor of the room marked "Accounts" (already covered by thick linoleum) mentioned in Appendix II, was recently further insulated with $\frac{5}{8}$ in. of "Celotex" board, and a 3-in. layer of insulating powder was spread between the joists. This additional insulation of the floor of the room has resulted in the energy consumption being reduced by 38 per cent for the same temperature-rise. I am sorry that Mr. Gamage does not agree with my view that the inverse-square law is inapplicable to the very extended sources of heat employed in the low-temperature ceiling-panel system. The fact remains that rooms or halls, of ceiling heights of 20 and 30 ft., are satisfactorily warmed by this method, and so I leave Mr. Gamage to suggest the explanation. With regard to the air temperature shown in Fig. 3, the

* "Heating and Ventilating Buildings."

furniture and the observers were not shown in the diagram, as it was not thought necessary to include these details. The air thermometer was located on a desk, and it is probable that this piece of furniture absorbed heat direct from the 300-watt lamp. Other explanations may be that the surface temperatures were taken by means of a Cambridge thermo-couple, and that the air temperature was registered by an ordinary glass-stem thermometer. Anyone who has had experience with commercial thermometers knows how difficult it is to get two thermometers, not specially calibrated, to read exactly the same temperature when hung side by side. I note that Mr. Gamage takes exception to the temperature of 62 or 63° F. It would be interesting to know what experience he has had with this system, and the temperatures he recommends and finds that his clients accept as satisfactory. Again, he indicates that rooms warmed by the low-temperature ceiling-panel system suffer from cold and draughty floors. If this is really the case, how does he explain the fact that the leading architects and the Government departments specify the system repeatedly? He inquires whether I would advocate the continuous heating of churches. In reply, I would say that I have still to find a church that is heated satisfactorily and is entirely free from down-draughts. Almost invariably people wear their overcoats and outdoor clothes during the service, thereby indicating that the outdoor conditions have been merely mitigated, which is very different from creating a condition of "perfect comfort."

In reply to Mr. Moffat, the operating temperature of the low-temperature ceiling panel is of the order of 85° to 100° F., and the life is indefinite, due to the low operating temperature of the element. I do not quite understand the logic of Mr. Moffat's argument, that because the floor temperature is 72° F. the temperature a few inches above the floor is 60° F., and at 100 ft. above floor-level it is 58½° F., in the Liverpool Cathedral (which is heated by floor panels), therefore floor panel-heating is desirable. Fig. 3 shows a more even temperature distribution, with the objectionable warm floor eliminated. Fig. 4 appears to me to indicate the desirability of floor warming to a more marked degree.

In reply to Mr. Hill, so far as I am aware no difficulty is experienced with a multiplicity of ripples on the Paris network, where the triple meter dials are operated by means of a superimposed musical frequency. The company are the only people who are authorized to inject these ripples, and either the sine wave is free from harmonics or, if any are present, their character is such that they do not interfere with the operation of the meters. Chokes are inserted at appropriate points in order to prevent the ripples from travelling beyond the predetermined areas of supply.

LOUGHBOROUGH.

I do not think that any useful purpose will be served by a detailed reply to the opening remarks by Mr. Grogan, as most of the points to which he refers are largely matters of opinion, and several have already been dealt with in my reply to other speakers. His argument, that because radiation becomes more intense at certain temperatures the property should not be employed at lower temperatures, leads to dangerous ground at once. One has only to recall that many of the dangerous poisons are beneficial if employed in small doses, and, in our own profession, while high voltages at 50 cycles are extremely dangerous, low-voltage currents (230–400 volts) are extremely useful for general work. In reply to his inquiry as to how I can justify the claim for radiant heating by low-temperature ceiling panels, I would remind Mr. Grogan that a block of ice can be made to boil a kettle of liquid air, purely by means of the radiant heat emitted by the ice. I would also refer him to the statement of Dr. Margaret Fishenden on page 1057 (vol. 69). In his defence of the small high-temperature source of heat, as exemplified in the electric fire, I think that Mr. Grogan will be interested in the views of Dr. H. M. Vernon, Investigator for the Industrial Research Board:* "In rooms warmed only by a gas fire, however, the inmates are apt to feel scorched on the side of the body exposed to the fire and too cold on the unexposed side." Again, "A person sitting in a room heated by a fire, in addition to receiving positive radiation from the fire and objects warmed by it, is also subject, as a rule, to what may be termed *negative* radiation from the windows, as they are generally colder than the air of the room." I am sorry that Mr. Grogan does not consider that we are justified in reducing the loading of the room, detailed in Table 7, by taking only 25 per cent of the full air losses, but the method cannot be really so reprehensible as Mr. Grogan would have us believe, in view of the fact that it has provided entirely satisfactory results in many buildings of the type mentioned on pages 1048 and 1049 (vol. 69). Again, Mr. Grogan criticizes the consumption shown in Appendix II, and suggests intermittent operation, but the results of the attempts are shown in Fig. 7, while the results of continuous operation are shown in Fig. 12. Regarding the results shown in Appendix IX, I am sorry that I must again disagree with Mr. Grogan, as these are the figures for my own dining-room, and when we adopted the intermittent system that he advocates we found it necessary to breakfast in our overcoats during spells of cold weather. These are results, and should not be confused with calculations or estimates. Again, I am sorry that Mr. Grogan did not produce the estimates, consumption, and thermograph charts for the rooms in his own residence. They would have been so much more convincing than the mass of estimates that he has produced. In regard to the table of costs that Mr. Grogan has prepared, I would refer him to the paragraph on page 1082 (vol. 69) in which I stated that many successful concerns are to-day selling large numbers of cars, the *annual cost* of which, to their respective owners, exceeds the *capital cost* of at least four, and possibly five, cars of the "baby" class. The reply to Mr. Grogan's final question is that many architects refuse to contemplate the types of heating installations that he advocates, and invariably employs the low-temperature ceiling-panel system, for the same reason that a very large number of people are prepared to pay relatively high prices for the necessities and the amenities of life—they consider that the results justify the additional cost, e.g. the extra cost of first-class fares over third-class fares.

* "The Measurement of Radiant Heat in Relation to Human Comfort," *Journal of Industrial Hygiene*, 1932, vol. 14, p. 110.

In reply to Mr. Webb's inquiry as to where the thermostat should be placed, I can only give general suggestions. The fundamental consideration is that it should be located where it is affected by the average conditions prevailing in the room—*not* in the draught from the door, *not* in the immediate vicinity of the heater, and *not* in a cupboard under the stairs and alongside the meters, as has been suggested to me on more than one occasion. Behind the door, and at a height of 5 ft., usually gives good results, but in some rooms it is desirable to fix it on the window wall, in order to ensure that the temperature is adequately maintained during spells of cold weather. As the thermostat will handle from 10 to 15 amperes (a.c.) without the interposition of a relay, the normal blocks of load are from 2 to 3 kW per thermostat. The corresponding cubes are difficult to state as they vary so greatly, but at 0·5 watt per cubic foot the space is obviously from 4 000 to 6 000 ft.

I should like to give a definite reply to the question put to me by Mr. Furse, but I do not consider that the time is yet ripe for such close comparisons, and one cannot ignore the correlated costs to which I have repeatedly referred in the paper. I think that the better course is to prepare a statement of costs for each individual installation. As an example, a difference of 1d. per day per room in a small house would probably be worth while paying. On the other hand, in a building of 500 rooms the additional cost per year becomes a substantial item and may not be justified. I would also refer Mr. Furse to my reply to Mr. Carr (Newcastle), in which I indicated the danger of the figures being misapplied. Thermostats incorporating a mercury tube are now available for use on d.c. circuits. As stated on page 1067 (vol. 69), the Satchwell thermostat will handle 0·1 ampere on d.c. circuits, and can be utilized to operate relays of the mercury tube or the contactor type, but this method usually involves an increase in the cost of wiring.

The positive statement by Mr. Driver regarding the great success of the electric heating of eight classrooms at Loughborough College is very welcome after the mass of adverse criticism expressed by so many members. It is also particularly interesting to note that, as a result of this test, the hall of residence for 90 students is to be similarly equipped. The low-temperature ceiling-panel system is essentially a continuous heating system, and has been especially developed for thermostatic control with a view to improving the load factor of the supply authority, and thereby qualifying for low-priced tariffs. Rapid heating inevitably involves heavy loading, large mains, peak loads, and bad load factors. Mr. Driver refers to " gradual heating," whereas I regard the problem as one of preventing excessive cooling, and particularly one of maintaining all rooms in a house above the dew point. In reply to Mr. Driver's criticism of " stuffing up the cracks," I can only refer him, once again, to the notes on pages 1064 and 1065 regarding this detail—particularly to the words printed in italics, "*for purposes of calculation only*." I do not know whether the suggestion to fix tubular heaters at picture-rail height is intended to be taken seriously. A large percentage of the heat emitted by the tubular heater is undoubtedly transmitted by convection, and it therefore follows that they should be located as near the floor as possible, except when they are employed for the purpose of preventing down-draughts from roof-lights (see also Fig. 4 for temperatures). The convection currents will inevitably deposit dust on the frieze.

I am in agreement with Mr. Jockel regarding the question of tariffs, and I am of the opinion that the type illustrated in Fig. 21 is worth very close study. The results obtained by the City of London Co., working along these lines, are stated to be very encouraging. The figure of 1·40 watts per cubic foot is unusually high, average values being of the order of 0·5 or 0·6 watt per cubic foot for the average rooms, whereas values of 0·2 or 0·3 are frequently obtained for the larger buildings. As I mentioned in my reply to a previous speaker, I hope to publish further information relating to the ripple-controlled 2- and 3-rate meters at a later date.

The remarks of Mr. Gill again come as a welcome counterblast to the criticism based on estimates and not on actual experience. Is it too much to hope that the sceptics will abandon their slide-rules and calculations, and spend their time and energy in installing electric heating and thermostatic control equipment, and in publishing their expressions of satisfaction?

Has Mr. Duncan never "rushed a hill" when driving a car? The extra burst of speed stores energy and the car breasts the hill with little or no effort. The walls of a 20-ft. × 16-ft. room have a total length of 72 ft., and if the height is 9 ft. 6 in. the gross superficial area is 684 sq. ft. Deduct the odd 84 sq. ft. for windows and doors, and the net area is 600 sq. ft. Assuming the walls to be 9 in. thick, the volume of brickwork is 450 cub. ft., which at 120 lb. per cub. ft. gives a total weight of 54 000 lb. Assume the specific heat to be 0·2 and we find that every degree Fahrenheit represents 10 800 B.Th.U. or 3·1 kWh. Thermal storage of this type is extremely useful to rush the cold spells, and indicates the "flywheel effect" available in the average building to smooth out the load curve. I have experienced difficulty in following Mr. Duncan's argument when he states that my theory does not apply in one single instance to the guaranteed figures for the running costs of tubular and other systems to which he has access. It is unfortunate that he does not publish facts and figures to support his statement. Again I fail to follow his argument when he refers to the impossibility of obtaining uniform temperatures with a low-temperature panel system. Conversely, I think that it must be self-evident that where a uniform temperature is essential, extensive areas of walls, ceilings, and floors at temperatures only slightly in excess of the desired temperatures are clearly indicated. Proof of this statement will be found in Figs. 3 and 4, and also in the remarks by Mr. Moffat at the Bristol meeting.

General Reply.

The undermentioned points appear to call for a brief review.

Economic Practicability of Electric Heating.—While I do not consider that factories, prisons, poor-law institutions, municipal housing estates, and buildings that fall into similar categories will be electrically heated in the near

TABLE B.—*Maximum, Minimum, and Mean Temperatures* (° F.) *for Various Stations throughout the British Isles.*

future, I feel even more definitely that there is a vast and ever-increasing scope for the sale of electrical energy for heating purposes. The majority of the adverse criticism has been based on calculations and on estimates built on false assumptions. Men who have had experience of modern installations controlled by thermostats are favourably disposed to the proposition.

For the "direct" type of electric heating the maximum flat rate is of the order of 24 units per shilling (0·5d. per unit), but the rate that will popularize the system is one that will differentiate between day and night, or "off peak," use. Such a rate might be 16 units per shilling for day use (0·75d. per unit) and 48 units per shilling for night and week-end use (0·25d. per unit). Assuming that during a week's run of 168 hours the thermostat is closed for 66 per cent of the time (112 hours), the allocation may be taken as two-thirds of the consumption or 67 hours at the $\frac{1}{4}$d. rate, and the balance of 45 hours at the $\frac{3}{4}$d. rate, thereby giving an average of 0·45d. per unit or 26·7 units per shilling.

For the thermal-storage system to compete with the oil-fired hot-water installation (in which the rooms and also the boilers are under thermostatic control), the oil flame being automatically started and stopped as required to maintain the boiler temperature, the maximum rate which is at all attractive is of the order of 40 units per shilling (0·3d. per unit), but the actual economic rate appears to be as low as 72 units per shilling (0·167d. per unit).

Current Consumption in Various Districts.—In the north it was suggested that my estimates for current consumption were based on the London area, where the climate is milder. To facilitate adjustments for the various districts, I have prepared Table B, showing the average maximum, minimum, and mean temperatures throughout the year, and Table C, showing the variation from the normal or "standard" consumptions.

As an example, if the "standard" consumption, calculated from Table 12, is found to be 10 000 units per annum for a mean temperature of 43° F. and 30 deg. F. rise of temperature, the consumption in Falmouth would be 8 380 units and in Dundee 11 120 units.

Main versus Room Thermostats.—Detailed study of the subject clearly indicates that the great difficulty experienced in the majority of installations is to find the "index room" in which to locate the main thermostat, where only one thermostat is to be installed. Almost every room in a building is subjected, more or less frequently, to some special disturbing factor, and the temperature in the remaining sections of the building will be either too high or too low.

Continuous versus Intermittent Heating.—Probably the main attack on the paper was concentrated on my support of the continuous system of heating, under thermostatic control, as differentiated from the intermittent method of operating the installation. Supply engineers have the matter in their own hands. A flat rate will induce the heavily loaded intermittent installation to become popular, and the peak load will coincide with the breakfast cooking load. Two- or three-rate meters, giving a specially low night and week-end tariff, will encourage the continuous load, and very large blocks of energy will be sold during the slack period. With the experience of both methods—both comfort and cost—I am still convinced that the continuous method is the essential one for real comfort. One cannot be really comfortable in a room in which the furniture, walls, floor, and ceiling are cold, and one is merely warmed by a blanket of air or by a concentrated and highly directional beam of radiant heat.

Margins in Thermal-Storage Installations.—It is interesting to note that practically the whole of the criticism of the margins that I have suggested to cover pipe and cylinder losses, came not from the experienced hot-water engineers who daily design, install, test, and guarantee their installations, but from electrical engineers who were relying on calculations. The practical difficulty experienced in utilizing the pipe losses to assist in heating the building is the fact that pipes must be run where they can be accommodated, and not in the most efficient places. Pipes are only a service, and the building is constructed for purposes other than to form pipe chase. To maintain a corridor at a temperature of 2 deg. F. in excess of the minimum, adds 10 per cent to the cost of energy.

Thermal-Storage versus Direct Heating Installations.—Further consideration has led me to the conclusion that the thermal-storage system will probably lead the field for the larger installations, and that the direct method will be employed for the smaller work. An important feature of the panel-type thermal-storage system that has been overlooked by all speakers is the fact that heat

can be made available at a relatively early stage in the completion of the building for the purpose of drying-out the structure, thereby reducing the time required for construction. This is due to the fact that the pipes are cast with the floors, and that it is not necessary to wait for the completion of any chimney-stack. Assistance of this type in reducing the constructional time for a large building, erected on a valuable site, may be a vital factor in the success of the enterprise.

Coal Conservation.—An interesting side-light on the argument of coal conservation was recently reported when a deputation of prominent men from South Wales waited on Mr. Stanley Baldwin and pressed him to endeavour to persuade the Government to order coal to be used in the Navy in lieu of oil, owing to the intense distress in the coal-mining districts.

Electrode versus Immersion-Heater Boilers.—So long as the multiple earthing of the neutral remains contrary to the Commissioners' Regulations, and so long as supply engineers insist on the installation of 1 : 1 ratio transformers in order to separate their distribution systems from the boiler electrodes, the extra-high-tension type of electrode boiler will make little serious headway. It suffers from the fact that the conductivity of the electrolyte varies both with the concentration or strength and also with the temperature, and this involves complicated automatic regulating equipment. A slight variation of conductivity involves a substantial variation in the load at the high voltages employed. On the other hand, immersion-heater units are manufactured in large quantities, their weak points have been eliminated, and the immersion-heater type of boiler can now be regarded as a very reliable piece of apparatus. The grouping of the units, which are frequently of the 3-kW rating, is rapidly increasing, for whereas, until quite recently, banks of 10 or 25 kW were regarded as standard, in the latest installations the units are banked in groups of 50, 100, and even 150 kW, balanced protective gear being employed for the protection of the individual elements in lieu of fuses or small circuit breakers.

Variation of Temperature of the Tank Water.—A point that requires careful consideration is the apparent loss in storage capacity of the tanks, due to the variation in temperature through the vertical section of the tanks. Circulating pumps have been suggested for the purpose of thorough mixing of the water, so that the temperature is approximately uniform throughout the tanks.

Use of Magnetic Valves.—Marked developments have occurred in connection with the design and manufacture of the solenoid valve illustrated in Fig. 10 of the paper. In a special triple form it is now extensively employed as the modulating valve for automatically maintaining the temperature of the circulation water, by adding, as required, small quantities of hot water from the storage cylinders of the thermal-storage system. It is also found extremely useful in installations where a mixed panel and radiator system is employed. In this case, the boiler runs at the temperature required by the radiators—usually between 180° and 140° F.—and the modulating valve simultaneously maintains the panel circuit at any desired temperature between 120° F. and 90° F. Although the $\frac{1}{2}$-in. valve is only rated at 12 watts, the $\frac{3}{4}$-in. at 15 watts, and the 1-in. at 30 watts, the load is a useful one for the supply authority, where the valves are fitted to room radiators and panels, because the load continues for a substantial part of each 24-hour day, throughout the heating season. In one case that I investigated, the annual consumption for the valve solenoids exceeded the lighting consumption of the building.

Thermostats.—A thermostat is now available for use on a.c. or d.c. circuits in which a mercury switch is combined with a bellows designed to expand and contract with small variations of temperature. The expansion and contraction of the bellows cause the mercury switch to rock and thereby to switch the current on and off and so to maintain the desired temperature. An ingenious type of silent relay takes the form of a "⌶"-shaped glass tube, the horizontal portion of which contains mercury. Contact wires are fused into the opposite ends of the horizontal portion of the ⌶, just clear of the mercury. The vertical leg contains a solenoid core and is surrounded with a magnet coil. When current flows in the coil the core is held clear of the mercury, but when the current is switched off the core falls into the mercury, and by mechanical displacement the level of the mercury rises, thereby electrically connecting the two contact wires that are fused into the glass.

The Heat Insulation of Buildings.—Much more attention is now being paid by architects to this extremely important aspect of building construction, and it is only a logical step to regard the problem of maintaining comfort during the winter months as one of preventing excessive cooling, rather than as one of heating the building. Two small houses were erected at the Building Research Station at Watford, one being of standard 9-in. brick construction and the other of brick and concrete lined with insulating material. The two houses were under thermostatic control, and every precaution was taken to ensure that the conditions would be identical for both houses during the test. The consumption for the brick house was 5 397 units, and for the insulated house 3 342 units, so that the heat insulation effected a saving of 38 per cent. In the new St. Swithun's School, recently erected at Winchester, to the designs of Messrs. Mitchell and Bridgwater, chartered architects, of Hanover Square, special attention was paid to the problem of heat insulation of the floors, walls, and roof, and thermostatic control was utilized. Although the new school has approximately twice the cubic contents of the old school and is in a very exposed position, as compared with a sheltered one, I am informed that the records of the first season (while the building is still being dried out) show that if the heating installation is run for nine months in the year the cost will still barely equal that of the fuel required to heat the old building.

Developments of the Warm-Ceiling System.—The low-temperature ceiling heating system, described on page 1049 (vol. 69), has now been very considerably modified. The latest form consists of a thin card or stiff canvas reinforced paper, in which the element is incorporated. The total thickness of the material is 1 mm, standard widths are 20 and 40 in., and it is available in continuous rolls that can be cut at intervals

of 24 in., so that any desired length may be obtained from the stock rolls. It is pasted to the ceiling in the same way as a substantial lining paper, and may be regarded as non-ignitable when fixed. The maximum surface temperature of the new form is approximately 100° F., and the normal loading is 23 watts per square foot or 75 watts per foot run.

Acknowledgments.—Several speakers have credited me personally with the invention of the low-temperature electric ceiling panel-heating system. In the development work, which has extended over a period of 10 years, I have merely contributed my quota in association with my colleagues, Messrs. J. L. Musgrave, R. G. Crittall, L. J. Fowler, B.A.(Cantab.), and Fernand Billerey.

Conclusion.—The work involved in writing the paper and in replying to the discussion has been most generously repaid by the widespread interest that the paper has aroused in the subject of electrical heating. Evidently it was a subject that required examination, and it will be generally agreed that it has been very thoroughly examined. My sincere thanks are due to all concerned. There are now some 3 000 electrical heating installations other than electric fires in the British Isles, and this total is increasing daily.

DISCUSSION ON "BUSHING INSULATORS FOR OUTDOOR TRANSFORMERS."*

NORTH-WESTERN CENTRE, AT MANCHESTER, 5TH JANUARY, 1932.

Mr. E. T. Norris: The paper may conveniently be divided into two parts, the latter part dealing with practical points in bushing-insulator design and manufacture. It is evident from this part of the paper that the present design and construction of high-voltage bushings is the result of operating experience rather than development based on fundamental principles. The first part of the paper deals with these fundamental principles, and attempts to derive from them the desirable characteristics of a bushing in regard to the transformer itself, the transmission line, and operating conditions. The author rightly describes the characteristics under impulse or surge conditions as being fundamental to the design of a bushing. Knowledge of surge conditions is rapidly developing, and during the last few years many of the early theories and deductions have been completely changed. The conclusion, for example, that the size of a transformer bushing should depend upon whether or not the transformer insulation is graded, is based entirely upon consideration of 50-cycle insulation stresses. The essential principle of graded-insulation transformers is that advantage should be taken of the fact that the neutral point is solidly and permanently earthed, to reduce the insulation to earth at the neutral end of the winding. The principle does not suggest that the line end of the winding should be any less well insulated than in ordinary transformers. Surges and travelling waves entering a transformer from the line impose just as severe a stress on the line end of the winding when the insulation is graded as when it is not. It is essential, therefore, that the insulation at the line end of the winding (this includes the bushing insulation) should not be reduced in graded-insulation transformers. In the first part of the paper the author refers frequently to co-ordination of line, station, and apparatus insulation, the principle being to grade the insulation of the various parts of a transmission system so that when breakdown is necessary to relieve the stress on the system, it occurs at a predetermined point where it can do little damage and will cause a minimum of inconvenience. Such correlation is possible where similar characteristics, e.g. the spark-over voltage of insulators and bushings, are being considered. The nature of the breakdown of such solid insulation as that of a transformer winding or a bushing is so fundamentally different from that of spark-over in air that a comparison can only be made if other and more complicated factors are considered. A bushing or line insulator flashes over when the surge voltage exceeds a certain value, but it will withstand without harm any number of surges of the same wave-shape whose voltage is below that value. A transformer winding or bushing consists largely of solid insulation. It is an important characteristic of such insulation that the damage done by surges is cumulative and progressive. Whilst, therefore, a single surge of sufficient magnitude would break down a given insulation, a number of surges of much smaller magnitude would also break it down. The damage done to an unprotected transformer or bushing by surges is so cumulative that its life will depend entirely upon the number and severity of the surges inflicted upon it. Owing to the erratic distribution of thunderstorms and lightning strokes, this life is governed largely by chance and coincidence. Any attempt, therefore, to co-ordinate line and transformer insulation on the basis just described must include not only the wave-shape of the surge and its maximum amplitude but also the number of surges and the desired life of the transformer or bushing. The author refers to the effect of reflection on a transformer bushing at the end of a transmission line. It is theoretically true that when a surge arrives at the end of a line it will be reflected and its potential may be raised to twice the original value, provided that the wave-front of the surge is rectangular. In practice, even with a rectangular wave-front, this reflected value is only possible during the time taken for the reflected wave to travel the 400 or 500 ft. from the bushing to the first line insulator, a matter of approximately $\frac{1}{2}$ microsecond. This time is too short for the increased surge potential to have any dangerous

* Paper by Mr. W. J. JOHN (see vol. 70, page 297).

effect. Moreover, the wave-front of surges is always sloping, never rectangular. The reflected wave will similarly be sloping, and will be superimposed on the original wave, giving a gradual increase in surge potential which will cause the line-insulator bushing immediately preceding the transformer to flash over and relieve the situation. In other words, the line insulator immediately preceding the transformer gives a very definite protection to the transformer bushing against the increased stresses due to reflection.

Mr. P. G. Ashley: I am disappointed that the author gives so little information regarding the condenser-type bushing. This was first developed by the Westinghouse Co. in March, 1910, since when thousands of condenser bushings manufactured in this country, in Europe generally, and in the U.S.A. have given excellent service. In view of this the statement on page 323 that many users have had trouble with bushings of the condenser type, whilst trouble with the oil-filled type is rare, is unfortunate, as I think it is contrary to engineering experience. Another statement on the same page to which I take exception, chiefly because it requires qualification, is that the condenser bushing is more expensive than the oil-filled type. My experience is that up to 100 kV the prices of the two types are comparable, and that over 100 kV the oil-filled bushing is the cheaper. Other features, however, such as the extra cost involved by switch top-plates, current transformers, etc., due to the larger size of the oil-filled bushing compared with the condenser bushing of the same rating, must be considered when making a comparison between the two types. It is true that recent developments in connection with the use of bushing-type current transformers have enabled the size of the latter to be reduced when used on oil-filled bushings, but, so far as I know, for the same rating the condenser bushing can still be made smaller than the oil-filled type. The principles inherent in the design of the condenser bushing allow the axial gradient at the air and oil ends of the bushing to be controlled, and this must result in smaller dimensions for the same performance. The author states (vol. 70, p. 323) that in his opinion condenser bushings can be obtained which will give no more trouble than any other type. I think that this statement is not a matter of opinion but an actual fact. Even years ago when the technique of bushing manufacture was certainly not at the high state to which it has attained within recent years, the condenser bushing could easily hold its own, and this is more than ever true at the present time. The safety of the oil-filled bushing depends upon the oil remaining in the porcelain top and bottom shells. A small crack in the porcelain or the starting of one of the oil joints will allow the oil gradually to leak away. This is bound to be followed by breakdown. On the other hand, even if the porcelain rain-sheds of a compound-filled condenser bushing were actually broken away, unless weather conditions happened to be very bad the bushing would still operate satisfactorily and thus allow time for alternative supply arrangements to be made. Although the author cites deterioration of the varnish paper as a condemnation of the condenser bushing, in another column he mentions that oil-filled bushings are fitted at the top of the reservoir with a tube open to the atmosphere. Oil is known to deteriorate rapidly on the addition of moisture, and though the tube is turned down to prevent rain from driving into it, moisture-laden air can readily pass into and out of the container. The illustration (Fig. 40) of a 220 000-volt oil circuit-breaker bushing made of porcelain is of particular interest; in this connection I should like to point out that one manufacturer in this country has for some time past been manufacturing complete condenser bushings 16 ft. long, and has also made 500 000-volt condenser bushings up to 24 in. diameter. It is stated that bushings for switchgear have to withstand mechanical stresses due to the shocks of making and breaking contact. One development, however, embodies an arrangement whereby the closing shock is taken on the arc shield enveloping the lower end of the bushing, and it is in fact possible to operate the circuit breaker with the actual condenser bushing removed. The current-carrying capacity of copper rods given in Table 20 does not hold for all designs. I should be glad if the author would state the conditions for which these figures hold good, and the circumstances under which the test reported in Table 22 was carried out. At the same service voltage an air-core porcelain bushing with a 1-in. conductor will carry quite a different current from that which might be carried by an oil-filled bushing or a porcelain-shrouded condenser bushing. On page 314 there is a rather confusing statement to the effect that the minimum commercial thickness of a wall of paxolin is about $\frac{1}{8}$ in. It may be pointed out here that "paxolin" is a proprietary name, and that it would have been better had the author used the term "synthetic resin varnish-treated paper," which has been standardized for this class of material. I assume here that he has in mind the use of a varnish-treated paper tube which will be slipped over the copper conductor by the manufacturer of the composite bushing. In this case it would probably be difficult to make a satisfactory job with a tube of less than $\frac{1}{8}$-in. wall thickness. The practice of pushing an insulating device on to a copper rod is not to be recommended, as it is extremely difficult to ensure that no air space is present between the copper and the internal bore of the tube. In a case of this kind it is much better to have the insulation wound directly on to the copper rod. The radial thickness may then be given any suitable value demanded by the design.

Mr. W. Fennell: With regard to the subject of joints between the bushings and the transformer casing, we are greatly troubled by oil leaks on outdoor transformers having conservators. I have not seen a pressure joint between porcelain and metal which could be regarded as satisfactory. To my mind the proper way to connect the insulator to the tank is to cement a metal ring to the insulator and to use the metal ring for the bolted joint. There is no need to make a new cemented joint each time a bushing is replaced. Instead of keeping the spare bushing separate from the ring, keep it cemented to the ring. The change may be effected in a few minutes, as one has only to make an ordinary metal-to-metal joint. I have specified this construction on several occasions, after somewhat serious trouble through leaving the matter open for the transformer manufacturer to decide. In

my opinion there is much unnecessary elaboration in regard to bushing insulators. For example, take the kinds of insulators to be used according to whether the star point is earthed or insulated. The paper shows that the specifications of the two do not differ greatly, and as regards appearance one would not know them apart. I do not think it is necessary or advisable to design a transformer bushing except on the assumption that the circuit is insulated. Transformers for voltages up to 33 000 volts are used in all sorts of situations. A transformer should be so constructed that it can be used anywhere, and therefore the highest possible surge voltage is the important consideration, not the question whether the star point is earthed or insulated. A great source of oil leakage with transformer bushings is the conducting rod in the middle. I do not think we have more than two or three transformers with conservators that do not leak at that point. The oil spreads down the bushing outside, collecting flies, dust, and filth. We therefore have to clean these bushings, which are the only insulators that are cleaned at all on our system. The conducting spindle carries a current and therefore gets warm; its coefficient of expansion is different from that of porcelain, and any packing (such as cork) put in to make a joint will eventually give rise to a leak. It usually does so after a few months. What we really need is some new form of elastic joint that does not depend upon the elasticity of the jointing material. After a year or two cork joints on transformer bushings begin to disintegrate and trickle out. Whatever material is used it should be permanent, a quality which neither cork nor rubber possesses.

Mr. A. M. Robertson: In connection with the wet flash-over test of bushings (page 309), it is rather unsafe to assume the resistivity of the water used in this test to be 10 000 ohms per cm cube. The value must be accurately determined before any test is carried out on the bushing. Can the author give any further information regarding the accuracy of the figure in question? The whole matter of this test is made to appear much more simple than it is in actual practice; one has to determine the value of the resistivity of the water, and then to observe the angle and rate of precipitation. In a large-size bushing, some difficulty will be experienced in adjusting these factors over a large area. I think that the author might well have given fuller information regarding test practice.

Dr. J. L. Miller: It would have been interesting if the author had given us some impulse figures. I suppose that one difficulty in doing this would be the lack of information available, as very little has been published on the subject in this country up to the present. The author gives the impression that the only way a transformer can be damaged under impulse conditions is by breakdown of the major insulation, i.e. a fault between the h.t. and l.t. windings or to earth. He neglects the other type of breakdown which occurs between turns or between coils, and thus, on a system where the major insulation of the transformer is so designed that its breakdown voltage is greater than the flashover voltage V of one of the "weak link" bushings, surges whose maximum values are less than V may still cause the inter-turn type of breakdown, or even—as a previous speaker pointed out—cause breakdown of the major insulation due to the cumulative damaging effect of travelling waves. It is therefore my opinion that transformers may break down under impulse conditions even if they are designed to stand the 1-minute test for fully insulated transformers; other factors must be taken into consideration in their design. I should like to amplify the author's remarks regarding the property which condensers and choking coils have

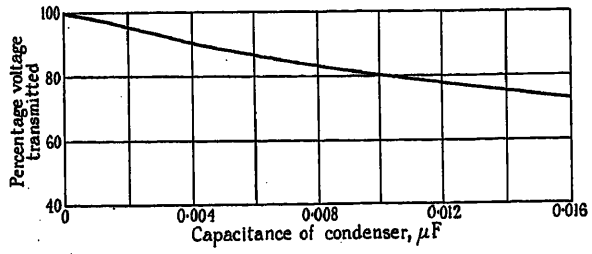

FIG. A.

of reducing the over-voltages passed on to transformers. The amount of amplitude reduction to be expected from the use of a practical and economical size of condenser and choking coil is not very great, and in this connection Figs. A and B have been prepared. They show the calculated reduction in the amplitude of a travelling wave for (Fig. A) condensers whose capacitances range in value from zero to 0·016 μF, and (Fig. B) choking coils whose surge inductances range from zero to 5 000 μH. The curves have been obtained from the

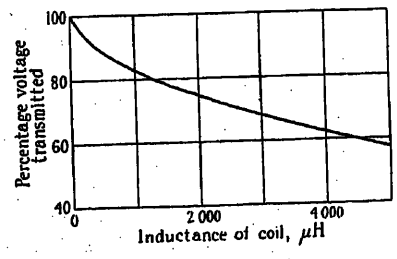

FIG. B.

maximum values of the families of transmitted-voltage curves given by

$$\frac{E}{0{\cdot}98 - 8{\cdot}7C}\left[e^{(-\,0{\cdot}05 \times 10^6 t)} - e^{(-\,5{\cdot}7 \times 10^3 t)/C}\right] - \frac{E}{0{\cdot}98 - 2{\cdot}56 \times 10^3 C}\left[e^{(-\,15 \times 10^6 t)} - e^{(-\,5{\cdot}7 \times 10^3 t)/C}\right]$$

and

$$\frac{E}{0{\cdot}98 - 7{\cdot}1 \times 10^{-5} L}\left[e^{(-\,0{\cdot}05 \times 10^6 t)} - e^{(-\,7{\cdot}0 \times 10^3 t)/L}\right] - \frac{E}{0{\cdot}98 - 2{\cdot}06 \times 10^{-2} L}\left[e^{(-\,15 \times 10^6 t)} - e^{(-7{\cdot}0 \times 10^3 t)/L}\right]$$

plotted as functions of C and L respectively, and the travelling wave on which the calculations were based rose to its crest value in 0·4 microsecond and fell away to half crest value in 14 microseconds. It will be seen that for a commercially-possible condenser capable of withstanding the high voltages which are likely to be

met, the reduction in amplitude is very little indeed, and for waves having longer backs than that which has already been considered (the cathode-ray oscillograph shows that longer waves do occur in practice) the amplitude reduction will be considerably less. The same remarks apply to the choking coil, although other important factors have to be considered in this case.

Mr. M. W. Singer: In spite of what some of the previous speakers have said in favour of the condenser type of bushing, I still believe that there is a great future for the all-porcelain multi-tubular type. The considerable amount of labour involved in dismantling the condenser-type bushing in the event of failure, in order to locate the fault, is an important factor which should be taken into consideration. On page 320 the author points out the dangers and disadvantages of filling with compound, and yet one or two pages afterwards he states that certain types of what he calls "all-porcelain" bushes are filled with compound. I am of the opinion that he has not heard of the type of all-porcelain bushing manufactured by Hermsdorf-Schomberg and Co., Germany, in which the interstices between the tubes of porcelain are filled with porcelain in the fluid state which afterwards hardens and forms one solid porcelain insulator. As regards the popularity of all-porcelain bushings, some valuable experience of their use has been obtained on the Continent over a number of years, and in the very severe winter of 1928–29 these bushings successfully withstood the extreme and abnormal temperature conditions. With regard to the rainfall statistics on page 332, I notice that Manchester is not included in the table. I do not understand why these figures of heavy rainfall were incorporated in the paper when such important factors as salt deposits, snow, fog, etc., were omitted. I am interested in the question of the production of an absolutely oil-tight joint. The author appears to get over the difficulty by making use of both cement and a gasket, evidently hoping that the deficiencies of one will be compensated for by the advantages of the other.

Mr. F. W. Taylor: The comprehensive way in which the author attacks the problem of bushing design, and the simple formulæ and curves given in the paper, make it appear at first sight that bushing design is a comparatively simple matter. For instance, on pages 312 to 314, formulæ are given for the potential gradients in various dielectrics on the assumption that the electrodes are concentric cylinders. Whereas this is true at some places in the bushing, there are other places where the assumption breaks down because there is a component of the field in an axial direction. Whilst this is not very important as regards porcelain, special care is necessary when dealing with laminated material, e.g. bakelite paper. Also critical gradients for air are rather indeterminate in enclosed places, and other factors such as the inconsistency and ageing of materials, and distortion of the field by deposits on the porcelain, all have their effect in nullifying theoretical assumptions. The author will no doubt agree that bushing design does not consist solely in the derivation or application of formulæ, valuable though they are; the important factor is the ability of the designer to determine how near the actual conditions in the bushing approach the ideal of the formulæ. Correlating the transformer insulation and bushing characteristics in the manner adopted by the author in the first part of the paper, would prove of no little value to the purchaser or consultant, and to the transformer manufacturer. In my opinion there is room for more investigation in this direction. When comparing the transformer and bushing insulation, however, the author does not make it quite clear whether he is referring to the major insulation (i.e. between winding and earth) or to the internal insulation between turns, layers, and coils. From the surge standpoint the latter is much the more important since the stresses between turns may be as much as 200 times normal, whilst the stresses to earth are of the order of 10 times normal. The amount of insulation necessary to protect against over-voltages due to surges therefore bears no simple relation to the test voltage on the transformer, and additional tests are necessary to correlate the strengths of the transformer and bushing insulation under transient conditions. In connection with the testing of bushings, I am surprised that the author makes no reference to the Schering bridge test. This is perhaps to be accounted for by the fact that he deals with porcelain and not with paper condenser bushings. The Schering bridge test is now recognized as of prime importance for most bushings in determining their quality before they are tested in the usual way, and also for ascertaining whether the voltage test has damaged them in any way. Unless a Schering bridge test is to follow, it is useless to test a bushing to an abnormally high voltage. Fig. 11 would be more valuable if the author stated the temperature and pressure of the air, whether it is enclosed or free, and the breakdown voltage of the oil in the standard test cell. As regards the question of puncture voltage (page 314), irregularities in the conductor, dust, etc., will encourage the formation of streamers when the air breaks down thus presenting needle-point electrodes to the porcelain instead of a cylinder of radius r_2. Under these conditions breakdown of the porcelain will occur much earlier. A bushing which the author has omitted to mention, and which is really a hybrid of the oil-filled and the condenser types, is the oil-filled condenser bushing consisting of dry paper insulation having foils wound in the usual manner of condenser bushings, the whole being impregnated in oil. This type has all the valuable properties of the oil-filled cable as regards reliability, power factor, smallness of dimensions, etc., without the disadvantages of bakelized paper.

Further Contributions to the Discussion.

Mr. A. O. Austin (*communicated*): In this discussion of the paper it is assumed that the scope of the latter is such that it is impossible to cover the various types of construction in sufficient detail to allow for material departure from present practice. Many factors are involved in the design and construction of bushings, so

that a discussion must usually be limited to a definite size and type, otherwise contradictory results might be cited, tending to disprove observations which might be correct for another size or a slight modification of the bushing. The effective insulation of transmission lines has increased materially in most parts of the world during recent years. This has necessitated much higher flash-over values for bushings than those shown in Table 8. The flash-over value of the bushings at normal

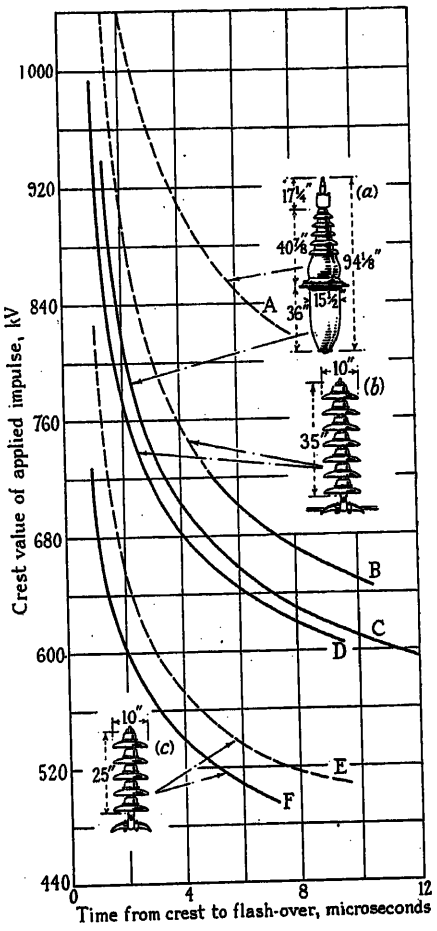

FIG. C.—Impulse-voltage/time-lag characteristics.

frequency is usually not so important as the relative time-lag for bushings and other station insulation under a high-voltage transient. Under an impulse voltage the relative characteristics of the bushing and other insulation may vary considerably from those indicated by the arcing voltage at normal frequency. Fig. C shows the impulse-voltage/time-lag characteristics of a 110/140-kV oil-filled bushing insulator and two suspension insulators, for impulses which rise to the crest value in ¼ microsecond and then fall to half the crest value in 100 microseconds. The desire to use a small diameter and to avoid radio interference has led to the almost total abandonment of bushings employing a zone of air for insulation, except for a lower voltage. One objection to using an air zone is that under a transient the air zone breaks down, robbing the bushing of a large part of the insulation just when it is most needed. The filling of a space by oil or compound, as indicated by the author's curves, is to be preferred. This gives rise to a material increase in the flash-over voltage, as indicated by Fig. 22. The advantage of placing a ring-type current transformer inside the bushing case is very material, particularly where the insulation is brought up over the current transformer. Used in this way, the lower end of the bushing is provided with much more insulation, a particularly valuable feature in circuit-breaker work. With this arrangement a larger diameter of the porcelain member may be used for the lower end, thus reducing the intensity of the electrostatic field. This is important, as a strong electrostatic field due to a small diameter or short length in the insulating member will tend to cause conducting matter to be precipitated and flash-over to occur in operation, even though the bushing may apparently have an ample factor of safety under test conditions. The increased insulation also reduces the danger of a hot pocket of gas shunting the insulating surface and causing a short-circuit. While the above applies to circuit breakers, the same type of construction is particularly applicable to bushings used with transformers in which there is considerable space above the oil, as it enables the lower end of the bushing to be made much shorter without danger of a discharge occurring over the surface. As explained by the author, bushings equipped with a wound primary for the current transformer are being used where conditions are unusually difficult. Bushings of this type have been produced having a number of ratios for the current transformer ranging from 25:5 up to 400:5 amperes. This range would be exceedingly difficult to provide for in an ordinary type of current transformer with a bushing having a flash-over voltage of 475 kV. In addition to the current transformer, the bushing is provided with a capacitance tapping. The coupling plate for this is placed between the current-transformer secondary and the main core of the bushing. Owing to the large amount of energy available from a wound-primary current transformer, it is possible to design such a transformer so that it has a good output even for small currents. Phase-angle and ratio corrections can be made over a wide range of current in the primary by the use of series or shunt impedance, which may be applied to either primary or secondary. The capacitance coupling method was used some years ago for voltage indication and synchronizing, and more recently it has been widely used for relay operation. As the author remarks, the use of the capacitance tapping for obtaining a voltage eliminates the hazard of a potential transformer and tends to give much greater reliability. The use of the capacitance coupling for metering is subject to certain limitations. Normally the voltage obtained from a capacitance coupling with a step-down transformer has an angle of lead of 60° or 80°. It is, of course, possible by the use of shunt or series impedances to bring the voltage of the capacitance coupling into phase with the voltage of the high side. In general, however, the voltage may be taken from one of the other phases, so that only a

small phase-angle correction is necessary. It is evident that the characteristics of the capacitance coupling will be entirely different from those of a potential transformer, and unless this is recognized errors may result if either is used for metering purposes. Improvements in wave-form materially reduce the error. On some systems it is possible, by applying a factor or adjusting the coupling, to use the capacitance coupling for metering purposes. While the general use of the capacitance coupling for such purposes may be questionable, there are many applications where a high degree of accuracy is not necessary and which will not warrant the installation of potential transformers, owing either to the increased cost or to the greater hazard. The use of the capacitance coupling for load dispatching or telemetering installations is another application of bushings equipped with internal current transformer and capacitance couplings. While there are certain limitations as to the capacitance coupling, it seems that the development of the internal current transformer with wound primary would make it possible to improve station design. The large output which may be obtained regardless of the current in the primary and the high voltage involved, makes it possible to use additional apparatus which would overload a current transformer of the ring type. By using a considerably higher voltage on the secondary the size and cost of the leads can be greatly reduced. This is particularly important where the switchboard or control apparatus is located at a distance from the current transformer. The internal current transformer having a wound primary has a particular application for interconnections where the current may vary over a wide range and may even reverse. The improved metering equipment for points of interconnection will enable interconnections to be made to advantage which are practically out of the question at present, owing to the cost of metering at a high voltage. The voltage gradient over the surface has much to do with the relation between the dry and wet arcing voltages for the bushing. A bushing with a rather poor stress distribution may have its gradient so improved in the rain or wet test that the flash-over voltage when wet will be approximately the same as, or even higher than, that when dry. This is particularly true where the artificial rain and conditions are such that the surface of the bushing will not become hot. It must be remembered that the charging current is materially in advance of the voltage, and that an appreciable drop in voltage may be developed over wet surfaces. The wet flash-over voltage is therefore not necessarily a function of the so-called wet "striking distance" for most designs. In fact, many bushings will give a higher wet flash-over voltage when the wet striking distance is reduced so as to prevent over-stress or "priming" of a zone which is carrying too high a voltage. In general, high wet flash-over voltages are more easily obtained with bushings having small flanges. The loss due to surface leakage, however, is generally higher with bushings of this type at normal operating voltages. A small heating element placed inside the shell of an oil-filled bushing will greatly reduce the leakage losses and improve the reliability of the bushing where it is likely to be subjected to severe fogs, salt, or dirt. Numerous types of bushings which have been successfully used over a period of years are likely to cause radio trouble and therefore cannot be employed at the present time in many districts. For some years manufacturers have been gradually increasing the flash-over voltages of bushings in order to prevent interruptions. Higher flash-over voltages will undoubtedly be used as means are found to increase the ability of apparatus to withstand high-voltage transients. Bushing specifications should be given careful consideration, as a severe specification may result in a poor design. Some designs of bushings which can withstand very severe transients will fail at a comparatively low voltage in a normal-frequency test where the voltage is applied for a length of time sufficient to cause breakdown due to a pyro-electric effect over the surface. A specification calling for a very high wet flash-over voltage may result in a bushing which has higher losses under conditions of rain at the normal operating voltage. Specifying an unnecessarily high current-carrying capacity in the bushing, or the application of a very high voltage for a considerable length of time, may necessitate the use of a larger diameter of lead, which will increase the gradient or surface stress on the outside of the bushing. This may make it necessary to use a larger or more expensive bushing without any improvement for operating conditions. One of the greatest difficulties in the design or manufacture of bushings, particularly those of large size, is to prevent cracking under operating conditions owing to differential expansion between the dielectric and the metal, or to shock in the case of circuit breakers. During the last 3 years bushing design has been so improved that the ability to withstand shock and thermal stresses is such that not a single large-size bushing has been lost, either in shipment or in operation, by the company with which I am associated. As the above applies particularly to circuit-breaker bushings having net weights from 1 500 to 2 500 lb., designed for operating voltages from 196 to 220 kV, it will be seen that the problem of building and shipping smaller and lighter bushings is easy nowadays compared with what it was a few years ago.

Dr. Eng. H. von Treufels (*communicated*): In regard to the relation of the flash-over voltage in oil to the flash-over voltage in air the author states that for smooth porcelain a factor of 2·5 should be applied, and that this factor should be a trifle higher for ribbed porcelain. This agrees with my experience. For purposes of calculation I generally employ a factor of 3. It is, moreover, customary in Germany to fix the flash-over voltage in air of the oil end of the bushing at 200 per cent of the working voltage. I agree with the author that the dry flash-over voltage depends upon (*a*) the dry flash-over distance, (*b*) the radial dimensions of the bushing, and (*c*) the nature of the dielectrics. I would point out that according to Toepler the "gliding spark voltage" ("Gleitfunkenspannung") at which short, blue, gliding discharges appear, may be computed from the formula

$$E_g = 74 \cdot 8\,(d/\kappa^{0 \cdot 44})$$

where d = thickness of insulating sheath, and κ = specific inductive capacity of insulating material. This calculation seems to me of importance inasmuch as the dry flash-over voltage may be adversely affected

by an essentially lower gliding spark voltage. The formula is very useful to the designer of multi-tubular bushings incorporating the condenser principle, as it enables him to satisfy himself that a normal relation exists between the thickness of the porcelain and the length of the bushing. For such bushings the gliding spark voltage of the entire bushing is easily calculated as it represents the sum of the gliding spark voltages appertaining to the separate cylinders or tubes. The curves reproduced in the author's Fig. 21 agree with the results of our investigations. In regard to the problem of oil-tight bushings, it is possible to construct the gaskets without using cement. For this purpose the porcelain parts require to be provided with bevelled shoulders at their flange ends, serving as seats for gasket and flange. In Fig. D(*a*) I have combined the gasket designs of Figs. 26 and 27 with the cementless type mentioned above. Investigations are now being made into the question whether cork linoleum or klin-

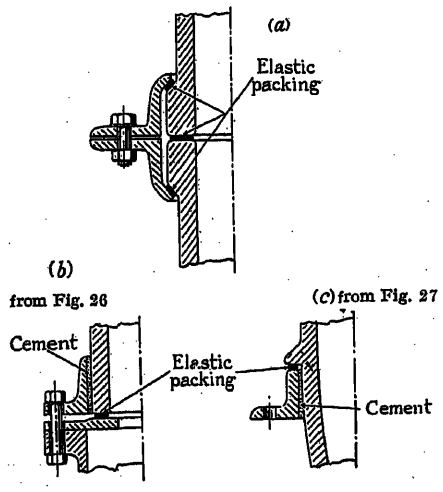

FIG. D.

gerite is the more suitable for packing purposes. The following are the unique advantages of all-porcelain multi-tubular bushings embodying the condenser feature. (i) No oil or explosive insulating material used. (ii) Smaller diameter of bushing. (iii) Minimum height of insulator part in consequence of favourable distribution of stress. (iv) Porcelain only employed as insulating material: no cementing material used. (v) Simple and clear calculation of the stress to which the separate parts are subjected. (vi) Insulation divided into separate elements, thus enhancing reliability of the bushing in service. (vii) Preliminary test of the separate cylinders or tubes can be made by subjecting them to over-voltages. (viii) Possibility of making direct connection between measuring devices and the layers or deposits on the surface of the porcelain. (ix) Maximum mechanical resistance to bending and axial pressure. (x) Simple mounting. Improvements in manufacturing methods and further practical experience will greatly enhance these advantages.

Mr. W. J. John (*in reply*): I agree with Mr. Norris that the present design and construction of bushings are based on operating experience rather than on fundamental principles, and I have attempted in the first part of the paper to do something to improve this state of affairs. The great difficulty, as Mr. Norris points out, is in allowing for the effect of surges due to lightning and other causes. He is of opinion that bushings should be identical whether the transformer insulation is graded or not; although I must confess to a considerable degree of sympathy with this point of view, I believe that on the whole a better procedure is that advocated in Table 9, where different characteristics are suggested, depending upon whether or not the insulation is graded. The 1-minute tests are different for the two types, and hence the bushing characteristics associated with them are also different. By a correct choice of line-insulation characteristics (see page 304) it is possible to reduce the magnitude of the incoming surges to a value which the graded-insulation bushing can withstand, thus enabling a cheaper bushing to be employed. While this may become important at the higher voltages, say 66 kV and above, up to 33 kV I agree with Mr. Norris that all bushings should be identical whether their transformers have graded insulation or not: the saving in cost is not sufficiently important to overcome practical objections to increasing the number of standard bushings. Mr. Norris's discussion of the different surge breakdown characteristics of air and solid insulation is valuable. I do not agree with his statement that the $\frac{1}{2}$ microsecond which elapses before a reflected wave causes flash-over at the nearest line insulator is so short that no damage results. Its possible effect on the solid insulation is pointed out by Mr. Norris himself earlier in his contribution.

Mr. Ashley is disappointed because I have given little information regarding the condenser-type bushing (page 318). The design and construction of this type are so distinctive that any attempt to deal with them adequately would have made the paper unduly long. I should like to make it perfectly clear, however, that I in no way disparage or undervalue condenser bushings. The paper makes fair statements regarding the relative advantages and disadvantages of this type of bushing, and none of these statements can be correctly classed as "unfortunate." Whereas condenser-type bushings have given trouble in the not far-distant past, trouble with oil-filled bushings has been very rare: I do not agree that the past record of condenser-type bushings of all makes is as good as that of oil-filled bushings. The modern condenser-type bushing is, however, an excellent product, and the operating record of an average bushing of this type will in the future probably be as good as that of an average bushing of any competitive type. The statement in the paper regarding the relative costs of the different types is a generalization, and I agree with Mr. Ashley that the comparison may be affected when extra features are included. It is true that the safety of the oil-filled bushing depends upon the oil remaining in the porcelain top and bottom shells, and the function of the gauge glass is to afford visible indication that the oil is so remaining. Any leakage which may occur will be very slow, and the fall of the oil-level should be noticed in ample time to prevent any damage. What Mr. Ashley claims for the broken porcelain rain-sheds of a condenser-type bushing can

be claimed even more positively for a leaky oil-filled bushing; with a slow leak "the bushing would still operate satisfactorily and thus allow time for alternative supply arrangements to be made." His queries regarding Tables 20 and 22 have been answered in the reply to Mr. Abell's contribution to the London discussion (see page 333). The use of the word "paxolin" in the paper must be regarded as a convenient abbreviation of "synthetic resin varnish-treated paper." It is pointed out on page 311 that paxolin is taken as being representative of this type of insulation.

Mr. Fennell's remarks are particularly valuable as coming from a user rather than from a manufacturer. His experience with oil leaks is, I believe, shared by many users of outdoor transformers having conservators. This trouble is being given careful attention by manufacturers, and a bushing can be produced which is completely oil-tight at both the flange and the top cap surrounding the centre conductor. The great trouble is that so many factors are involved that it appears to be impossible to obtain by a reasonably simple commercial method a joint which is consistently oil-tight. Of 12 joints made by commercially identical processes, 10 may be good and 2 bad. A further hazard is introduced by the stresses placed on the joints in the process of connecting the leads to the completed bushing. I agree with Mr. Fennell that a metal ring cemented to the insulator is the proper medium for connecting the bushing to the transformer tank. As stated in my reply to Mr. Norris, I also agree that up to 33 kV no distinction should be made in the bushing whether its transformer has an earthed or an insulated neutral.

I support Mr. Robertson's opinion that any assumption as to the resistivity of the water used in the wet flash-over tests is dangerous. The resistivity should always be checked, and simple instruments are obtainable for measuring it quickly and accurately. Full details of wet tests are given in several specifications.*

The question of impulse figures raised by Dr. Miller is very interesting, and much information regarding it is accumulating as a result of modern research work. Much still remains to be cleared up, however, and agreement has not yet been reached concerning such important matters as the shape of the impulse wave experienced in practice and how far laboratory tests made by means of surge generators and cathode-ray oscillographs actually reproduce any desired wave-shape. I agree with Dr. Miller that the question of the effect of surges on the inter-turn insulation as distinct from the major insulation is important, and his opinion that transformers may break down under impulse conditions even if designed to stand the 1-minute test for fully insulated transformers shows the importance attaching to a study of this matter. I return to this subject in my reply to Mr. Taylor. I thank Dr. Miller for including in his contribution to the discussion an account of some valuable work on the effect of inductances and condensers in reducing over-voltages.

Mr. Singer believes in the future of the all-porcelain multi-tubular type of bushing. While this is undoubtedly an excellent type, it becomes heavy and costly for voltages much in excess of 66 kV (see Fig. 38). The all-porcelain multi-tubular bushing incorporating the condenser principle retains all the advantages of the plain multi-tubular type and very considerably reduces its disadvantage of excessive bulk. Regarding compound filling, this is perfectly satisfactory provided the correct kind of compound is used and a certain technique is adopted. I am not acquainted with the type of all-porcelain bushing manufactured by Hermsdorf-Schomberg and Co., in the manufacture of which porcelain in the fluid state is used, and I therefore cannot express any opinion concerning it. The figures of heavy rainfall were included in the paper because of all the atmospheric conditions which affect bushing performance rain was the only one for which information was available in statistical form. Appendix IV justifies the rate of precipitation used for the artificial rain tests in Section 2.

I am in complete agreement with Mr. Taylor's summary of the reasons for exercising caution when attempting to design a bushing from formulæ and curves. Mr. Taylor, like Dr. Miller, draws attention to the necessity for distinguishing between major insulation and internal insulation. The formula (page 303) connecting surge strength of complete transformer and 1-minute transformer test is based on operating experience and therefore deals with the transformer insulation as a whole, both major and internal. It assumes that the internal insulation of transformers tested to the 1-minute test values specified in B.S.S. No. 171—1927 follows normal practice, since the formula is, of course, a generalization. Regarding Schering bridge tests, these were not included because—as Mr. Taylor suggests—the paper does not deal in detail with condenser-type bushings, and it is only for these that the Schering bridge has been used commercially. The electric strengths of air and oil given in Fig. 11 are taken from results obtained by Peek. The air under test was enclosed between concentric cylinders open at both ends. The temperature was 25° C. and the pressure 76 cm of mercury. When tested between standard discs 0·5 cm apart the oil withstood 58 kV (max.) at 25° C. The effect on the puncture voltage of the various factors mentioned by Mr. Taylor is allowed for because the values for the electric strength of porcelain tubes were actually obtained by tests on bushings. These bushings were tested when made for ordinary operating conditions and so, if preferred, the equations used for the determination of puncture voltage (see page 314) may be regarded as empirical, $g_{max.}$ being obtained from analysis of test results. The "hybrid" oil-filled condenser-type bushing is interesting, but it is not described in the paper because details of condenser-type bushings are omitted.

Mr. Austin's contribution is particularly welcome, seeing that it comes from a leading American authority who has had unrivalled experience of high-voltage insulation problems. I am particularly interested in the information he gives concerning the use of wound-primary current transformers and capacitance tappings.

Dr. von Treufels makes a number of interesting remarks as to German practice. He sets out very fairly the claims of the multi-tubular all-porcelain bushing incorporating the condenser principle of construction. In my opinion this type of bushing has much to commend it.

* See, for example, B.S.S. No. 223—1931, p. 12.

AN EXPERIMENTAL AND ANALYTICAL INVESTIGATION OF EARTHED RECEIVING AERIALS.*

By F. M. COLEBROOK, B.Sc.

[From the National Physical Laboratory.]

(*Paper first received 25th June, 1931, and in final form 15th January, 1932.*)

SUMMARY.

The paper is concerned with the behaviour of earthed open-aerial receiving systems. The analysis of such systems is based on the classical transmission-line equations, as modified by Moullin to apply to distributed excitation.

Part 1 gives the theoretical formulæ so obtained for the case of a plain aerial with uniformly distributed constants, and the detail of the variation with frequency of the resistance and reactance components of the effective impedance of such an aerial.

It is shown that successive resonances (i.e. conditions of zero reactance) are given by an equation of the form

$$\lambda = (4h/n)(1 + Ah^2)$$

where n is any integer and A is a small factor depending on n and on the attenuation constant of the aerial considered as a transmission line. The corresponding values of the resistance are shown to be $Rh/2$ (approximately) when n is odd, and a very high value when n is even, R being the total effective resistance per unit length of the aerial.

The actual variation of the impedance of a plain uniform aerial as a function of frequency was determined experimentally, and a detailed analysis of the results in relation to the theory is given.

The observed variations of resistance and reactance are shown to be in substantial agreement with those deduced from the analysis, but it appears that the actual length of the aerial (h) must be replaced by an effective length $h + \varepsilon$, ε being about 5 per cent of h. This is in agreement with a more rigid analysis by Abraham, and with experimental results obtained by Wilmotte. The observed aerial resistance was found to be mainly due to parasitic eddy-current and dielectric losses. It was reduced to less than one-third of its value by using a single-wire "earth screen."

The validity of the fundamental assumptions, to a useful degree of approximation, having been established by measurement, Part 2 of the paper is devoted to obtaining additional information by purely analytical methods. The analysis is mainly based on the case of a plain aerial divided into three parts in each of which a uniformly distributed e.m.f. is assumed to be induced, the intensities being different in the three parts.

By an analytical manipulation of this three-part case a line integral formula is found for the effective e.m.f. induced in a uniform aerial by a non-uniform field (Section 7). The variation of the effective e.m.f. induced by a uniform field is considered as a function of frequency and aerial height, and it is shown that no advantage is gained by making $h > \lambda/4$ unless certain parts of the aerial are compressed (Section 8).

The relative effectiveness of different parts of a receiving aerial is considered in Section (9), and it is found that in an L aerial short compared with the wavelength the addition of a down-lead from the open end nearly to the ground may actually increase the total effective e.m.f. in spite of the reversed e.m.f. induced in the added length.

An earthed aerial of this shape with the vertical members of length $\lambda/4$ and the horizontal member of length $\lambda/2$ is shown to have a figure-of-eight polar diagram with a law of the form $\cos(\frac{1}{2}\pi \cos\theta)$ (Section 10).

The effective e.m.f. formulæ of the three-element case are applied to the Franklin suppressed half-wave construction and afford means of allowing for the effect of aerial resistance in this system (Section 11).

In Section (12) the effective e.m.f. of the present formulation is related to the original conception of "effective height." It is suggested that the idea of "effective height" is one which has to a great extent outlived its usefulness.

The analysis of a receiving aerial considered as a collector of energy from the incident wave is given in Section (13). The figure of merit from this point of view is $|e_\theta|^2/R_\theta$, which is determined as a function of h and λ. It reaches a maximum when h is very approximately $\lambda/4$, and thereafter oscillates with rapidly diminishing amplitude. Considered as a collector of energy the suppressed half-wave construction will not apparently give an increase in useful power proportional to the increase in height, owing to the corresponding increase in R_θ.

Current and potential distributions in receiving and transmitting aerials are discussed in Section (14). It is shown that they depend on the distribution of the exciting field, and that the current distribution in a receiving aerial may be totally different from that in a transmitting aerial of the same height. Current nodes in a receiving aerial may be any distance apart from 0 to λ, and are not necessarily separated by half a wavelength as in a transmitting aerial with a point source of excitation.

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

Part I.

(1) INTRODUCTION.

The author has given in an earlier paper* an analytical discussion of the behaviour of a receiving aerial, this paper being an extension and generalization of a paper by E. B. Moullin† on the same subject. A further degree of generalization was arrived at by R. M. Wilmotte.‡ Various formulæ for the effective resistance and reactance of a receiving aerial were given in these papers, and also formulæ for the effective height of the aerial under various conditions. A more general result was also deduced analytically and confirmed by experiment,

* See Bibliography, (1). † *Ibid.*, (2). ‡ *Ibid.*, (3).

namely, that the current at the base of a receiving aerial could be represented as the vector quotient of an effective e.m.f. divided by the vector sum of the tuning-circuit impedance and an effective aerial impedance. It was shown that the latter would be independent of the distribution of e.m.f. in the aerial and could therefore be determined by measurements made with a locally induced e.m.f.

Since the above papers were written a method of measuring resistance and reactance at radio frequencies has been developed at the National Physical Laboratory.* The method is very conveniently applicable to the measurement of aerial impedance and it was decided to make measurements on a small receiving aerial with a view to finding out how closely the simple transmission-line equations that had been used in the analysis represented the actual state of affairs. At the same time the analytical side of the subject was further extended, particularly with a view to arriving at a practical general formula for the effective e.m.f. induced by a non-uniform field, and also to arrive at some knowledge of the current distribution in an aerial under transmission and reception conditions. The paper records the progress made in these directions.

(2) Analysis of the Variation with Frequency of the Impedance of a Plain Aerial.

This subject has already been considered to some extent in the earlier paper referred to in the first Section, but the most important features will be re-stated here for convenience of reference, and developed in a form suitable for experimental verification.

The aerial is assumed to have a uniform resistance, inductance, and capacitance per unit length, represented by the symbols R, L, and C. This assumption is obviously open to question both as to the uniformity and to the precise significance of the symbols R, L, and C. The question of significance need not be considered at this stage. It will be sufficient for present purposes to consider the symbols as being virtually defined by the differential equations in which they appear—to regard them, that is to say, as the coefficients of the " in phase " and " in quadrature " potential differences assumed to exist in the differential elements of the conductor. These coefficients will be assumed uniform because it is one of the objects of the investigation to find to what extent this assumption, known to be inexact but without which the equations are practically impossible to solve, is a sufficiently close approximation to be useful.

The aerial is assumed to be of total length h and to be connected to earth through an impedance Z_0. It is situated in an electric field the precise configuration of which need not be specified at this stage, beyond stating that its variation with time is sinusoidal, with pulsatance ω. As shown in the earlier paper, the current at the base of the aerial can be represented in the vector form

$$i_0 = \frac{e_e}{Z_0 + Z_e} \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where e_e is an effective e.m.f. depending on the constants and configuration of the aerial and of the field, and Z_e is an effective aerial impedance which is independent of the field and is thus a characteristic of the aerial alone. For the present we shall be concerned only with this quantity Z_e. It is of the form

$$Z_e = Z \coth Ph \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where $$P^2 = j\omega C(R + j\omega L) \quad . \quad . \quad . \quad . \quad . \quad (3)$$

and $$Z = P/(j\omega C) \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

Writing $P = \alpha + j\beta$, the components α and β depend on the constants L, C, and R as follows. If $R^4/(\omega^4 L^4)$ be neglected compared with 1

$$\alpha = \frac{R}{2}\sqrt{\left(\frac{C}{L}\right)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

and $$\beta = \omega\sqrt{(LC)}\left(1 + \frac{R^2}{8\omega^2 L^2}\right) \quad . \quad . \quad . \quad (6)$$

If in addition $R^2/(8\omega^2 L^2)$ is negligible compared with 1, we have the simpler result

$$\beta = \omega\sqrt{(LC)} \quad . \quad . \quad . \quad . \quad . \quad . \quad (7)$$

Under the conditions of the second approximation, if

$$Z = a + jb \quad . \quad . \quad . \quad . \quad . \quad . \quad (8)$$

then $$a = \left(\frac{L}{C}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

and $$b = -\frac{R}{2\omega\sqrt{(LC)}} \quad . \quad . \quad . \quad . \quad (10)$$

The separation of Z_e into its resistive and reactive components R_e and X_e presents no difficulty. It gives

$$R_e = \frac{R}{2\alpha\beta} \cdot \frac{\beta \sinh 2\alpha h - \alpha \sin 2\beta h}{\cosh 2\alpha h - \cos 2\beta h} \quad . \quad . \quad (11)$$

$$X_e = \frac{1}{\omega C} \cdot \frac{\alpha \sinh 2\alpha h + \beta \sin 2\beta h}{\cosh 2\alpha h - \cos 2\beta h} \quad . \quad . \quad (12)$$

The above are exact formulæ. In making any approximations some care must be exercised. It is true that αh is small in many, if not most, practical cases, but the βh terms vanish periodically, so there will always be regions where the αh terms, small though they may be, are the principal factors. Further, it will be apparent from the consideration of actual magnitudes in a later Section that there will be many cases where the αh terms are not negligible compared even with the maximum values of the other quantities. With these reservations, however, we can form some idea of the general character of the variation of R_e and X_e with frequency by assuming that $\alpha^2 h^2$ is small compared with 1, so that $2\alpha h$ can be written for $\sinh 2\alpha h$ and 1 for $\cosh 2\alpha h$. Then

$$R_e = Rh\frac{2\beta h - \sin 2\beta h}{2\beta h(1 - \cos 2\beta h)} \quad . \quad . \quad . \quad (13)$$

except when $\cos 2\beta h$ is in the neighbourhood of unity. Thus, apart from the variation of R itself with frequency, R_e will vary with frequency in the manner of the function

$$\frac{\theta - \sin\theta}{\theta(1 - \cos\theta)}$$

* See Bibliography, (4).

which is shown plotted in Fig. 1. (The infinities of this function are regions where the approximation is no longer valid.) The observed variation of R_e is of this character, but, as will appear later, it is complicated by the fact that R itself increases with frequency. It should be noted that the function has the limiting value $\frac{1}{3}$ when $\theta \to 0$, corresponding to the fact that R_e tends to the limit $Rh/3$ when the aerial is small compared with the wavelength.

In a similar manner the expression for X_e can be approximated to

$$X_e = -\frac{1}{\omega C h} \cdot \frac{\beta h \sin 2\beta h + 2\alpha^2 h^2}{1 - \cos 2\beta h + 2\alpha^2 h^2} \quad . \quad . \quad (14)$$

and except in the region where $1 - \cos 2\beta h$ is nearly zero, this approximates very closely to

$$X_e = -\frac{1}{\omega C h} \cdot \beta h \cot \beta h = -\sqrt{\left(\frac{L}{C}\right)} \cot \beta h \quad . \quad (15)$$

Thus the general character of the variation of the

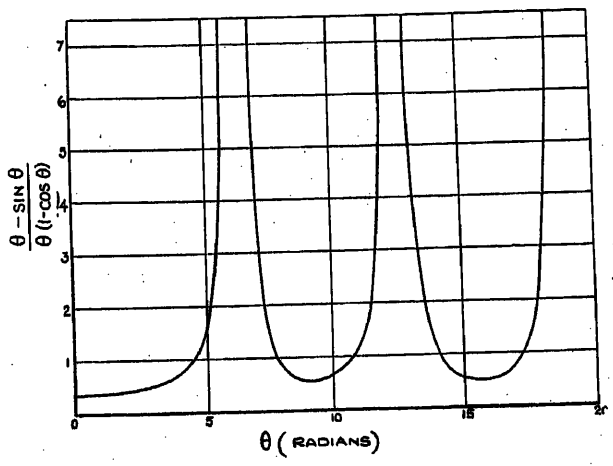

FIG. 1.

reactance is that of the variation of $-\cot \frac{1}{2}\theta$, using θ in the same sense as above, but the effect of the resistance terms is to convert the $\pm \infty$ discontinuities into a very steep variation between finite limits. The variation is illustrated pictorially in Fig. 2. The observed variation of X_e is known to be of this character.

The critical values of X_e and R_e will now be examined in more detail for comparison with observed values.

(3) DISCUSSION OF CRITICAL VALUES OF AERIAL RESISTANCE AND REACTANCE.

(a) *The Resonance or Zero-reactance Conditions.*

Since

$$X_e = -\frac{1}{\omega C} \cdot \frac{\alpha \sinh 2\alpha h + \beta \sin 2\beta h}{\cosh 2\alpha h - \cos 2\beta h}$$

the condition for zero reactance is

$$\alpha \sinh 2\alpha h + \beta \sin 2\beta h = 0 \quad . \quad . \quad . \quad (16)$$

No exact explicit solution is obtainable in general terms, but the solution is obviously of the form

$$2\beta h = n\pi + \theta \quad . \quad . \quad . \quad . \quad (17)$$

where θ is small and n is any integer. The assumption that θ is small leads by ordinary methods to the solution

$$\theta = (-1)^{n+1} \frac{4\alpha^2 h^2}{n\pi} \quad . \quad . \quad . \quad . \quad (18)$$

giving as the values of βh corresponding to zero reactance

$$2\beta h = n\pi \left\{1 + (-1)^{n+1} \frac{4\alpha^2 h^2}{n^2\pi^2}\right\} \quad . \quad . \quad (19)$$

It will be convenient to express β in terms of λ. For this purpose we have, from the definition of α and β,

$$\beta^2 = \omega^2 LC + \alpha^2 \quad . \quad . \quad . \quad . \quad (20)$$

If we now assume that the velocity of electric waves along a resistanceless wire is the same as that in free space, we have

$$\omega^2 LC = 4\pi^2/\lambda^2 \quad . \quad . \quad . \quad . \quad (21)$$

so that

$$\beta = \frac{2\pi}{\lambda}\left(1 + \frac{\alpha^2\lambda^2}{8\pi^2}\right) \text{ very approximately} \quad . \quad (22)$$

By a simple process of successive approximation we can obtain as the resonance or zero-reactance relations between h and λ

$$\lambda = \frac{4h}{n}\left(1 - \frac{2\alpha^2 h^2}{n^2\pi^2}\right) \text{ when } n = 1, 3, 5, \text{ etc.} \quad . \quad (23)$$

$$= \frac{4h}{n}\left(1 + \frac{6\alpha^2 h^2}{n^2\pi^2}\right) \text{ when } n = 2, 4, 6, \text{ etc.} \quad . \quad (24)$$

The odd values of n correspond to the ordinary $\frac{1}{4}$ wavelength and $\frac{3}{4}$ wavelength resonances (points P_1 and P_3 in Fig. 2). The even values of n correspond to the zero reactance points at the centre of the steep variation between the apparent discontinuities (points such as P_2 in Fig. 2). Thus the reactance is not infinite or very large when the height is half a wavelength, but is actually zero, with very large positive and negative values on either side of this condition. The impedance, however, is very large in this region, since R_e is very large.

It will be shown later that the correction terms in the above resonance relations are, in general, very small—parts in a thousand only. The observed differences between λ and $4h/n$ will be found to be due to another cause and not the inherent resistance correction given above.

It is again emphasized, however, that in spite of the smallness of the correction terms they must be taken into account when the variations of the impedance and the effective e.m.f. under resonance conditions are being considered, for at certain of the resonances the variation with frequency is so rapid that the small correction terms are actually the decisive and important ones. This is, of course, a general observation applicable to all analyses of resonances. Though the effect of the resistance terms may in general be negligible they become

the principal determining factors in the neighbourhood of resonant conditions, so that any analysis of the behaviour of receiving aerials which neglected the resistance terms would be useless in relation to some of the most interesting and important features of the problem.

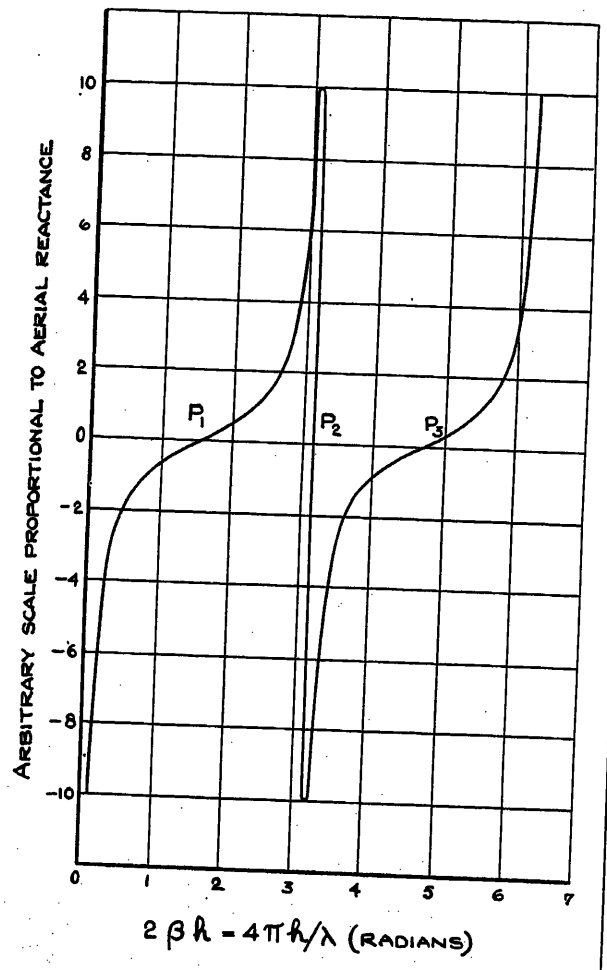

FIG. 2.

Certain other particular values of the reactance are of interest, namely those for which

$$2\beta h = (2n + 1)\pi/2$$

or

$$h = (2n + 1)\lambda/8$$

For these points, assuming that $2a^2h^2$ is negligible compared with 1 and βh,

$$X_e = \pm \frac{\beta h}{\omega C h} = \pm \sqrt{\frac{L}{C}} = \pm \frac{1}{C \times 3 \times 10^{10}} \quad . \quad (25)$$

These points are therefore convenient for determining the apparent value of C, the capacitance per unit length. Another condition useful for this purpose is given by

$$Ch = -\lim_{\omega \to 0} \frac{lt}{\omega X_e} \quad . \quad . \quad . \quad . \quad (26)$$

(b) Critical Values of the Effective Resistance.

In general

$$R_e = \frac{R}{2a\beta} \cdot \frac{\beta \sinh 2ah - a \sin 2\beta h}{\cosh 2ah - \cos 2\beta h}$$

Some interest attaches to the values of R_e corresponding to the resonant frequencies considered in the preceding Section. In the case of the quarter wavelength resonances, R_e is not varying very steeply with frequency, and the approximation $\lambda = 4h/n$ can safely be used. This corresponds to $2\beta h = n\pi$, $n = 1, 3, 5$, etc., and gives

$$R_e = \frac{R}{2a\beta} \cdot \beta \cdot \frac{\sinh 2ah}{1 + \cosh 2ah} \quad . \quad . \quad (27)$$

$$\approx \frac{Rh}{2} \text{ if } a^2h^2 << 1$$

In the case of the half- and full-wave resonances R_e is varying very rapidly with frequency and is very large. An exact solution can be carried out by substituting the relevant resonance condition in the general formula for R_e, but it leads to a complicated result which cannot safely be approximated.

Other convenient particular values are those corresponding to

$$h = (2n + 1)\lambda/8 \ (n = 0, 1, 2, 3, \text{etc.})$$

which give for $h = \lambda/8$

$$R_e \approx Rh(1 - 2/\pi) \approx 0{\cdot}36Rh \quad . \quad . \quad (28)$$

and for $h = 3\lambda/8$

$$R_e \approx Rh(1 + 2/\pi) \approx 1{\cdot}21Rh \quad . \quad . \quad (29)$$

etc.

where a^2h^2 is neglected by comparison with 1. Finally, when $\beta h \to 0$, i.e. when the aerial is short compared with the wavelength,

$$R_e \to Rh/3 \quad . \quad . \quad . \quad . \quad . \quad (30)$$

(4) Measurement of the Effective Impedance of a Typical Small Receiving Aerial.

Measurements were made of the impedance between the aerial and earth terminals of a plain aerial of 3/19 S.W.G. copper wire having a total length of 38·6 m (about 127 ft.) from free end to earth. The aerial consisted of two parts, a horizontal part about 29 m long at a height of about 7·5 m, the remainder of the length being in a sloping lead to earth. The aerial and earth leads were brought in through the wall of a wooden hut running parallel to the horizontal part of the aerial. The length of the earth lead (included in the total length given above) was about 2·5 m. The earthing system consisted of a line of buried copper plates running along the foot of the wall of the hut.

The impedance of the aerial with respect to an e.m.f. applied between the aerial and earth terminals was determined in the form $R_e + jX_e$ by the methods described in the paper listed as No. 4 in the Bibliography, over a range of frequencies of 200 to 7 000

kilocycles per sec. The results are shown in curve A of Fig. 3 (for R_e) and in Fig. 4 (for X_e). The reactance variation appears to be qualitatively consistent with the generally accepted simple theory, but the second branch appears to have been displaced downwards. This effect was eventually traced to the influence of the earth lead and it was found possible to apply a correction in a manner to be described more fully later on. The corrected reactance/frequency curves for an aerial of length $38{\cdot}6 - 2{\cdot}5 = 36{\cdot}1$ m (i.e. shortened by the length of the earth lead) are given in Fig. 5.

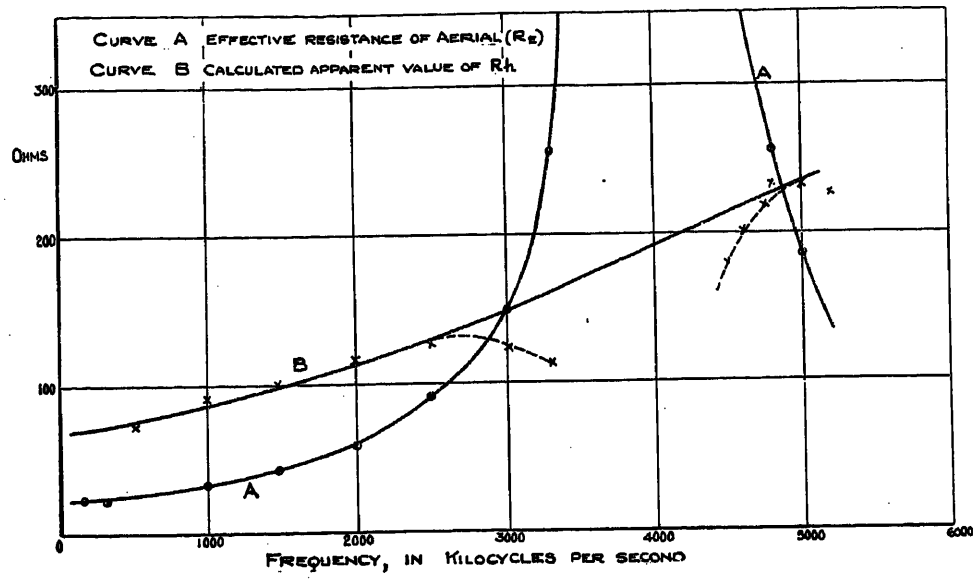

FIG. 3.

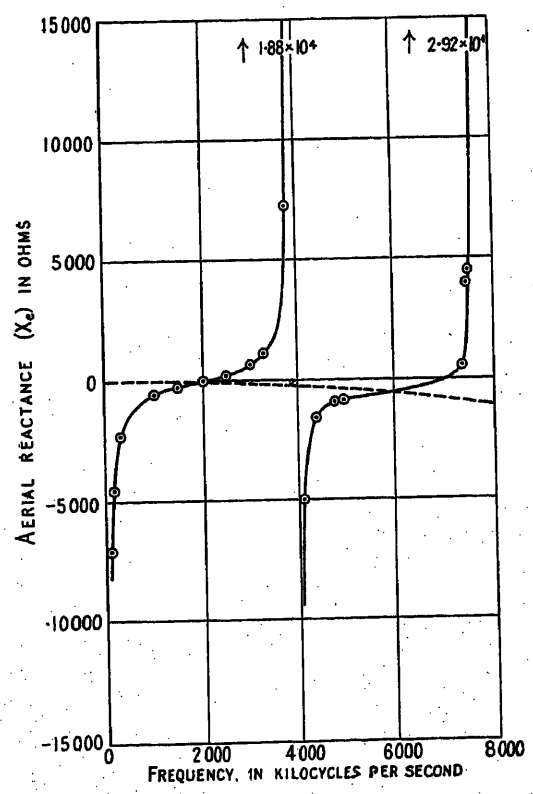

FIG. 4.

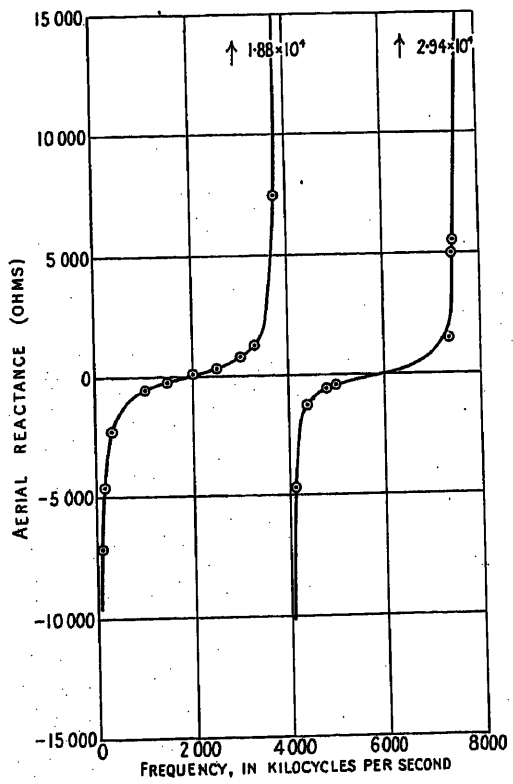

FIG. 5.—Aerial reactance curves corrected for effect of earth lead.

The data represented by curve A of Fig. 3 and the

curve of Fig. 4 will now be compared with the theory given in Section (3).

(5) Quantitative Analysis of the Measured Values of Aerial Impedance.

In order to explain the correction for the earth lead referred to in Section (4) it will be necessary to describe in outline the method of measurement. Referring to Fig. 6, the measurements were made by determining the changes in the apparent constants (resistance and reactance) of the coil $L_1C_1R_1$ when the aerial was connected at the point A, the earth lead being connected all the time. What was actually measured was, therefore, $Z_e + Z_l$ (see Fig. 6*b*), Z_e being the impedance of the aerial alone ($38{\cdot}6 - 2{\cdot}5 = 36{\cdot}1$ m long) and Z_l the impedance of the earth lead as modified by the capacitance to earth of the screening cases of the condensers

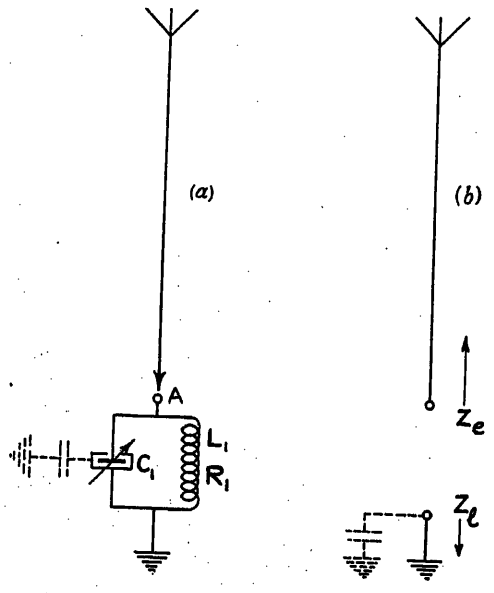

Fig. 6.

employed (shown dotted in Fig. 6*a*). The apparent zero-reactance conditions were therefore those for which the reactance of Z_e was equal and opposite to that of Z_l. Though the impedance of the earth lead alone would not have been very large it was evidently very greatly increased by the parallel capacitance C_e, which was estimated to be of the order of 10^{-11} at least. Unfortunately the very appreciable effect of the earth-lead impedance was not realized until the measurements had been completed, or steps would have been taken for its minimization. However, the measurements having been made, it was decided to allow for the effect by assuming that the displacement of the centre of symmetry of each branch of the reactance curve below the axis gave the magnitude of the reactance of the earth-lead system at the frequency concerned. This gave the origin and two other points through which to draw a line showing the reactance of the earth-lead system as a function of frequency. From this line the necessary correction was found and applied to the apparent reactance to obtain the true reactance of the aerial of length $38{\cdot}6 - 2{\cdot}5$ m. The curve of Fig. 5 was obtained in this way. This process may perhaps be regarded as begging the question as to the cause of the displacement of the reactance curves, but a calculation based on measured and estimated data showed the magnitude of the effect to be quite consistent with the assigned cause. The following comparisons of calculated and measured values are based on Fig. 5, which is taken to represent the variation with frequency of the reactance of an aerial of length $h = 36{\cdot}1$ m.

The observed variation of resistance will first be considered, as resistance terms are involved as corrections in the resonance conditions.

(*a*) *Analysis of the Observed Variation of Aerial Resistance.*

It was shown in Section (2) that, except for frequencies in the immediate neighbourhood of those for which $\cos 2\beta h = 1$, the value of R_e is given by

$$R_e = Rh\frac{2\beta h - \sin 2\beta h}{2\beta h(1 - \cos 2\beta h)}$$

The form of the expression emphasises the fact that R_e depends on two factors—the first being the resistance per unit length multiplied by the total length, and the second a factor expressing the way that the current distribution controls the extent to which the first factor enters into the effective resistance. The first factor is, of course, not a constant with respect to frequency, since it involves radiation resistance, ordinary ohmic resistance, and dielectric and eddy-current losses in the surroundings. It will obviously be of interest to separate these two factors of R_e. Unfortunately β, and therefore the current distribution factor, involves R as a small correction term, as already explained, but as a first approximation this can be neglected. We then have from the curve of Fig. 5 that

$$2\beta h = \pi \text{ when } f = 1\,970 \text{ kilocycles per sec.}$$

and since on the above assumption β is proportional to f

$$2\beta h = \frac{\pi}{1\,970}f$$

Thus βh can be found for any assigned value of f, and the corresponding value of the current distribution factor read from the curves of Fig. 1. Rh can then be found as a function of frequency. The result is shown as curve B in Fig. 3. The dotted deviations from the full-line curve are obviously associated with the region $2\beta h = \pi$, where the approximate formula is no longer valid.

It appears that Rh rises fairly rapidly with frequency. Actually measurements were made at much higher frequencies—up to 10 000 kilocycles or so (30 m)—but subsequent checks on the measuring apparatus revealed a possibility of error in the results and it was thought necessary to discard them. However, allowing for this possibility, it seemed that Rh tended to rise very rapidly at the higher frequencies and might possibly become an appreciable factor in the natural frequencies of the aerial under such conditions.

(*b*) *Additional Measurements of Effective Resistance.*

For wavelengths long compared with the length of the aerial the effective resistance R_e has been shown by analysis to approach the value $R_e = \frac{1}{3}Rh$, where R is the assumed uniform resistance per unit length of the aerial.

The term R is obviously a summation of all the factors which give rise at any point in the aerial to potential differences which are in anti-phase with the current at that point, and therefore includes ohmic resistance, radiation resistance, and dielectric and eddy-current losses in the surroundings of the aerial. Of these the ohmic resistance is the only one which is dependent on the actual material of the aerial, for a given length and configuration. Thus

$$R_e = \frac{R_0 h}{3} + \frac{R_c h}{3}$$

where R_0 is the ohmic resistance per unit length and R_c is a composite effective resistance representing the remaining power-dissipating elements.

To get some idea of the relative magnitude of these terms, measurements were made of the effective resistance of the aerial at about 842 kilocycles per sec. (i.e. λ about 9·4 times h) with conductors of 3/19 S.W.G. enamelled copper, No. 34 tinned copper, and finally No. 47 double-silk-covered copper. The results were as given in Table 1.

The values of $R_0 h$ at the frequency concerned (calculated from the measured d.c. values by applying the appropriate skin-effect correction) are also shown in Table 1. It will be seen that $R_e - R_0 h/3$ is approximately constant, consistent with the above simple analysis.

It appears, therefore, that with the aerial of 3/19 copper the resistance term is almost entirely due to radiation resistance and to eddy-current and dielectric losses in the surroundings of the aerial. Of this the radiation resistance is only a small part. Its value is calculable from the well-known formulæ, and would only be about 0·5 ohm. Thus practically the whole of the aerial resistance in the case under consideration is due to purely parasitic eddy-current and dielectric losses.

T. L. Eckersley* has shown how these losses can be minimized by the use of a screen of high-conductivity wires shielding the ground in the immediate neighbourhood of the aerial from the relatively concentrated electric fields in that region. His work was concerned with transmitting aerials but is equally applicable to receiving aerials. With a view to confirming the assumption as to the nature of the losses represented by the resistance of the aerial, the buried copper-plate earthing system was replaced by a single insulated wire running parallel to and underneath the horizontal part of the aerial at a height of about 1 m above the ground. The effective resistance was measured and found to have been reduced from 30 ohms to 9 ohms by this rudimentary form of screen. With the same wire lowered on to the surface of the ground the effective resistance increased to 108 ohms. With a small earthing pin the effective resistance was 150 ohms. All these results are consistent with the view that the resistance of an earthed aerial can only be minimized by avoiding, as far as possible, any concentration of electric field in the earth in the neighbourhood of the aerial.

It is not possible to make a detailed comparison of the observed and calculated variation of R_e with frequency, since the necessary data are not available. There is some slight evidential value in Table 1, but a more satisfactory comparison of theory and observation can be obtained by an analysis of the reactance curves, the necessary correcting factors due to resistance being determined from the observed resistance variation.

TABLE 1.

Aerial	R_e	R_0h (d.c.)	R_0h (a.c.)	$R_e - (R_0h/3)$
3/19 S.W.G. enamelled copper	30	0·35	2·45	29·2
No. 34 tinned copper	33·8	15·8	17·4	28·0
No. 47 d.s.c. copper	138·5	329	329	28·8

(*c*) *Analysis of Observed Variations of Aerial Reactance.*

The resistance measurements are considered quite reliable up to about 5 000 kilocycles per sec., and the data obtained can be used for determining the effect of resistance on the critical reactance conditions corresponding to the lower natural frequencies of the aerial.

The value of ah is derived from the value of Rh and Ch as follows. From the definition of α and β

$$2\alpha\beta = \omega CR \quad . \quad . \quad . \quad . \quad . \quad (31)$$

From this can be derived

$$ah = \frac{3 \times 10^{10}}{2h} Ch \,.\, Rh \quad . \quad . \quad . \quad (32)$$

The value of Ch (see below) is very approximately 230 $\mu\mu$F, and, from the curves of Fig. 3, Rh is 110 at 1 970 kilocycles per sec.

Therefore $$ah = 0{\cdot}105$$

Referring to equation (23), the correction term involved in the resonance relations between λ and h is, for the fundamental resonance ($n = 1$), $2(ah)^2/\pi^2$. The value of this is 0·0022. Thus, so far as the critical reactance conditions are concerned, the resistance correction can be neglected to an accuracy of about 2 parts in 1 000. The correction will probably decrease with the order of the harmonic concerned, since n^2 appears in the denominator, but since $(ah)^2$ appears in the numerator and a

* See Bibliography, (5).

increases fairly rapidly with n (i.e. with the frequency), it is not necessarily safe to assume that it is negligible at very high frequencies. This is a matter requiring further investigation. Up to $n = 3$ or 4, however, it is clear that we can use the simple relationship

$$\lambda = \frac{4h}{n} \qquad n = 1, 2, 3 \quad . \quad . \quad . \quad (33)$$

for the comparison of measured and calculated resonance conditions. The comparison is given in Table 2 in the form of observed and calculated values of λ, assuming h to be 36·1 metres.

The most striking feature of the results is that the difference between the observed and calculated values is about 5 per cent throughout. If the length were assumed to be 36·1 + 5 per cent, i.e. 36·1 + 1·8 = 38 m, the observed and calculated values would be in agreement to about 1 per cent, which is about the probable accuracy of measurement. Thus the assumptions on which the analysis is based would appear to be valid to 1 per cent

TABLE 2.

n	λ (obs.)	λ (calc.)	f (obs.)	f (calc.)	Percentage difference
	metres	metres	kilocycles/sec.	kilocycles/sec.	
1	152·4	144·4	1 970	2 080	5·2
2	76·0	72·2	3 950	4 160	5
3	50·3	48·1	5 970	6 240	4·2
4	38·5	36·1	7 800	8 310	6·2

or so, provided the actual length of the aerial be increased by 1·8 m, i.e. the resonances are given by

$$\lambda = \frac{4}{n}(h + \epsilon) \quad . \quad . \quad . \quad . \quad . \quad (34)$$

ϵ being the above small correction term, presumably attributable to end-effect. This is analogous to the similar correction applied to the open organ pipe (i.e. + 0·58 × radius of pipe).

Wilmotte* found the result $\lambda = 4 \cdot 2h$ for a transmitting antenna 11 m high, the conductor being of cage form about 11 cm in diameter. He also states in the paper referred to that Abraham and Föppl arrived at the figure 4·2 by a more rigid analysis than that given in this paper. The results of the present measurements are in very satisfactory agreement with Wilmotte's measurements and Abraham and Föppl's calculation, for they give

$$\lambda = 4 \cdot 22h$$

(From the agreement between the present measurements and Wilmotte's result it would appear that the end correction is not critically dependent on the ratio of length to diameter of the aerial conductor.)

Certain other points on the reactance curves lend themselves to quantitative comparison of the theoretical and observed behaviour, namely those for which $2\beta h = (2n + 1)\pi/2$. As shown in Section 3(*b*), the corresponding reactances are $\pm 1/C \times 3 \times 10^{10}$. In addition, when $\beta h \to 0$, the reactance tends to $-1/\omega Ch$.

* See Bibliography, (11).

From reactance curves drawn to a large scale and corrected as already explained for the reactance of the earth lead, it was found that the reactances for these points with $n = 0$ and $n = 1$ (i.e. $\lambda = 8h$ and $8h/3$) were − 550 and + 530 ohms respectively, giving C as 0·061 and 0·063 $\mu\mu$F. The corresponding values of Ch (taking h as the corrected value 38 m) are 230 and 239 $\mu\mu$F. At low frequencies Ch is found from the curve to approach the limiting value 227 $\mu\mu$F. The experimental curves are thus self-consistent to this degree.

The general conclusion is that the analysis gives a satisfactory account of the behaviour of the aerial impedance as a function of aerial length and of frequency, provided the actual length be replaced by the slightly increased effective length (i.e. $h + 0 \cdot 05h$) as already explained.

The analysis and the fundamental assumptions having been confirmed to this degree by experiment, we can now proceed with a certain assurance to the further examination of the subject, with a view to obtaining the maximum amount of information by purely analytical methods.

Part 2.

(6) Further Analysis of the Behaviour of a Receiving Aerial as Deduced from the Transmission-Line Equations.

The work already described has established the fact that the classical transmission-line equations, with the assumption of uniform distributed constants, can be applied to the case of a receiving aerial, and that the results so deduced will be in agreement with observation to an approximation sufficiently close to be practically useful. In this second part of the paper, therefore, the purely analytical examination is continued, and information is obtained on the following points:—

(*a*) The magnitude of the e.m.f. induced in a plain aerial in a non-uniform field.
(*b*) The nature of the variation of the induced e.m.f. with aerial height and with frequency.
(*c*) The efficiency of an aerial as a collector of electrical energy from an electric field.
(*d*) The difference between the current distribution in receiving and transmitting aerials.

It happens that for the above purposes it is necessary to consider the case illustrated in Fig. 7, i.e. an aerial assumed to have uniform distributed constants, but divided into three distinct parts, of lengths h_1, h_2, and h_3, as far as the inducing electric field is concerned. In each part it is assumed that a uniform electric field of intensities e_1, e_2, e_3, and of pulsatance ω, acts along the respective parts of the aerial. The analysis of this case is naturally somewhat laborious, but does not differ in any essential respect from that of the simpler case and need not therefore be given in detail.

It is found that the current at the base of the aerial can be expressed in the form

$$i_0 = \frac{e_{e1} + e_{e2} + e_{e3}}{Z_e} \quad . \quad . \quad . \quad . \quad (35)$$

where e_{e1}, e_{e2}, and e_{e3} are elements of effective e.m.f. due to the assumed intensities e_1, e_2, and e_3 respectively. The full expressions for these three effective e.m.f.'s are as follows:—

$$e_{e1} = \frac{\cosh Ph - \cosh P(h_2 + h_3)}{\sinh Ph} \cdot \frac{e_1}{P} \quad . \quad . \quad (36)$$

$$e_{e2} = \frac{\cosh P(h_2 + h_3) - \cosh Ph_3}{\sinh Ph} \cdot \frac{e_2}{P} \quad . \quad . \quad (37)$$

$$e_{e3} = \frac{\cosh Ph_3 - 1}{\sinh Ph} \cdot \frac{e_3}{P} \quad . \quad . \quad . \quad . \quad . \quad . \quad (38)$$

where P has the significance already defined. It is

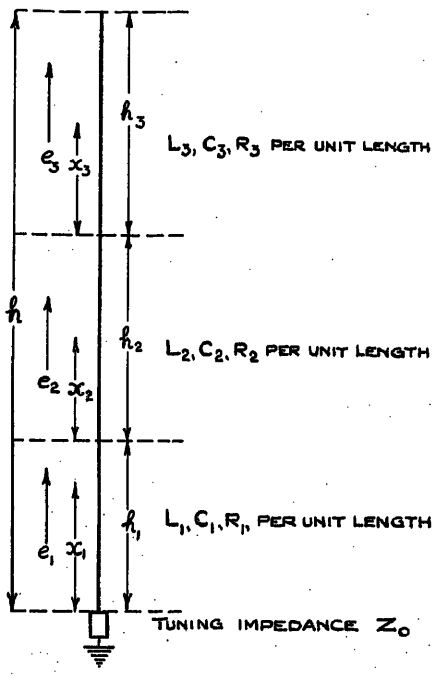

FIG. 7.

important to note that the effective impedance associated with each element of the e.m.f. is the same, i.e. Z_e or $Z \coth Ph$.

The above configuration may seem somewhat artificial and elaborate, but its justification lies in the facility with which important practical cases can be derived as special cases of the general formulæ.

(7) DEDUCTION OF A LINE INTEGRAL FORMULA FOR THE E.M.F. INDUCED IN A PLAIN AERIAL IN ANY GIVEN NON-UNIFORM FIELD.

Consider first the special case, illustrated in Fig. 8(*a*), where $e_1 = e_3 = 0$ and $e_2 = e$. This is not, of course, a practical case but is a purely analytical manipulation for the purpose stated in the heading. Then

$$e_e = \frac{\cosh P(h_2 + h_3) - \cosh Ph_3}{\sinh Ph} \cdot \frac{e}{P} \quad . \quad . \quad . \quad (39)$$

By a familiar transformation this can be put in the form

$$e_e = \frac{2 \sinh P(h - h_1 - h_2/2) \sinh Ph_2/2}{\sinh Ph} \cdot \frac{e}{P} \quad . \quad (40)$$

Now let h_2 be reduced to the ultimately vanishing element dx, and put $h_1 = x$, as shown in Fig. 8(*b*). Writing de_e for the resultant element of effective e.m.f. we have

$$de_e = \frac{2 \sinh P(h - x - dx/2) \sinh Pdx/2}{\sinh Ph} \cdot \frac{e}{P}$$

Now the limit of $(2/P) \sinh (Pdx/2)$ when $dx \to 0$ is dx. Therefore in the limit we have

$$de_e = \frac{e \sinh P(h - x)dx}{\sinh Ph} \quad . \quad . \quad . \quad (41)$$

If we now assume e to be a function of x (both as to amplitude and phase in general), and write it $e(x)$ to emphasize this functional character, then $e(x)dx$ is the

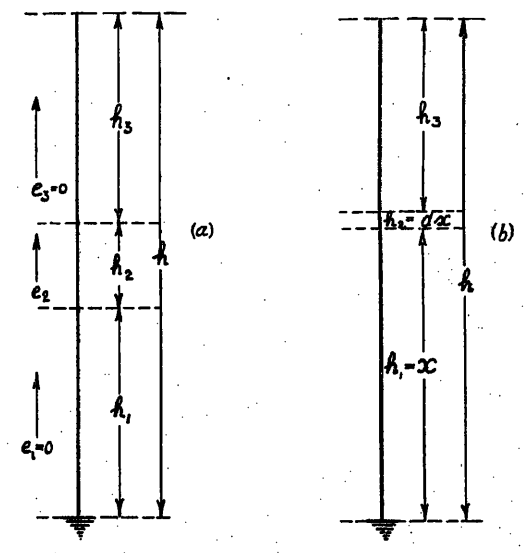

FIG. 8.

component of the field along the aerial at the point x. Since as far as the current at the base of the aerial is concerned the effective impedance associated with each element of e.m.f. is the same, the total effective e.m.f. can be obtained by the summation or integration (in the vector sense, of course) of all the elements of e.m.f., and is given by

$$e_e = \frac{1}{\sinh Ph} \int_0^h e(x) \sinh P(h - x)dx \quad . \quad . \quad (42)$$

This formula was obtained in a less intelligible operational form in the original paper by the present author.* R. M. Wilmotte has also derived and published a similar line integral formula† though it appears in a somewhat different form, the resistance component of P being omitted and the sign of the e.m.f. reversed. (This would appear to be an error, since some experimental work by

* See Bibliography, (1). † *Ibid.*, (7).

the Post Office, referred to more fully below, was found to be in agreement with the formula as stated above.) Actually the effect of the resistance term in P is likely, in general, to be negligible and the integral can be simplified somewhat to

$$e_e = \frac{1}{\sin \beta h}\int_0^h e(x) \sin \beta(h-x)dx \quad . \quad . \quad . \quad (43)$$

$$= \frac{1}{\sin 2\pi h/\lambda}\int_0^h e(x) \sin \frac{2\pi}{\lambda}(h-x)dx \quad . \quad . \quad (44)$$

but this formula cannot be applied when $h = n\lambda$, as the first factor becomes infinite. For such cases the more exact form is required. It should be borne in mind that this formula refers to the value of e due to the transmitting system when the receiving system is present. In certain cases, e.g. aerial and reflector systems, the current in the transmitting system, and therefore the field due to it, will be modified by the presence of the receiving (or reflecting) system. The formula will, however, still be applicable. It has, in fact, already been applied to such a system by the Post Office Engineering Department; it gave results consistent with actual measurement.

The evaluation of $e(x)$ in such cases can be arrived at by a method such as McPetrie's,* provided the current distribution as modified by the presence of the reflecting system be used as the basis for the calculation. This determination, though not rigid, appears to be sufficiently accurate for practical purposes, and is simpler than the more exact formulation of the problem given by Bechmann.† Bechmann's work on this subject is, however, of major importance and is likely to have very great practical value.

It should be noted as a special case that if e be assumed uniform we arrive at

$$e_e = \frac{e}{\sinh Ph}\int_0^h \sinh P(h-x)dx \quad . \quad . \quad (45)$$

$$= \frac{\cosh Ph - 1}{\sinh Ph}\cdot\frac{e}{P} \quad . \quad . \quad . \quad . \quad . \quad (46)$$

which is in agreement with previous results.

(8) General Character of the Variation of Effective E.M.F. with Frequency.

To obtain first some general idea of the variation of the effective e.m.f. with frequency it will be well to consider the simplest case, e.g. a plain aerial of height h in a uniform field. The corresponding formulæ are

$$e_e = \frac{e}{P}\cdot\frac{\cosh Ph - 1}{\sinh Ph} = \frac{e}{P}\tanh\frac{Ph}{2} \quad . \quad (47)$$

and $$Z_e = Z \coth Ph$$

If as a first approximation we neglect α altogether

$$e_e = \frac{1}{\beta}\tan\frac{\beta h}{2}e = \frac{\lambda}{2\pi}\tan\frac{\pi h}{\lambda}e \quad . \quad . \quad . \quad (48)$$

* See Bibliography, (9). † *Ibid.*, (8).

The limiting value when $\beta h \to 0$, i.e. when h is very short compared with λ, is $\frac{1}{2}he$—corresponding to the well-known result that the "effective height" is half the actual height under such conditions. The variation of e_e with frequency with the resistance neglected is of the form

$$e_e = \frac{\lambda}{\pi h}\tan\frac{\pi h}{\lambda}\cdot\frac{he}{2} = \frac{1}{\theta}\tan\theta\cdot\frac{he}{2} \quad . \quad . \quad (49)$$

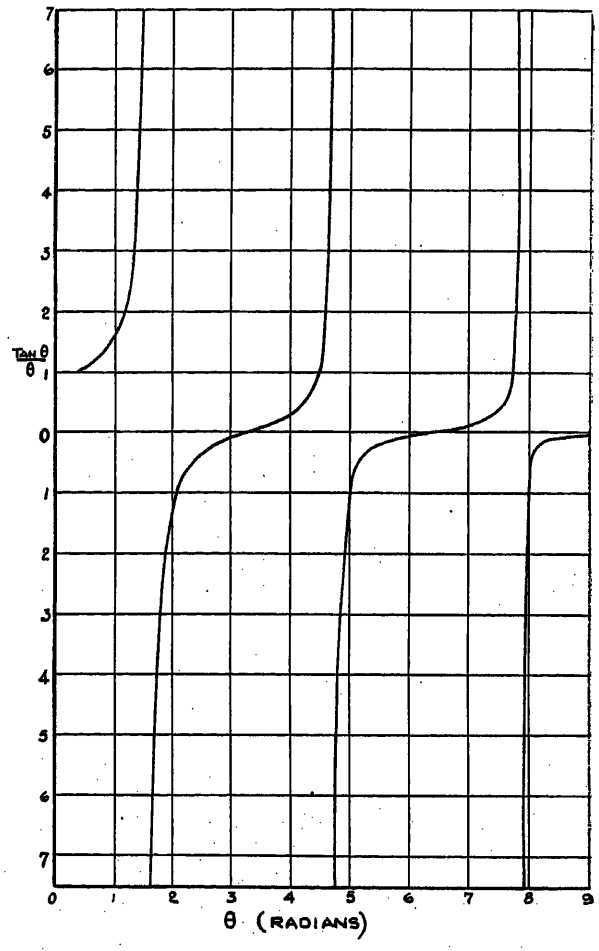

Fig. 9.

where θ is written for $\pi h/\lambda$. The function $\tan\theta/\theta$ is illustrated in Fig. 9.

One important practical conclusion is already obvious. For a given wavelength the variation of e_e with h is, apart from any effect of resistance terms, periodic with constant amplitude. In other words, if

$$\frac{\pi h}{\lambda} = n\pi + \phi$$

$$e_e = \left(\frac{\lambda}{2\pi}\tan\phi\right)e$$

i.e. e_e does not increase with n. Thus for a given value of ϕ an aerial several wavelengths high is no better than the shortest aerial which will give the same value of ϕ,

unless, of course, means are adopted for suppressing the undesired half wavelengths as in the case of the well-known construction introduced by Franklin.

For a more detailed examination of the critical values of the effective e.m.f. it is necessary to take the resistance terms into account. The exact formula is

$$|e_e| = \frac{e_{max.}}{\sqrt{[a^2+\beta^2]}} \cdot \frac{\sqrt{[\sinh^2 ah + \sin^2 \beta h]}}{\cosh ah + \cos \beta h} \quad . \quad (50)$$

The function does not vary steeply in the regions corresponding to the $(2n+1)\lambda/4$ resonances, and for these points the approximation

$$\beta h = (2n+1)\pi/2$$

may be safely used. For such values of βh

$$|e_e| = \frac{e_{max.}}{\sqrt{[a^2+\beta^2]}} \quad . \quad . \quad . \quad . \quad (51)$$

Now as $a/\beta = R/(2L)$, $a^2/(2\beta^2)$ will be negligible compared with 1 in all ordinary cases, so that when $h = (2n+1)\lambda/4$,

$$|e_e| = \frac{e_{max.}}{\beta} = \frac{\lambda e_{max.}}{2\pi} = \frac{2}{(2n+1)\pi} h e_{max.} \quad . \quad (52)$$

confirming the fact already noted, that for a given wavelength $|e_e|$ does not increase with n.

In the neighbourhood of the resonances corresponding to $h = (2n+1)\lambda/2$, e_e obviously becomes very large. In fact when $h = (2n+1)\lambda/2$, i.e. $\beta h = (2n+1)\pi$,

$$|e_e| = \frac{e_{max.}}{\sqrt{[a^2+\beta^2]}} \coth \frac{ah}{2} \quad . \quad . \quad . \quad (53)$$

but owing to the steepness of the variation with frequency in these regions the exact value of the resonant frequency would have to be used in determining $|e_e|$ at resonance, leading to a complicated expression which does not permit of approximation.

For $h = n\lambda$ (i.e. $\beta h = 2n\pi$), $|e_e|$ is very small, being given by

$$|e_e| = \frac{e_{max.}}{\sqrt{[a^2+\beta^2]}} \tanh \frac{ah}{2} \quad . \quad . \quad . \quad (54)$$

(9) Relative Effectiveness of Different Parts of a Receiving Aerial.

The formulæ for the contribution of each element of the system considered in Section (6) to the total effective e.m.f. at the base of the aerial afford interesting information as to the relative effectiveness of successive elements of the length of a plain receiving aerial from this point of view.

If the total height of the aerial be small compared with the wavelength of operation, the resistance terms in the formulæ can safely be neglected and they take the simple form

$$e_{e1} = k\{\cos \beta(h_2 + h_3) - \cos \beta h\} \quad . \quad . \quad (55)$$
$$e_{e2} = k\{\cos \beta h_3 - \cos \beta(h_2 + h_3)\}$$
$$e_{e3} = k\{1 - \cos \beta h_3\}$$

where $k = je/\beta \sin \beta h$

e being the intensity of the field, assumed uniform with respect to h.

Suppose, for example, that $\beta h = 0{\cdot}3\pi$ or $h = 0{\cdot}15\lambda$, and that $h_1 = h_2 = h_3 = h/3$. Then

$$|e_{e1}| = k(\cos 36° - \cos 54°) = 0{\cdot}221k$$
$$|e_{e2}| = k(\cos 18° - \cos 36°) = 0{\cdot}142k$$
$$|e_{e3}| = k(1 - \cos 18°) = 0{\cdot}05k$$

showing that the contribution of the top third of the aerial is less than a quarter of that of the bottom third. Thus the most important effect of the upper elements of the aerial is to increase the effectiveness of the lower parts rather than to make their own direct contribution to the effective e.m.f. This fact can be illustrated further by considering the two systems illustrated in Fig. 10. These are assumed to be excited by a wave travelling normal to the plane of the paper. It might be thought that since the e.m.f. induced in the far downward element C_2D_2 in the second system is opposed to that induced in the earthed vertical element C_1D_1, the resultant e.m.f. induced in the whole system would be very small. Actually, the additional length in the second system

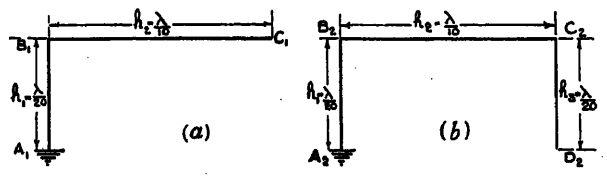

Fig. 10.

represented by the downward element C_2D_2 so much increases the effectiveness of the upward vertical element that the total resultant e.m.f. is not decreased but is even greater by a small amount than that given by the first system. For the first system

$$|e_e| = k\{\cos 36° - \cos 54°\} = 0{\cdot}221k$$

and for the second

$$|e_e| = k\{(\cos 54° - \cos 72°) - (1 - \cos 18°)\}$$
$$= k\{0{\cdot}279 - 0{\cdot}049\}$$
$$= 0{\cdot}230k$$

It must be remembered, however, that the resistance of the second system is higher than that of the first, so that whether in practice a larger received current would be obtainable from the second system than from the first would depend on other circuit conditions. If, however, the function of the system be to provide e.m.f. rather than power, a gain of 5 per cent is obtained at no additional cost for masts. The increase would, of course, be even greater for a wave travelling in the direction of the horizontal element, for the phase difference between e_3 and e_1 would then be less than 180°. However, the case is put forward for the sake of the interest of the somewhat paradoxical result obtained, rather than as a practical suggestion.

(10) A Simple Directive Receiving System.

The conclusions of the preceding Section do not, of course, apply to cases where the aerial is not short compared with the wavelength. Consider, for example, the system illustrated in Fig. 11. For a vertically polarized wave travelling normal to the plane of the paper $e_1 = -e_3 = e$, and $e_2 = 0$. Omitting for the present the resistance terms from the e.m.f. formulæ, we have

$$e_{e1} = k\left\{\cos\frac{3\pi}{2} - \cos 2\pi\right\} = -k$$

and

$$e_{e3} = -k\left\{1 - \cos\frac{\pi}{2}\right\} = -k$$

where k is written for $je/(\beta \sin 2\pi)$ (apparently infinite, but limited by the resistance terms of the exact formula). Thus for a wave in the specified direction

$$e_e = e_{e1} + e_{e3} = -2k$$

If, however, the wave arrives in the direction of the horizontal half-wave element of the aerial, then, owing

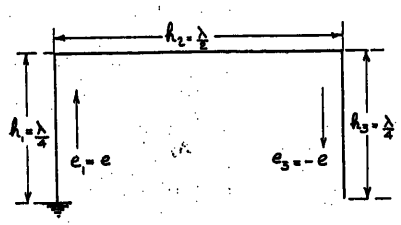

Fig. 11.

to the phase difference of the fields at the two vertical elements,

$$e_1 = e_3 = e$$

so that

$$e_e = e_{e1} + e_{e3} = -k + k = 0$$

Such an aerial system will, therefore, have a polar diagram of figure-of-eight type for its receptivity similar to that of a frame aerial but with a different law. Neglecting resistance terms, the law will be $\cos(\frac{1}{2}\pi \cos\theta)$, θ being the angle between the plane of the aerial and the vertical plane containing the direction of the wave. It is, of course, similar in principle to the free-ended half-wave systems commonly employed in beam transmitting systems.

The simple theory given above is, of course, modified somewhat when the exact formulæ are used. It may be pointed out that the difference between the approximate and exact formulæ may be greater than is commonly assumed, and that the effect of the resistance terms may introduce quite appreciable differences between the simply calculated and the actual behaviour. From the measurements described in Section (4), for example, it appears that the value of ah_1, when h is $\lambda/4$, is about 0·1, so that in the system described above ah might easily have a value of 0·4 or more, giving cosh ah about 1·08 instead of 1 as assumed in the simple theory. In addition there is the fact already mentioned in the discussion of the measured values, namely, that the effective length of the aerial may be 5 per cent or so longer than the actual length.

These possible discrepancies between the simple theory and observed behaviour are likely to be greater at higher frequencies. In this matter there is a need for more information than is at present available.

(11) The Principle of the Suppressed Half Wavelength Aerial.

The principle of the suppressed half wavelength aerial, developed by Franklin, is made very clear as far as reception is concerned by means of the effective e.m.f.

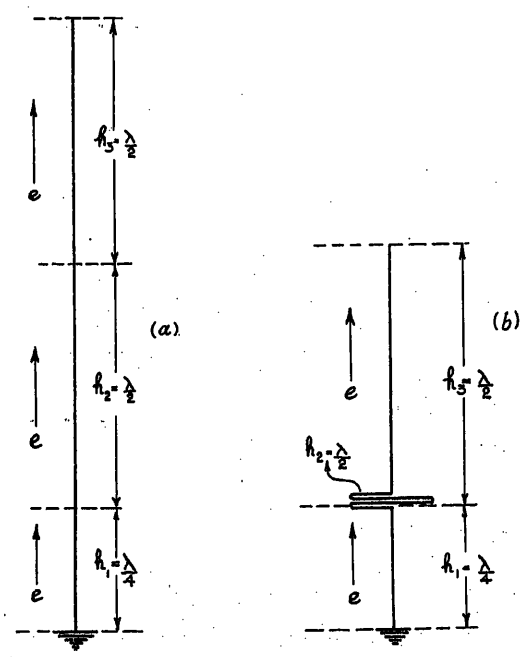

Fig. 12.

formulæ. Consider the system illustrated in Fig. 12(*a*), the aerial being assumed to be excited by a uniform field. Using the same symbols as in Section (9) and omitting the resistance terms for sake of simplicity of explanation

$$e_{e1} = k(\cos 2\pi - \cos 5\pi/2) = k$$
$$e_{e2} = k(\cos\pi - \cos 2\pi) = -2k$$
$$e_{e3} = k(1 - \cos\pi) = 2k$$

Therefore $e_e = e_{e1} + e_{e2} + e_{e3} = k$

which is the same value as would be obtained by h_1 alone (i.e. the first quarter wavelength element), but associated with a higher aerial resistance and therefore very much less effective as a source of power. If, however, the field be prevented from acting on the element h_2 [by a suitable disposition of the wire, as in Fig. 12(*b*)], then $e_{e2} = 0$ and $e_e = e_{e1} + e_{e3} = 3k$.

As already pointed out, the actual behaviour may be appreciably modified by the effect of the resistance terms

in a manner easily determinable from the exact formulæ (assuming the necessary data to be available), but the principle will be the same.

The power aspect of the matter will be referred to again in the following Section.

(12) The "Effective Height" of a Receiving Aerial.

In the case of a receiving aerial system in which the vertical part, of height h, is parallel to a uniform field of intensity e, the aerial can be said to have an effective height h_e defined by the relation

$$|e_e| = |e|\,h_e \quad . \quad . \quad . \quad . \quad . \quad . \quad (56)$$

This is a generalized definition of effective height for reception which is consistent with the accepted usage of that term. For example, if the aerial is a plain vertical aerial in a uniform vertically polarized field

$$e_e = \frac{e}{P}\tanh\frac{Ph}{2}$$

and if Ph is small (i.e. if h is small compared with λ) $\tanh Ph/2$ is very approximately equal to $Ph/2$, so that

$$e_e = \frac{e}{P}\cdot\frac{Ph}{2} = e\frac{h}{2}$$

and

$$h_e = \frac{h}{2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (57)$$

The conception of "effective height" is, however, of very doubtful utility. In the first place it is misleading in so far as it implies that the "effective height" of an aerial is a quantity characteristic of the given aerial structure concerned and thus useful as a criterion of its effectiveness for reception. In actual fact it is a quantity dependent on the wavelength of operation, the configuration of the field and, in many cases, on the direction of the wave in relation to the configuration of the aerial. Only in the very special case of a non-directional receiving system the effective elements of which are assumed to be parallel to a uniform field has the conception any very clear physical significance, and even in this case it is a function of frequency unless the latter is assumed to be low compared with the natural frequency of the aerial.

It would, of course, be a convenience if an aerial structure could be characterized by some constant which was useful as a criterion of its effectiveness in relation to its intended function, but the number of variables involved in practice makes any complete generalization on these lines impossible. In general nothing short of a complete geometrical and physical description of the structure will give the information required for the determination of its behaviour in response to assigned conditions of excitation, and any description in terms of some single quantity such as "effective height" is likely to achieve a deceptive simplicity at the expense of exactness.

There is, however, no need to labour this point, as the term, whether in relation to reception or transmission (when similar criticisms apply) is now much less frequently used than was formerly the case. It was a term appropriate to the early days of the development of the science and art of radio communication, but it has now to a large extent outlived its usefulness.

(13) A Receiving Aerial Considered as a Collector of Power.

It is perhaps an arguable question whether the valve receiving systems of the present day should be regarded as power or potential-operated devices. In practice the actual requirements and consequently the circuit conditions will vary considerably, so that sometimes the one and sometimes the other point of view will be appropriate. There certainly are many cases where the function of the receiving aerial should be considered as the absorption of power from the field. In relation to all such cases the representation of the received current at the base of the aerial in the form

$$i = \frac{e_e}{Z_e + Z_0}$$

where Z_0 is the impedance of the tuning circuit (including of course the input impedance of the detecting or receiving apparatus), has the important advantage of depicting the system as a source of power. It is well known that the maximum power available for utilization in such a system is given by*

$$W_{max.} = \frac{1}{4}\cdot\frac{E_e^2}{R_e}$$

where E_e is the R.M.S. value of e_e. Thus E_e^2/R_e or $|e_e|^2/R_e$ is the appropriate figure of merit for the system considered as a collector of power from the field and as a source of power for the operation of the receiving system.

The formulæ already developed enable this factor to be expressed in terms of the constants of the aerial and the configuration and intensity of the field. For the simple case of a plain vertical aerial in a uniform field of intensity $e_{max.}$ volts per cm the formula becomes

$$\frac{|e_e|^2}{R_e} = \frac{\alpha\beta}{\alpha^2+\beta^2}\cdot\frac{(\cosh 2\alpha h - \cos 2\beta h)^2}{(\cosh\alpha h + \cos\beta h)^2(\beta\sinh 2\alpha h - \alpha\sin 2\beta h)}\cdot\frac{e_{max.}}{R} \quad . \quad . \quad . \quad . \quad (58)$$

or, since

$$(\cosh^2\alpha h - \cos^2\beta h) = (\sinh^2\alpha h + \sin^2\beta h) = \tfrac{1}{2}(\cosh 2\alpha h - \cos 2\beta)$$

is very approximately

$$\frac{|e_e|^2}{R_e} = \frac{\{(1-\cos\beta h) + \alpha^2h^2/2\}^2}{(2\beta h - \sin 2\beta h)}\cdot\frac{4}{\beta}\cdot\frac{e_{max.}^2}{R} \quad . \quad (59)$$

The general character of this function is fairly clear. It will reach a maximum value in the region of $\beta h = \pi/2 (h = \lambda/4)$, after which it will oscillate about a

* See Bibliography, (12).

decreasing positive mean value with a decreasing amplitude.

For $h = (2n + 1)\lambda/4$

$$\frac{|e_e|^2}{R_e} = \frac{2\lambda}{(2n + 1)\pi^2}(ah \coth ah)\frac{e^2_{max.}}{R} \quad . \quad (60)$$

The quantity $(ah \coth ah)$ will not differ greatly from 1 as long as ah is small, so that for a given wavelength the available energy decreases as the number of quarter wavelengths in the height of the aerial.

For $h = (2n + 1)\lambda/2$ and $n\lambda$, $|e_e|^2/R_e$ is very small and decreases with the value of n in a similar manner.

The variation of $|e_e|^2/R_e$ as a function of h is illustrated in Fig. 13, for the values 0 to 4π of βh, assuming $\alpha/\beta = 1/5\pi$ (making it a case comparable with the experimental aerial). It reaches a maximum in the immediate neighbourhood of $h = \lambda/4$ ($\beta h = \pi/2$), and thereafter oscillates with rapidly diminishing amplitude.

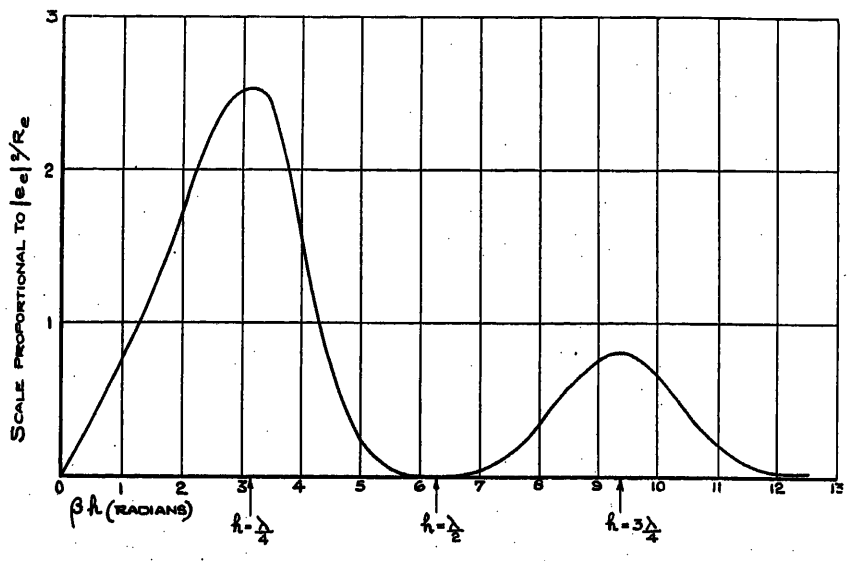

FIG. 13.

The above conclusions as to the undesirability of using aerials of multiples of a quarter wavelength in height (impracticable in any case except at short wavelengths) do not, of course, apply to systems where parts of the height are virtually out of the action of the field, as in the Franklin construction. It has been shown in the preceding Section that with such a construction the effective e.m.f. for $h = 5\lambda/4$ would be three times that for $h = \lambda/4$. It should be borne in mind, however, that the resistance in the former case may be expected to be greater than that in the latter. The gain in available power will only be as 3 : 1 if it be assumed that the resistance of the compressed element is negligible. The radiation resistance of the compressed element is certainly eliminated, but this is not necessarily the major part of its total resistance. If the radiation resistance is small compared with the total resistance, the power gain will only be as 9 : 5. The actual gain will presumably be somewhere between these limits, and will thus in general be less than the ratio of the heights of the two structures. The matter is one on which more experimental data are required.

(14) CURRENT DISTRIBUTION IN TRANSMITTING AND RECEIVING AERIALS.

The analysis has up to this point been mainly concerned with the magnitude of the current at the base of a receiving aerial as a function of the aerial constants and the field. By the same methods, however, an important result relating to current distribution in transmitting and receiving aerials can be demonstrated —namely, the fact that for a given aerial and a given frequency of operation the current distributions may be quite different in the two cases, i.e. reception and transmission. It is commonly assumed that for a given aerial height or length and a given frequency of sinusoidal excitation the current distribution is in the form of a sine wave with the aerial as axis, successive nodes being half a wavelength apart. It appears that this is not generally true. In the case of uniform excitation, for example (a plain vertical receiving aerial in a uniform field), successive current nodes may be separated by any distance from 0 to λ.

This interesting result was apparently first demonstrated by von Korshenewsky* by a simple physical and analytical argument, which was, however, confined to an isolated conductor wire in free space. After reading this paper the present author realized the probable applicability of similar reasoning to the more familiar earthed transmitting and receiving systems, and found that similar conclusions could, in fact, be demonstrated.

The system illustrated in Fig. 14 will serve for both cases under consideration, i.e. transmission and reception. The aerial constants are assumed uniform and the same in both parts $(h_1 + h_2)$. A uniform field (e volts per cm) is assumed to act on the part h_1 only. From

* See Bibliography, (10).

the equations already given, it is a simple matter to derive the formulæ for the currents i_1 and i_2 in the two parts h_1 and h_2 of the aerial, and the current-distribution formulæ for a plain aerial under conditions of reception and transmission respectively can be obtained respectively by making $h_2 = 0$ for the first case and taking the limit when $h_1 \to 0$ with the condition $h_1 e \to e_0$ for the second. This latter process enables us to arrive at the condition somewhat loosely described as a point source of e.m.f. by a continuous variation not involving any discontinuities.

The resistance terms cannot be entirely neglected in the above analysis, because, although the form of the current distribution is practically unaffected by them, they nevertheless determine the maximum amplitudes and their omission would therefore make impossible a

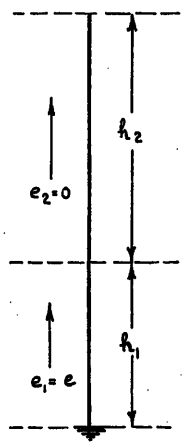

FIG. 14.

full quantitative comparison of the two cases. In each case it is assumed that the aerial is connected to earth through a negligible impedance (i.e. $Z_0 = 0$).

The analysis need not be detailed as it is quite straightforward. The results obtained are

$$i = \frac{2e}{PZ \cosh Ph} \sinh \frac{P(h+x)}{2} \sinh \frac{P(h-x)}{2} \quad . \quad (61)$$

and

$$i = \frac{e_0}{Z \cosh Ph} \sinh P(h-x) \quad . \quad . \quad (62)$$

for reception and transmission respectively. For the actual distributions, apart from resonance conditions, the formulæ in which resistance terms are neglected can be used, and are, of course, somewhat simpler. They are:—

$$i_{max.} = \frac{e_{max.}}{\omega L}\left(1 - \frac{\cos 2\pi x/\lambda}{\cos 2\pi h/\lambda}\right) \text{ for reception} \quad . \quad (63)$$

and

$$i_{max.} = \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L} \cdot \frac{1}{\cos 2\pi h/\lambda} \sin \frac{2\pi}{\lambda}(h-x)$$
$$\text{for transmission} \quad . \quad (64)$$

Note that $i_{max.} = 0$ when $x = h$ in all cases. The omission of the resistance terms clearly leads to infinite values for $i_{max.}$ at resonance conditions for which $\cos 2\pi h/\lambda = 0$, and for all such cases it is essential to apply the exact formulæ for the comparison of the current maxima. The results obtained are:—

h	x	$i_{max.}$
		Reception.
$\frac{1}{4}\lambda$	0	$\coth ah \frac{e_{max.}}{\omega L} \simeq \frac{1}{ah} \cdot \frac{e_{max.}}{\omega L}$
$\frac{1}{2}\lambda$	0	$\frac{1+\cosh ah}{\cosh ah} \cdot \frac{e_{max.}}{\omega L} \simeq \frac{2e_{max.}}{\omega L}$
$\frac{3}{4}\lambda$	0	$\coth ah \frac{e_{max.}}{\omega L} \simeq \frac{1}{ah} \cdot \frac{e_{max.}}{\omega L}$
λ	$\frac{1}{2}\lambda$	$\frac{2e_{max.}}{\omega L}$
		Transmission.
$\frac{1}{4}\lambda$	0	$\coth ah \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L} \simeq \frac{1}{ah} \cdot \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L}$
$\frac{1}{2}\lambda$	$\frac{1}{4}\lambda$	$\frac{\cosh ah/2}{\cosh ah} \cdot \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L} \simeq \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L}$
$\frac{3}{4}\lambda$	0	$\coth ah \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L} \simeq \frac{1}{ah} \cdot \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L}$
λ	$\frac{1}{4}\lambda$	$\frac{\cosh 3ah/4}{\cosh ah} \cdot \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L} \simeq \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L}$

The actual current distributions for $h = \frac{1}{4}\lambda$, $\frac{1}{2}\lambda$, $\frac{3}{4}\lambda$, and λ are shown and compared in Fig. 15. They are sinusoidal in all cases, but the receiving aerial is not in all cases the axis of symmetry of the curve representing the current distribution.

This latter feature is made more clear by considering the case $h = \lambda + h_0$, where h_0 lies between 0 and $\frac{1}{4}\lambda$. For this case

$$i_{max.} = \left(1 - \frac{\cos \pi x/\lambda}{\cos 2\pi h_0/\lambda}\right) \frac{e_{max.}}{\omega L}$$

so that $i_{max.} = 0$ when $x = h$, h_0, and $h - 2h_0$. The distance between the first and third nodes is λ, but between the first and second it is $2h_0$, which is not equal to $\frac{1}{2}\lambda$. The case is illustrated in Fig. 16.

For the transmitting aerial of the same height

$$i_{max.} = \sin \frac{2\pi}{\lambda}(h_0 - x) \cdot \frac{2\pi}{\lambda} \cdot \frac{e_{0max.}}{\omega L \cos 2\pi h_0/\lambda}$$

so that $i_{max.} = 0$ when $x = h_0$, $h_0 + \frac{1}{2}\lambda$, and $h_0 + \lambda$. The nodes are therefore $\frac{1}{2}\lambda$ apart. This is also illustrated in Fig. 15.

Actually in the cases where there is the greatest difference between the transmission and reception current distributions (i.e. $h = \frac{1}{4}\lambda$ and λ), the current is small compared with that corresponding to the quarter wavelength resonances. Thus the maximum current for $h = \frac{1}{4}\lambda$ is $\frac{1}{2}ah$ times that for $h = \frac{1}{2}\lambda$, probably about 10 to 1 in practice.

The cases considered, i.e. uniformly distributed e.m.f.

and point-source e.m.f., may be taken as extremes of possible variation of the distribution of e.m.f., and non-uniform distributions of e.m.f. will presumably give rise to current distributions intermediate between those described. In general, therefore, we may conclude that the current distribution is a function of the distribution of the exciting field, and that only in the special case of a single-point source of e.m.f. will it be safe to assume

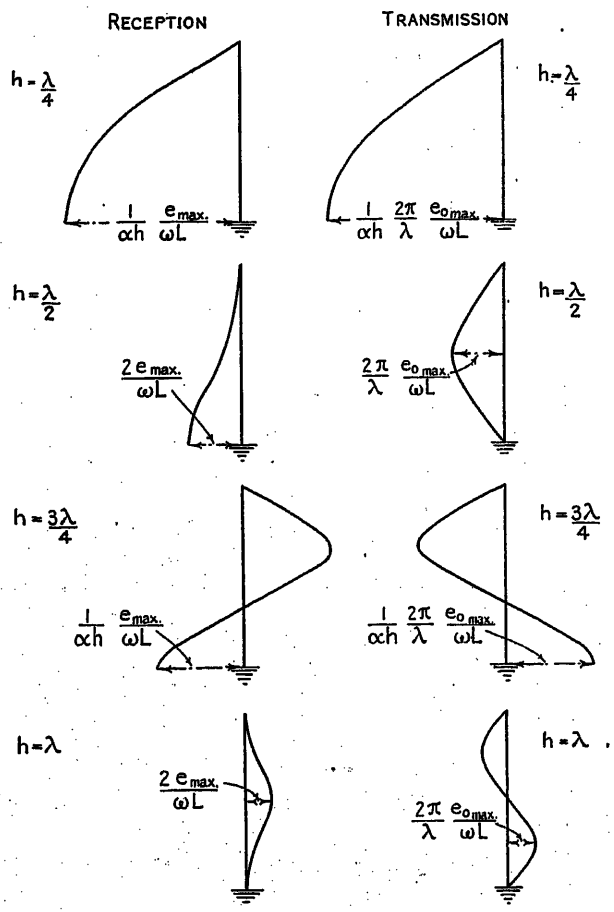

FIG. 15.

that the current nodes are separated by exact half wavelengths.

The distribution of potential is immediately derivable from the relation

$$v = -\frac{1}{j\omega C}\cdot\frac{\partial i}{\partial x}$$

which gives

$$\text{(Receiving)} \qquad v = \frac{e}{P}\cdot\frac{\sinh Px}{\cosh Ph}$$

$$\text{(Transmitting)} \qquad v = e_0\frac{\cosh P(h-x)}{\cosh Ph}$$

so that $v = 0$ and e_0 when $x = 0$ in the two cases respectively, as required by the assumed boundary conditions. The potential distributions are therefore not, in general, the same in the two cases, but in each case the distribution is sinusoidal (except for the small resistance effect), with half wavelength separation of successive nodes and antinodes. It should be pointed out, however, that this uniformity of separation of successive nodes depends on the assumption of uniformity of exciting field. In the more general case of a non-uniform field distribution a more complicated expression results for the current distribution—one containing e as a function of x, and e as a function of x will also appear in the expression for the voltage distribution. The matter does not permit of generalization, but in the absence of more detailed investigation there is no warrant for assuming uniformity of separation of successive nodes and antinodes of potential in the general case.

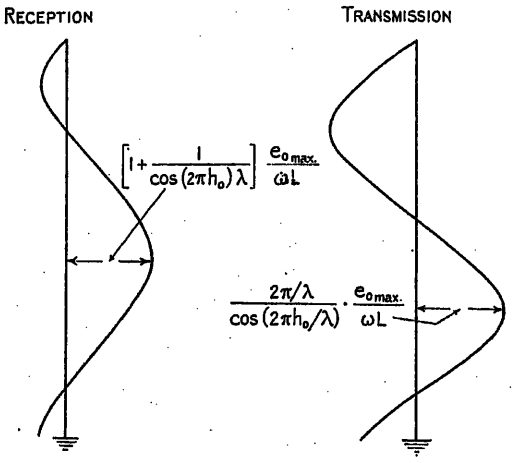

FIG. 16.

The author wishes to acknowledge his indebtedness to Mr. A. C. Gordon-Smith, who carried out practically the whole of the experimental work described, and to Dr. R. L. Smith-Rose for valuable criticism and advice on the compilation of the paper. The work was carried out as part of the programme of the Radio Research Board and is published by permission of the Department of Scientific and Industrial Research.

DISCUSSION ON

"INTERFERENCE BETWEEN POWER AND COMMUNICATION CIRCUITS: SUMMARY OF RECENT INFORMATION (1926 to 1929)." *

Mr. D. W. Roper (*communicated*): On page 1133 the author recommends that "when a high-tension 3-phase supply is transmitted by three single-conductor cables, these should be laid as close together as possible and transposed. Triangular spacing is preferable, but if flat spacing is adopted, regular transposition is essential." All of these recommendations are quite contrary to the practice in Chicago; therefore, in order to ascertain whether the author's recommendations found any warrant in American experience, I have corresponded with the engineers in charge of 66-kV and 132-kV single-conductor cable installations in New York, Philadelphia, Cleveland, and St. Louis, and with their assistance have prepared the following brief summary of practice and experience in the United States. In the cities I have mentioned, where all the 66-kV and 132-kV underground lines in this country are situated, there are now in service 109 miles of 132-kV and 485 miles of 66-kV single-conductor cables. The cables are laid in standard conduits in which the ducts have a spacing horizontally and vertically of about 6 or 7 inches. In no case is equilateral spacing adopted. The 132-kV cables in New York and Chicago are largely installed in a vertical row in conduits built especially for these lines. The use of special conduits for 66-kV cables is practically universal except in Chicago, where they are usually installed in the same conduit with lower-voltage cables. Local conditions determine whether the cables are installed in a vertical row, a horizontal row, or a right-angled triangle. Some of the underground lines in these cities are transposed, but there is never more than one complete transposition per line. The transpositions were made solely for the purposes of equalizing the power currents and voltages, not for eliminating or reducing inductive disturbances to adjacent telephone lines. In Chicago there are 10 telephone exchanges within ½ mile of our 66-kV single-conductor underground lines, and at numerous points the underground telephone cables run parallel to and cross these lines. The engineers of the telephone company were advised of the work on the earlier lines and were furnished with plans showing their routes, in order that they might make tests on the telephone lines most likely to be affected. Since the first power cables were placed in service in 1926, however, no adverse comment has been made regarding their influence on the telephone service. At the Midwinter Convention of the American I.E.E. held in New York in January 1931, a symposium of four papers† on the co-ordination of power and telephone plant, the joint work of the National Electric Light Association and the Bell Telephone System, was presented. No mention is made in these papers of any adverse effects of underground cables on underground telephone circuits. On the contrary, it is stated by Messrs. Harrison and Silver that the installations of 66-kV and 132-kV cable in this country "have a definitely favourable effect upon co-ordination problems within the territories surrounding them." If American practice had resulted in unsatisfactory co-ordination between power and telephone cables, it is inconceivable that all reference to such conditions would have been omitted from this discussion. It is considered good engineering practice to install telephone cables in separate conduits from power cables, and, where feasible, to install these conduit lines on opposite sides of the street. It is also customary to install high-voltage single-conductor cables for 3-phase transmission as close together as possible so as to reduce the induced sheath voltages or losses. Experience in this country indicates,

* Paper by Mr. W. G. RADLEY (see vol. 69, p. 1117).

† *Transactions of the American I.E.E.*, 1931, vol. 50, p. 437.

therefore, that when power cables and telephone cables are installed in accordance with good engineering practice there is no occasion to fear adverse inductive effects on the telephone circuits due to the power cables. Theoretical considerations and practical experience are in accord on the point that inductive effects are possible when the cables are separated by only a few feet and run parallel for a considerable distance. As such parallels are present, in general, along only a very small fraction of the total length of an underground transmission line, any rules which may be adopted as a result of the author's recommendations should be limited to that portion of the power line where the close parallel exists, as the extra expense of meeting the requirements at other portions of the line is entirely wasted.

Mr. W. G. Radley (*in reply*): The interference arising from power cables may often be reduced to negligible proportions by what Mr. Roper terms "good engineering practice," i.e. the installation of telephone cables in separate ducts and, where feasible, on the opposite side of the street. Were the circuits composed of overhead conductors such separations would not, in general, suffice. On account of the smaller conductor spacing and the screening effect of the cable sheaths, the transmission of power by cables instead of by overhead conductors must always assist in solving the problem of co-ordination between the two interests involved. The validity of Mr. Roper's contention that good engineering practice is a sufficient guide in the construction of an underground cable system, depends on the interpretation of the term. The "good engineering practice" of to-day becomes obsolete to-morrow, and it is not necessarily the same at one time under different conditions in different countries. One important difference in the present case is that in Great Britain the onus is on the power company to avoid interference, so that if it seems possible that interference arising at a future date would involve the power company in costly alterations, it is good engineering practice to avoid the risk, even if later experience proves the precaution to have been unnecessary. In effect Mr. Roper claims that from the point of view of interference with communication circuits it is not essential to lay three single-conductor cables as close together as possible, or to transpose them; though he admits that both these practices are customary in the United States for the purpose of reducing induced sheath voltages and balancing impedances. In this respect American practice supports the recommendations made in the paper. It happens that in Great Britain the direct method of laying cables, which has been preferred for reasons other than interference, permits of closer spacing than the duct system preferred in America; and the information available at the time the paper was written suggested that this feature could be made use of in minimizing the risk of interference. In the light of later knowledge and further experimental work, however, I agree with Mr. Roper that the spacing could be extended to that usual in duct systems without risk of greatly increasing interference. His record of practice and experience in America, particularly the joint experiments of the National Electric Light Association and the Bell Telephone System, is of great interest and value. A full account of these experiments would be very welcome.

DISCUSSION ON "COIL IGNITION SYSTEMS."*

NORTH-WESTERN CENTRE, AT MANCHESTER, 8TH DECEMBER, 1931.

Prof. E. W. Marchant: I should like, first of all, to say something with regard to the question of magneto versus coil ignition. On page 105 (vol. 70) the author says:—"It is now generally recognized that the amount of energy delivered in the discharge by the ignition system, whether coil or magneto, bears no direct relation to the energy necessary for ignition of the explosive charge." I am sure that this statement is the result of much investigation, but most people must have come across the following difficulty when driving a car. I used to have a 4-cylinder car equipped with a magneto, and on long downhill stretches of road the plug on the cylinder nearest the front end of the car nearly always became gummed up, and had to be taken out and cleaned. I replaced that magneto by one capable of giving a rather larger power output, with the result that I had no more trouble due to gummed-up plugs. The reason, I think, is evident. Although the energy required for exploding the charge was no greater, the amount of energy in the spark was sufficient to stop carbon from accumulating at the plug and preventing the spark discharge from occurring. Therefore, although on theoretical grounds there is no necessity to have more than a limited amount of energy available for igniting the charge in the cylinder, in practice there seems to be a good deal of advantage in having some energy to spare, so as to ensure the regular firing of the engine. I have had experience with both magneto and coil ignition, and it is only after reading the paper that I have realized the limitations of coil ignition. There is much to be said for magneto ignition under certain circumstances. I have heard a good deal about the ignition troubles that occur in a damp tropical climate such as that of Nigeria. I think most cars are apt to give trouble in very damp climates, but the amount of trouble encountered with magneto ignition has been sensibly less than that with coils. The chief trouble in damp and tropical climates is that the battery is very apt to run down. A spare battery ought always to be available. Under these conditions I think there is still something to be said for magneto ignition, although, in general, coil ignition is more popular. I should like to ask whether there has ever been any suggestion of using condensers for the storage of energy, instead of inductances. Possibly a condenser might be a good thing to use because it can be charged up more quickly than the current can be established in an inductance. With regard to the coil itself, the reason why one cannot sensibly improve the operation of a coil by closing the magnetic circuit is because the losses go up as the amount of iron in the circuit increases. In this connection I am reminded of the "hedgehog" transformer designed by Swinburne about 35 or 40 years ago. Swinburne's theory was that the losses could be minimized by reducing the iron in the transformer by providing an air return circuit for the magnetic fluxes. In those days central station engineers did not mind so much about lagging currents as they do to-day. The open-core coil referred to in the paper is a development of the same kind. I presume there is a limit to the amount of iron one can use in the core, and that there is an amount of iron which gives the best results in the system. I am interested in the question of ballast resistances for regulating the current through the primary winding. Have iron resistances in glass tubes ever been tried, or are they thought to be too dangerous? They have extraordinarily good regulating qualities, and are used for all sorts of purposes in connection with thermionic valves.

Mr. Wilfred Holmes: I notice that the author mentions many limits, such as those set by heating, induction, and arcing. There is, however, another important limit, which arises when the battery voltage is nearly zero. This usually happens when the engine is cold and the oil has stiffened in the cylinder. The battery will then only give sufficient current to the starter motor to turn the engine very slowly, and the battery voltage becomes so low that there is not sufficient voltage to give a spark from the ignition coil. Laborious hand-winding of the engine then becomes necessary. Would the author advise another battery of small size in parallel with the starting battery, or is it practicable to have a couple of spare terminals with a disconnecting switch so that a small stand-by dry battery could be used for such an emergency? Probably this system would be cheaper than fitting a magneto, and it would have the advantage of low-speed starting.

Mr. S. R. Mellonie: The interesting devices described in the paper depend for their operation upon a primary supply of energy from a battery, which, in turn, is usually supplied by a small dynamo driven by the engine. Experience shows that the design of these small machines leaves much to be desired. In two machines recently examined the electrical creepage distance was only $\frac{1}{16}$ in. This was exposed on the outside of the machine to the mud thrown up from the road and on the inside to the carbon dust and copper particles which ultimately form a conducting path from the live brushgear to the earthed end-shield. In consequence of this weakness in the design the insulation of the two machines was burned away. Such clearances are obviously much too small and could easily be increased threefold without adding to the cost. Another curious characteristic of these small dynamos, which are usually of the 3-brush type, is overheating to such an extent that solder is thrown out of the armature on to the brushgear. It is generally understood that this is due to the third brush sticking in its holder, and if this is the case more attention should be given to

* Paper by Mr. E. A. WATSON (see vol. 70, page 105).

this feature of the design, as until such defects are remedied engineers are not likely to recommend the adoption of coil ignition systems.

Mr. J. B. Lees: Some time ago I bought four 1931-type 3-point plugs of a well-known make which proved to be very unsatisfactory. I returned them to the makers with a request to exchange them for single-point plugs, and received in reply the usual letter saying they saw no reason why the 3-point plugs should not be satisfactory. In answer I gave the following account of what I considered to be the cause of the trouble. The peak voltage becomes the breakdown voltage for a given set of gap conditions. The peak voltage must be proportional to the gap impedance, and, if we have three gaps in parallel as with a 3-point plug, the impedance will be lower than that of a single-point plug having the same gap dimension. The breakdown voltage of the 3-point gap will thus be lower, and the resultant arc will therefore not be so intense. I experimented with a 3-point plug at a pressure of 90 lb. per sq. in., and observed that at the instant of spark-over between the centre electrode and any of the three earthed ones, a brush discharge took place on the remaining two, thus indicating the lack of concentration of the available arc energy. Fig. 25 shows three oscillograms which would appear to confirm my suggestion, the reduction in peak voltage with reduction in impedance being clearly shown. I should be glad if the author would comment on my hypothesis and confirm that as a result of using a single-point instead of a 3-point plug, one would normally get a hotter spark. It may be of interest to add that the plug manufacturers agreed with me and sent me four single-point plugs, the operation of which proved to be absolutely satisfactory.

Mr. G. H. Sammons: During the War I supervised the maintenance of a large number of automobiles fitted with coil ignition systems. At that time American automobiles were mainly provided with coil ignition systems, while most of the British manufacturers still clung to the magneto. My experience was that the coil ignition system stood up better than the magneto to the rough usage to which these machines were subjected. Thus either the American system was inherently better for the purpose than the English system, or the American coil ignition system was better designed than the British magneto. In my opinion the workmanship and finish of the coil ignition systems was in general not so good as that of the magnetos. The coil ignition systems gave quite a lot of trouble due to wear of the distributors. The relays frequently stuck and caused the resistances and switchboards to burn out. At the end of three or four years there was very little left of the original coil ignition systems. Coil ignition systems have recently received a considerable amount of attention and research, and they are consequently very much improved. The chief trouble experienced nowadays with any ignition system is associated with the sparking plugs, and I think that if the sparking plug had received as much attention as the remainder of the ignition system, the performance of the system as a whole would be much more satisfactory. The performance of a coil ignition system depends almost entirely upon the condition of the battery, which as a rule is very bad. A central-station engineer spends hundreds of pounds a year in an endeavour to maintain his batteries in perfect condition, and by so doing he sometimes maintains his positive plates in good order for a period of 6 years. On the other hand, I am surprised that motor-car batteries last more than 2 years. It is much easier to repair a coil ignition system than a magneto. Another advantage of the coil over the magneto is that if the former is adopted it is possible to incorporate a device whereby the spark may be automatically advanced and retarded as the speed of the engine varies. There is no doubt that a system with an automatic adjustment has a distinct advantage over a fixed or a hand-operated system.

Dr. J. L. Miller: The author, referring to the possibility of developing loosely-coupled coils for coil ignition systems, states that one great disadvantage of having an arrangement which must be adjusted to correspond to optimum conditions is that these conditions would only hold for one particular type of sparking plug and one particular length of cable. The capacitance load of a length of h.t. lead and a plug would be rather uncertain, but I should think it would be of the order of 20 $\mu\mu$F. In view of the fact that the secondary capacitance is 100 $\mu\mu$F, small changes in the 20 $\mu\mu$F when the plug or lead was changed would not make much difference. At any rate, in the loosely-coupled circuits I have handled such a small change would not have made more than about 15 per cent difference. A great deal depends, of course, on the circuit constants, and I should be glad of the author's comments in this connection. Regarding the question of the primary condenser, it would be interesting to see an oscillogram giving the voltage wave-form across this apparatus, and to know the value of the maximum voltage reached. Can the author give the actual puncture values of the condensers used, and the voltage at which they are tested?

Mr. E. A. Watson (*in reply*): In reply to Prof. Marchant, the statement that the amount of energy delivered by the ignition system has no direct relation to the energy necessary for ignition of the explosive charge must not be confused with the phenomenon to which he refers, and which, I admit, is one well known among motorists. It is agreed, of course, that under conditions where a sparking plug is liable to oil up, the ignition system which will give a large amount of energy in the form of an arc or flame will burn away the oil and ensure regular ignition, but there is the other side of the picture to be taken into account, and that is the fact that this energy which burns away the carbon will also burn away the plug electrodes. The real remedy is so to arrange the plugs and the lubrication system as to prevent their receiving an excessive amount of oil under conditions such as those referred to, with the engine running on light throttle. I think that most modern cars, even with coil ignition, are fairly free from this trouble. Prof. Marchant mentions the use of a charged condenser as a means of energy storage. This has already been referred to in the paper and will be found on page 121 under the heading "Condenser and Transformer Systems." As regards the limit to the amount of iron that can be used in the core, this is

difficult to express exactly, but I think one may say briefly that if too much iron is used the coil becomes inefficient, with the result that the heating and sparking limits are reached, while if too little iron is employed the coil becomes expensive, owing to the large number of turns and the large amount of copper which is necessary, and the present-day coils are really a compromise between these. The suggestion of using an iron-wire resistance in a glass tube in hydrogen as a regulator has often been made, and such a resistance would be quite practicable. It is, however, rather more expensive than the open-type resistance generally employed, and present-day practice is in general to dispense with the resistance altogether.

In reply to Mr. Holmes, the limiting condition when the battery voltage is low has been taken into account in the paper. Of course, it is impossible to take this limit so low as to rule out absolutely all cases when the battery is very badly exhausted indeed, but with coils as designed to-day the battery has to be in a very bad condition before a spark cannot be obtained, and, although a spare battery substitutes an additional safeguard, I really do not think that its adoption is necessary.

Replying to Mr. Mellonie, the question of adequate creeping surface and adequate insulation was referred to in my reply to the London and Birmingham discussions, and will be found on page 134. I am naturally all in favour of adequate insulation being provided, even though the voltage is only a low one. The trouble to which Mr. Mellonie refers, of third-brush machines overheating, is not due to the third brush sticking in its holder, as the only effect of this would be to lift the brush off the commutator and break the field circuit, but it is generally due to the machine being run on open-circuit, possibly with the battery disconnected, so that the dynamo ceases to regulate and generates an excessive voltage, leading to overheating and burning out of field and armature winding.

Mr. Lees raises the question of 3-point versus single-point spark-gaps. I am afraid I cannot entirely accept his explanation. 3-point plugs for the same electrode dimensions have practically the same breakdown voltage as single-point plugs, but they have the advantage that there is less variation between the successive discharges, as the impulse ratio is less. For detailed information on this I must refer Mr. Lees to some of the published work on spark-gaps. The chief drawback of 3-point plugs is that under oily conditions, when incorrectly fitted, they are rather more liable to become short-circuited than the single-point plugs, but on the other hand their performance is more consistent and they last a good deal longer before burning away.

In reply to Mr. Sammons, I doubt whether his experience during the War, of the relative merits of coil and magneto ignition, can be taken as applying to present-day practice. In the first place the magnetos then available were either of American origin (and the Americans had very little experience in magneto manufacture), or, if they were made in this country, they were made by firms who were only just commencing magneto production, and who had, of necessity, to place all their best resources and experience at the disposal of the aircraft industry; but even so I note that Mr. Sammons goes on to state that the coil ignition systems gave a lot of trouble and that at the end of 3 or 4 years there was very little of them left. Mr. Sammons's remarks as regards batteries are certainly correct. The average motor-car battery, particularly on a private car, receives extremely bad treatment. It is sometimes grossly overcharged in summer, although not so frequently undercharged in the winter. On certain commercial vehicles and in particular in motor-bus services conditions are different, as the usual practice here is to fit a constant-voltage dynamo with a vibrating-type regulator, under which conditions the battery is much better treated and a substantially longer life is obtained.

Dr. Miller's remarks as regards the relative capacitance of the high-tension lead and the coil itself are, I think, substantially correct, although I should put the secondary capacitance of a modern coil as being rather lower than the figure he gives. It is not, however, only the capacitance which is likely to alter, but also the leakage loading, and this will, I think, have the same general effect. I am not able, at the moment, to publish an oscillogram giving the primary voltage wave-form, although I have actually made observations on this. Generally speaking, the primary-voltage wave is very similar to the secondary-voltage wave, and shows the existence of the high-frequency component due to the independent oscillation of the primary circuit impressed on the main fundamental oscillation due to the two circuits oscillating together. It is, of course, essential that the maximum voltage reached on the primary under any conditions should not exceed the figure at which a spark can pass across the contact points during the early stages of separation. Replying to Dr. Miller's query in regard to condenser puncture voltages, the usual figure is from 1 500 to 2 000 volts, the testing voltage varying between 500 and 1 000 for different manufacturers.

Scottish Centre, at Edinburgh, 26th January, 1932.

Prof. S. Parker Smith: The calculations associated with the design of a coil ignition system are difficult compared with those involved in the design of a turbo-alternator, transformer, or ordinary induction motor. Designers know that in general the smaller the unit, the more difficult are the calculations involved. One advantage of coil ignition is that a smaller starting set can be used with it than with the magneto. This is an important matter when one considers what a large percentage of the cost of the automobile goes to provide electrical equipment. The author has often drawn attention to the necessity of keeping the plug points properly adjusted and so avoiding the great danger to the insulation incurred by having too wide a spark-gap. With a coil the amount of plug adjustment necessary is usually far less than with a magneto. I have known a plug with multiple points burn away more quickly when used with a magneto than a single-electrode plug used with a coil. Apart from the risk of breakdown of the insulation, is there any such thing as plug deteriora-

tion, i.e. a progressive decrease in the efficiency of the sparking system with time? I should also like to know whether the fibre heel wears more rapidly than the contact points.

Dr. M. G. Say: I should be glad if the author would give a little more clearly the derivation of his equivalent circuit, with a diagram showing the assumed positive directions of the various currents and voltages. Without this the validity of the expression at the top of page 107 is not immediately apparent. This expression presumes negligible self-capacitance. Is this assumption justified? The capacitance C, referred to the secondary side, is given by $(C_2 + C_1/r^2)$. The ratio r may be 40 or more, so that even with a large primary (contact-breaker) capacitance the effect of the latter in the secondary must be comparatively small. Thus the secondary capacitance C_2 becomes the more important, and it must surely consist chiefly of self-capacitance, so that the voltage obtained at the secondary terminals is less than that given by the theory, quite apart from the effect of damping. It would appear that any reduction of the self-capacitance would be advantageous, in that the available energy would be more usefully employed in charging up the small external (plug and h.t. lead) capacitance to a higher voltage. If the author has available any oscillograms showing the growth of the primary current, their publication would be of interest. I should like to know what is the effect of sparking at the contact breaker. Presumably such sparking reduces the efficiency and available energy. It appears that if the contact-breaker condenser is too small, sparking occurs, whereas if too large it reduces the energy imparted to the secondary winding and in turn lowers the peak voltage reached. I should appreciate details of the wattmeter, electrostatic voltmeter, and rectifier valve shown in the test circuit of Fig. 27.

Mr. E. Seddon: The electrical ignition of the earlier type of internal-combustion engine was by means of trembler coils, then came the plain make-and-break, after this the magneto, and now we are back to the coil again. American cars, on the other hand, have always been fitted with coil ignition. The omission of the magneto drive no doubt makes for a quieter engine, and the majority of light 6-cylinder cars now appear to be fitted with coil ignition, but—possibly owing to mass production on cheap lines—the reliability of coils leaves much to be desired. I had only used my present car for a month when the coil broke down: I now carry a spare coil, as I have not as much confidence in this form of ignition as I had in the magneto. It is logical that a stationary piece of apparatus such as a coil should be the most reliable part of an engine unit, but I am afraid that the desire for cheapness makes it difficult for the makers to turn out a first-class article. I should like to ask the author which part of a coil is responsible for the largest number of failures: is it not the high-tension winding? The coil introduces a further weak link by placing more responsibility on that mechanically weak assembly, the accumulator. Now that the coil is replacing the magneto, it would seem desirable to run two separate sets of batteries in parallel in case of trouble. It is possible that one pair would still be in a sufficiently satisfactory condition to operate the coil, even if the other broke down. I should like to ask the author whether the coil could not be satisfactorily built-in with the distributor unit, in order to reduce the number of separate parts which have to be wired up. I should also like to know whether any experiments have been carried out with the rotary type of make-and-break, as at high speeds inertia causes difficulties in connection with all types of reciprocating motions.

Mr. E. R. L. Fitzpayne (*communicated*): I should like to give some statistics bearing on the question of magneto versus coil ignition. The City of Edinburgh Transport Department operates 61 omnibuses fitted with coil ignition; between May 1931 and January 1932 46 coils developed faults, 26 of these coils being under guarantee. The inconvenience caused thereby has not been as serious as it would at first appear, for each omnibus is fitted with two coils. When one coil becomes defective the driver connects up the other one. The remaining 90 omnibuses operated by the Department are fitted with magnetos, and over the same period 22 magneto failures occurred, but 200 magnetos had to be removed, dismantled, and overhauled in the ordinary course of maintenance. On our first coil-ignition omnibuses the coils were fitted in an enclosed box which was badly ventilated, causing overheating of the primary resistance. The box was earthed through the screws fixing it to the dashboard, and this arrangement also gave trouble by causing arcing at the points. However, when the box was properly earthed and ventilated no more trouble was experienced. The latest omnibuses have the coils fitted on an open board under the bonnet, and are much more satisfactory. In the paper the author states that the maximum current is obtained under low-speed conditions and also that voltages at starting are usually higher than at speed. This of course means that a good spark is obtained at starting —when it is most required—and is probably the reason why certain cars employ coil ignition for starting and magnetos for running. The author also states that the practice of mounting the condenser on the outside of the distributor is gradually being abandoned. In Edinburgh we have experienced so much trouble owing to the condenser becoming saturated with oil when inside the distributor, that we insist on its being outside. We still have some trouble owing to oil creeping into the distributor and getting on to the points, but we have eliminated it to a large extent by having an oil thrower fitted between the skew wheel drive and the spindle. On page 123 coil construction is described, and out of curiosity I therefore pulled a coil to pieces. This coil had a wire core, whilst round the primary was placed a plain tin sheath instead of the slotted and laminated iron sheath described by the author. In order to improve the performance of the petrol engine modern research is endeavouring to increase the compression ratio, and it would therefore be interesting to know how this will affect coil ignition.

Mr. E. A. Watson (*in reply*): Prof. Parker Smith's point as regards the burning away of plug points has been dealt with in my reply to Prof. Marchant. As regards progressive plug deterioration, I have never noticed actual deterioration of the insulation, other than by charring and roughening of the surface, permitting

of the deposition of a conducting film of carbon, although mica plugs will occasionally gradually develop leakage through the insulator itself, owing to disintegration of the mica under the effect of temperature-changes. As regards the wear of the fibre heel, the makers naturally endeavour to make the fibre heel and the contact points wear at equal rates, so as to avoid any readjustment.

In reply to Dr. Say, my assumption that the secondary self-capacitance is all concentrated at the end of the winding is doubtless not perfectly accurate, but I am afraid that if one endeavoured to take everything into account the mathematical considerations would become excessively involved. Dr. Say is quite right in saying that any reduction in self-capacitance would be advantageous, and I have always found it helpful in designing coils to aim at keeping this as low as possible. Generally speaking, to obtain a low self-capacitance necessitates increased thickness of insulation between the layers of the winding, which in effect increases diameter, the length of mean turn, and the cost of the copper, so that there is naturally an economic limit to this. The curves showing the growth of primary current to which Dr. Say refers are ordinary exponential curves and do not give any particular information, while the chief effect of sparking at the contact-breaker is to destroy the contact points and cause premature failure of the system.

Mr. Seddon will find the question of magnetos versus coil ignition systems dealt with on page 132, while as regards the point which he raises of failures in the high-tension winding I would say that in my experience the bulk of these have not been due to any attempt to cheapen the coil, but to lack of appreciation by manufacturers in the early days of the severe stresses caused by concentration of stress at the end-turns, due to the high-frequency surges produced at each spark. Modern coils, in which suitable reinforcement is used on the end-turns, are, like modern transformers, very reliable indeed. Mr. Seddon's suggestion of building the coil in with the distributor as one unit has often been put forward, but there are many constructional difficulties involved. After all, a coil has to be given certain dimensions, if only to enable it to radiate the heat if it is left on circuit, and these dimensions usually make it inconveniently large to combine with the distributor itself. Mr. Seddon's query as regards the use of the rotary-type make and break will be found answered on page 134.

I am very interested in Mr. Fitzpayne's statistics as regards service troubles on buses fitted with magneto and coil ignition. It is, of course, essential that the mounting of the coil should be given a certain amount of attention, and troubles can occur through incorrect mounting and insufficient ventilation, as the dissipation of a certain amount of heat must, of course, be provided for. I think that the coil which Mr. Fitzpayne took to pieces must have been of rather old design, as the use of sheet laminations for the core is practically universal to-day, while the sheath is either slotted, as indicated in the paper, or consists of two or three layers of thin metal superimposed. As regards the effect of increased compression ratio, this does not seriously affect the plug voltage, as in general increased compression ratio means a hotter-running plug, and the increased temperature of the electrode reduces the sparking voltage very nearly as much as it would be raised by the increase in compression.

Additional Communication to the Discussion.

Mr. J. Bethenod (*communicated*): I should like to point out that formulæ very similar to those of the author were derived in my paper "Sur l'allumage par batterie des moteurs à explosion" which was published in *Journal de la Société des Ingénieurs de l'Automobile* in June 1929, pp. 650–658.

Mr. E. A. Watson (*in reply*): I am indebted to Mr. Bethenod for drawing my attention to his previous paper, which had not come to my notice at the time my paper was written. I am interested to note that his results in general confirm my own—although he obtains a figure of 1·27 for a value of Rt/L in equation (3) on page 126 against my value of 1·256. This value must in the nature of things be a mathematical constant, and it would be interesting to know exactly what the value is. In my case it was only obtained through solution by trial of equation (2), while I fancy that in Mr. Bethenod's case it has been obtained by plotting the curve and taking the point at which it attains its maximum value.

DISCUSSION ON

" TWO TRANSMISSION-LINE PROBLEMS—SUSPENSION INSULATORS FOR INDUSTRIAL AREAS IN GREAT BRITAIN; CONDUCTOR VIBRATION." *

NORTH MIDLAND CENTRE, AT LEEDS, 12TH JANUARY, 1932.

Mr. S. R. Siviour: It is quite evident that the use of 4 discs in series on the 66-kV lines of the North-East Coast system gave too small a margin of safety. In this area we started with 5 discs on suspension sets and 6 on strain sets and these have given satisfaction, although regular cleaning is necessary at points subject to severe contamination. The nature of the deposit varies considerably with local conditions, but our chief trouble has been with an oily, tarry deposit: the amount varies considerably, even between insulators on the same pole, due to the shielding effect of the latter. I agree with the author's remarks on the British Standard Specification ratings, the flash-over values of which obviously refer to new, clean insulators, whereas when these insulators are tested after a short exposure under average service conditions they show greatly reduced flash-over values. Experience in industrial areas indicates that the wet flash-over voltage should be 60 to 70 per cent higher than the B.S.S. ratings. I should like to ask whether the line insulators concerned in the author's investigations were fitted with arcing rings or horns, and whether these materially affect the results. My experience is that flash-overs occur more frequently in the early morning or late evening, when presumably the equipment is covered with a film of moisture. Pollution appears to affect suspension sets chiefly: strain sets keep much cleaner and pin-type insulators are generally satisfactory if the design is right. We also find that cement-dust deposit is less serious than the oily, tarry deposit I have mentioned. As regards the proposed insulator (Fig. 5), I question the advisability of providing such deep overhung pockets between the fins. Regarding Part 2 of the paper, I should like to ask the author whether during his investigation into the problem of " stiction " he was able to trace the effects associated with steel-cored aluminium conductors and whether the results differ from those obtained with ordinary copper strand. It is generally understood that when steel-cored aluminium conductors are used regard must be had to the relative amount of the two metals. The author's demonstration of travelling waves in connection with the problem of conductor vibration reminds me of the so-called " dancing " conductors which some years ago kept two parallel lines out of use for several hours. The centres of the wires were at a vertical distance of 18 inches, and the vertical movement was such that the top and bottom wires were making periodic contact. The cause was sleet and ice loading under rapid changes of temperature, combined with an oblique wind: the majority of the binders held, but it was necessary to renew all of them and to adjust the sag. Does not the author's investigation lead to the conclusion that the addition of bird guards to insulators aggravates the flash-over difficulty? The material of which such guards are made has a surface which might collect dirt and possibly increase the risk of trouble. Bird guards can be eliminated by a suitable design of bracket which does not provide perches for the birds.

Mr. E. A. Logan: In common with the author I gained my first experience of overhead transmission in the neighbourhood of Newcastle-on-Tyne, and in consequence I was for a long time in the habit of regarding the detrimental deposition of dirt as normal to overhead-line insulators. At that time I thought that to overcome troubles arising from dirt deposits it was necessary to provide insulators of a size greatly in excess of that necessary to withstand with a large factor of safety the line voltage under wet test conditions. The precise effect of dirt in causing breakdown was then not fully appreciated, but breakdown was generally attributed to a covering of rain or mist over the whole of the leakage surface of the insulators not overhung by sheds. Acting on this assumption, with disc insulators it was decided to allow one more unit in tension or horizontal positions than in suspension or vertical positions, since it was supposed that the tension insulator could be wetted over its whole surface whilst the suspension insulator would remain dry on its under-side. Hence the 4 units and 5 units mentioned on page 806 as being provided on the N.E.S. Co.'s lines. This would have been quite logical had the insulators remained clean, but it was not anticipated that the unwashed surface of the suspension insulators would be fouled at the rapid rate which was, in fact, experienced. Very shortly after the lines had been put into commission, line patrols reported heavy discharges on certain lines at times of fog. Apparently, in the most affected situations sufficient dirt may be deposited in 3 months to cause trouble even in spite of the increased insulation resulting from the addition of the extra disc. I infer this from the statement on page 806 that the cost of cleaning is £5 per circuit per mile per cleaning, and that in the worst sections the annual cost is £20 per circuit-mile. I take it that this £5 per circuit per mile does not represent the whole cost to the supply authority, but only the cost of the labour and materials. In addition there will be the quite appreciable items of interest on idle transmission investment and the less tangible value of the loss of a line as part of a ring main, thus depriving some areas of a fully available duplicate supply and causing delay in restoring supply in the event of breakdown on another part of the circuit. Whilst the figure is not stated, the annual cost of all the cleaning, etc., necessary on the system must be considerable, and it should suffice to purchase and erect quite a number of the improved patterns of insulators. Since the paper was submitted to the Institution sufficient experience

* Paper by Mr. P. J. RYLE (see vol. 69, p. 805).

should have been obtained to permit the author to make a definite pronouncement on the relative merits of the two types illustrated in Figs. 5 and 6. The detrimental effect of the gaseous discharge from pulverized-fuel plants is of particular interest to the designers of super-power stations. The means of disposal of the electricity produced by a station is at least as important as the means of generation and, therefore, in these days of outdoor main switchgear and overhead outgoing main transmission it should be reasonable to allow a sum for the cost of additional insulation of these items when comparing a proposed pulverized-fuel system with other systems. Whilst for convenience of study of the problem discussed in Part 2 the author chooses to separate the small, relatively high-frequency, vertical oscillations of the conductor from the swinging movements, in practice one condition can, under suitable conditions, merge into the other and obscure or complicate the effects. One explanation of the vibration effect is that the force on the conductor arises from a lack of parallelism between the axis of the slip stream of the air behind the conductor and the streamlines of the general direction of the air flow which constitutes the breeze due to the formation of a non-symmetrical eddy. The conductor is thus responsible for causing a change of direction of the air flow, as a result of which it experiences a force. In general, the eddies form successively on alternate sides, but under special circumstances they may be maintained in a stable state on one side only, e.g. by causing the cylinder to rotate. The force thus becomes unidirectional. An example of the utilization of this unidirectional force is the so-called "rotor ship," which attracted a certain amount of Press comment some years ago. In this example the eddy was caused to remain in the air stream on one side of the cylinder by causing it to rotate, the resultant force being utilized to propel the vessel. An example of the formation of eddies on either side of a cylindrical body is provided by the flapping of a flag attached to a flagstaff. Here the flag waves in the breeze due to the eddies, which may be seen running along it. With regard to standing waves: a standing wave is the particular case of two travelling waves each of half amplitude travelling in opposite directions. Here the positive and negative energy-transfers along the wire obviously cancel out. The device suggested in Fig. 20 can apparently only act by causing bending of the conductor at the entrance to the clamp, and in this connection the author states: "It is obvious that this bending involves highly localized energy dissipation . . . and may be injurious to the cable." From this one would infer that the conductor clamp is not the best place at which to attach an energy-absorbing device, particularly as experience of actual conductor fracture and theoretical considerations alike indicate that the clamp, which is the only permanently nodal point on the line, is also the only potential danger point.

Mr. B. D. Youatt: Whereas the problem of the polluted overhead-line insulator is important, the danger arising from conductor vibration is not great where lines are designed for ice loading. We are accustomed to select our insulators on the basis of the B.S.I. tests, but these have nothing to say with regard to depreciation under operating conditions. Some form of pollution test with a specified minimum flash-over voltage is urgently required. A good deal of work has been done in this direction, but so far with no great measure of success. In Table 2 the author gives an indication of how this question might be dealt with. In that table he compares the total leakage resistance of different types of unit with the leakage resistance of their rain-washed portions. If the parts of an insulator which are shielded from rain and which therefore collect dirt were short-circuited by means of some conducting paint and then subjected to the standard rain test, the latter would probably give a better indication of their insulating value under operating conditions. A fog test would be preferable, but it is very difficult in practice to produce a convincing fog by artificial means. I note that the author does not subscribe to the theory that the electrostatic field appreciably affects the rate or extent of pollution. With regard to vibration, the theory that he puts forward to account for the limitation of amplitude by friction is interesting, as it explains the observations made by Varney and others that a vibration angle of 0·5° is rarely exceeded in practical cases. A solution of the problem of vibration which is not mentioned in the paper might be deduced from the methods adopted at sea in dealing with a similar trouble during the War. In order to counteract the danger from mines, paravanes were attached to the ship's bows by means of cables under considerable tension extending at right angles to the side of the ship. At first the vibrations produced in the cables securing the paravanes were so severe that they had a very short life. It was finally discovered that if the cables had a cross-section approximating to a triangle the vibrations were much reduced, and that considerable improvement was obtained if three cables were laid up to form one cable.

Mr. J. H. C. Brooking: I should like to refer to the three methods of overcoming trouble due to conductive deposits which have been tried in practice. The first, which consists in the use of more and deeper sheds, is stated by the author to have proved unsatisfactory in some cases. The second, that of increasing the size of the insulators, provides not only a longer but also a broader leakage path, and therefore affords wider scope for surface conductance. The third remedy proposed is to increase the area of the rain-washed portion of the insulator by putting the ridges outside, and this also has been criticized at previous discussions on the paper. A solution which does not appear to have been dealt with is that of considerably increasing the length of the surface path by extending the sides of the insulator in the form of sleeves covering the exposed part of the conductor adjacent to the insulator, or the suspension shackle of the string type. It may be that this suggestion has not been considered because of the limitations of porcelain, in regard to the likelihood of breakage by vibration of the wire where so enclosed, but it provides a possible method of getting over the trouble if the right kind of material is used. At the time of the salt storms in December 1928, my company heard from some users of Pernax bird-guards that wherever these were fitted to line insulators shut-downs of the lines did

not occur, whereas lines not equipped in this way were affected by the conductive condition of the atmosphere and thrown out of use. As a result of this experience a hood made of "Pernax" has been designed, which covers the whole of the porcelain insulator, whether of the pin or the shackle type, and thus prevents the conductive moisture from affecting its surface. Pernax seems to be less retentive of conductive moisture than porcelain. It may, however, not be due so much to the material or the design of the bird guard which is now incorporated in this insulator hood, as to covering up the live wire on each side of the insulator, thus keeping it at a great distance from the earthed pin or shackle. This form of bird guard has saved overhead lines from trouble during salt storms; the sleeves on either side provide a longer path for the current to traverse to earth. The top of the insulator is covered by the Pernax cap and is thus probably kept clean. A further type of bird guard has since been designed especially to cover the whole of the external surface of porcelain insulators on pins. The sleeves on either side cover a length of conductor also. They can be extended to any distance, because Pernax is not friable or likely to be broken by vibration. A lantern slide shows a string of eight insulators hooded with Pernax for use at 132 000 volts, and these sleeves also can be extended to any length on either side. The Central Electricity Board have decided to test this design at one of their stations. This type of hood for lessening conductive-deposit troubles can be made not only of Pernax, but also of any other highly insulating material that is unlikely to be broken by overhead-line vibration, and is not affected by the weather.

Mr. W. R. T. Skinner: With regard to the design of insulator shown in Fig. 5, would it be practicable to use a spiral groove on the outer surface, instead of a series of circular grooves? The circular grooves have to be sloped outwards and downwards in order to provide drainage, whereas a spiral groove would be self-draining even if the groove were sloped outwards and upwards. The information given in the paper leads me to think that an upward sloping groove might be even more effectively cleaned than one with a downward slope. The scouring action of water draining down the spiral groove should be considerable.

Mr. C. R. Clarke: It appears that the so-called "suspension" insulator has given no trouble when used as a tension member, and I therefore see no reason why the two surfaces of a tension unit should not be similar. Could not both surfaces be corrugated, and, if so, would it then be possible to dispense with one unit of a string, giving an increased clean leakage surface?

Mr. R. G. Ward: I should like to ask two somewhat simple questions. First, the author mentions that "Pyrex" has been used for insulators; I take it that he refers to the electrical resistant glass. Has any other kind of glass been tried, and why particularly was Pyrex used? I have always been led to understand that glass is one of the best insulators, and in this case it will probably be one of the worst for collecting dirt of the type which accumulates on the under-side of an insulator. My second question is: What is the effect on the conductor when it gets into a swing similar to that which the author obtained with a chain? Is there any tendency to unwind the strands?

Mr. E. A. Mills: I should like to inquire the object of corrugating the suspension insulator shown in Fig. 5, as in view of the tendency of dirt to collect on the under-sides of the corrugations a smooth surface would appear to provide better results. Corrugations on any form of insulator are difficult to clean, and I feel that it is a retrograde step to introduce them on insulators of modern design.

Mr. P. J. Ryle (*in reply*): Mr. Siviour mentions that, in the Yorkshire Electric Power Co.'s area, the chief trouble has been from the oily, tarry type of deposit, and that the intensity of deposit varies greatly even on insulators on the same pole. The paper is intended to give a general review of the problem, and no detailed consideration is given to different types of industrial deposit or to different degrees of fouling. My experience is similar to Mr. Siviour's in regard to the surprising degree of non-uniformity of deposit intensity which is often noticed in a given area. I think Mr. Siviour's estimate of 60 per cent to 70 per cent over British Standard Specification ratings is a little pessimistic and I am of the opinion that, for pin-type insulators of normal shapes, 50 per cent would probably be a reasonable margin. At the same time it must be reiterated that the wet flash-over test is not necessarily a good guide to the performance of insulators in dirty areas. In my opinion it is not improbable that insulators could be made of such shapes that they only just complied with the British Standard requirements, whilst giving much better service results than standard shapes designed to meet the same wet flash-over specification. I do not think that arcing rings or horns would have any appreciable effect, one way or the other, on the performance of insulators up to, say, 66 kV. At 132 kV and upwards, arcing rings may be of some benefit since they help to equalize the voltage per unit of the long insulator strings. Without such rings, the last unit of a 132-kV string may have to carry 25 to 30 per cent of the total voltage and therefore may be a very weak link in the electrical chain. On the other hand, when insulators are heavily coated with semi-conducting deposits there is already a considerable self-equalization of voltage over the string, so that the arcing ring may not be of much additional benefit. The chief aim of arcing horns and rings is to minimize damage to the conductor and the insulator string itself caused by the power-arc following flash-over. With regard to Fig. 5, several speakers have been under the impression that the external ribs are overhung. This is not so. Fig. 5 is, perhaps, misleading in this respect, and Fig. O is given on page 262 to show, to a larger scale, the actual shapes of these ribs as adopted on the insulators now undergoing trial. On the Newcastle Electric Supply Co.'s system I do not think that bird guards have had any appreciable effect on tendency to flash-over. On the 66-kV lines no bird guards have been used, and on the lower-voltage (pin insulator) lines the bird guards, where used, have been of types fixed to the cross-arms only. For the last three or four years bird guards have been entirely abandoned, except on certain special switching poles, etc., and complete im-

munity against bird troubles has so far been given by tilted cross-arms on which birds will not perch. With regard to Part 2 of the paper, my discussion of inter-strand friction and its effects is so far entirely theoretical, and I have not yet had opportunity to carry out any experimental work on the subject. There is no doubt that the effects would vary with different conductor materials, as well as with different strand diameters, angles of lay, etc., as will be evident from a study of Appendices I and II. Mr. Siviour's experience of " dancing " conductors, whilst not within the scope of the paper, is of interest. I have known a case where " dancing " must have been the cause of clashing which definitely occurred between conductors at 4 ft. vertical spacing (400-ft. spans, 0·1 sq. in. copper conductors). In this case there was no question of sleet or rapid temperature-changes. The phenomenon occurred on two different dates, at a certain individual span, each time putting the line out of service. On both occasions there was a high wind, but the phenomenon was not actually observed by anyone. After the second occasion I made a point of visiting the particular span several times when high winds were blowing but saw no signs of dancing, the conductors merely being blown out of the vertical and remaining steadily in their normal relative positions. So far, the phenomena of " dancing " are far more obscure than those of vibration as defined at the beginning of Part 2 of the paper.

Mr. Logan infers that the approximate costs of insulator cleaning given on page 806 (vol. 69) are only inclusive of actual labour and materials. This is correct, and he rightly calls attention to the less tangible costs which may have to be borne by the supply authority, such as interest on idle capital investment and temporary loss of service reliability owing to non-availability of complete duplicate supply. In some cases one might also include cost of additional copper losses where both circuits of a double-circuit line, or both sides of a ring are normally maintained in service. Of course, many such incidental costs would usually not be very serious since cleaning would be confined to week-ends or times of light load, and the work can always be called off at, say, half an hour's notice, if necessary. On this subject, I would refer Mr. Logan to Mr. Stedman's contribution to the discussion at Newcastle. It becomes very obvious that the industry could well afford to pay for a large amount of serious research on the subject. I agree, in principle, with Mr. Logan's suggestion that in comparing a projected pulverized-fuel station with an ordinary coal station something should be allowed for the additional cost of outdoor insulation required for the former. Since, however, we know neither how far from the station the polluting effects may be serious nor, in the present state of knowledge, what improved insulation to use, no very reliable estimate could be made. In actual fact the additional cost of any improved insulation would probably be very small in comparison with the total power-station costs. As regards service performance of the insulators shown in Figs. 5 and 6, 36 strings of 5 units of each type have now been in service on lines for a year without trouble. A string of 4 units of each type has also been kept alive on the testing rack for well over a year without flash-over. None of these special insulators has been cleaned, but in the period under review dirt pollution has been less than normal owing to the industrial depression, and unusually few serious fogs have occurred in the district. Little definite information has therefore yet been obtained, except that either type of insulator is, in itself, quite satisfactory for normal operation. Mr. Logan's remarks on eddy formation in Part 2 of the paper summarize clearly the phenomena involved. It is, unfortunately, impracticable to rotate overhead line conductors, but the formation of stable eddies on one side of the conductor only could also be obtained by the use of specially shaped (non-circular) conductors. A brief reference to this solution in connection with paravane towing cables is made on page 812 of the paper. I believe that the use of non-circular conductors is actually being considered in the United States for certain future 220-kV lines. There would be no great difficulties in manufacturing such cables, but serious difficulties arise in connection with fittings, especially the tension clamps and joints. Mr. Logan's reference to the visual illustration of eddy formation by a flag pole and flag is extremely interesting, but it is possible that the flag itself may have something to do with the eddy formation. A flag attached to a fine taut wire, instead of to a pole, would probably show evidence of non-stability of air flow. Mr. Logan's conception of standing waves is identical with that indicated in my reply to Prof. Thornton at Newcastle. With regard to the device shown in Fig. 20 I agree that the clamp is not the best place for a true anti-vibration device, but it is a convenient place and one not introducing any new " hard-spots " or points of possible risk due to clamping indentations. A hydraulic damper, if one could be made to have ideal characteristics, might act in such a way that no appreciable vibration amplitudes would ever build up. If this were the case, the fact that it added to the mass associated with the clamp would be of no importance.

Mr. Youatt implies that the risks of conductor vibration, where the lines are designed for ice-loading, are not very great. In general, I agree, but heavy vibrations are frequently observable on large-conductor lines in this country and I have recently had my attention called to various minor troubles such as loosening of bolts on insulator fittings, and even breakages of certain parts where trouble would never be expected. Time alone can show whether or not the conductors of any particular type of line will stand up to the effects of vibration. I agree with Mr. Youatt that some standard pollution test for insulators is very desirable, but can see no possibility of formulating such a test in the present state of knowledge. The proposal to paint those parts of insulators which normally collect most deposit with conducting paint prior to rain or mist flash-over tests, is of considerable interest and might lead to useful information on the relative values of insulators of widely different shapes. In connection with cables of non-circular section I would refer Mr. Youatt to my reply to Mr. Logan.

Mr. Brooking refers to the possible use of " Pernax " or similar material for covering, wholly or partly, the

insulator and also covering the line conductor at either side of the insulator with a view to lengthening the leakage path to any desired extent. This suggestion, although at first sight revolutionary, is not to be summarily dismissed and I hope that Mr. Brooking will follow it up by research and test. If a pin-type insulator or suspension string were to be completely enclosed in a "Pernax" shield, it might be difficult to ensure satisfactory service under heavy rain, and new troubles might be introduced by moisture condensation or by air ionization inside the enclosing shield.

Mr. Skinner suggests a suspension unit generally similar to that shown in Fig. 5, but with an upwardly-opening spiral groove. Messrs. Steatite and Porcelain Products, Ltd., have already made experimental units of this type, and a string of four units is now on the testing rack at North Tees. This string has, so far, only been alive for a few months, but without flash-over. There is a slight tendency for dirt to collect in the bottom of the groove, presumably due to rain washing it off the sides of the groove and leaving it at the bottom when drying. It would need a very heavy rain indeed to produce anything like a scouring action at the groove bottom.

In reply to Mr. Clarke, there is no reason why both surfaces of a tension unit should not be similar and corrugated, if necessary, excepting, possibly, certain manufacturing difficulties and the fact that since tension strings of normal units give good service there would be no incentive to manufacture units of non-standard and probably expensive design. Some development work is, however, being done on tension units designed to give the maximum rain-washed surface.

In reply to Mr. Ward, I have no direct experience of either "Pyrex" or ordinary glass suspension insulators, except that a string of purely experimental "Pyrex" insulators is erected on the testing rack. There are fields of use for both "Pyrex" and ordinary glass pin-type insulators to-day, but, as far as I am aware, these materials have not yet proved themselves suitable for disc-type insulators owing to mechanical-strength requirements. From visual examination, only, of the experimental strings on the testing rack, "Pyrex" appears to be neither better nor worse than porcelain from the point of view of collecting dirt deposits. Referring to the experimental demonstration of rotating waves (see Appendix III of the paper), although the loops rotate, the chain itself does not revolve and there is no twisting action. For instance, in demonstration (*b*) one end of the chain is held firmly in the hand and the other is held on a fixed hook so that there can be no rotation or twisting of the chain itself. The vibrations of a transmission-line conductor are usually plane or nearly so. This can sometimes be seen very well at a tension string on a 132-kV line where a circular guard ring is attached to the line end of the string. Under suitable conditions of heavy vibration the oscillations of the guard ring clearly indicate the vertical plane of the conductor vibrations. The top and bottom of the guard ring appear blurred, whilst points on the horizontal centre line across the guard ring remain perfectly clear.

In reply to Mr. Mills, the object of corrugating the upper surface of the insulator shown in Fig. 5 is that of increasing the length of the clean, and therefore most effective, part of the leakage path. There is practically

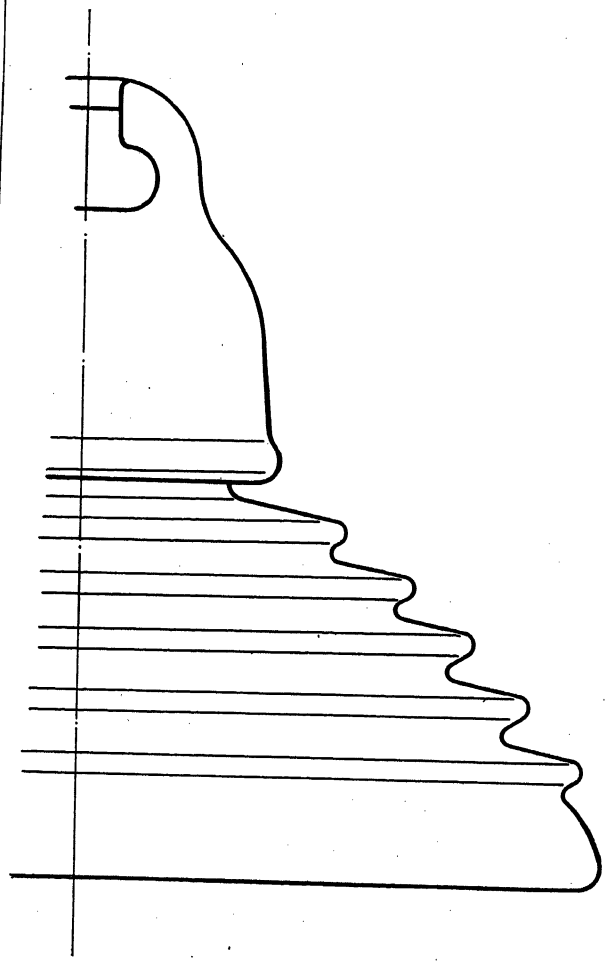

FIG. O.—Enlarged view of suggested suspension insulator shown in Fig. 5 of paper.

no tendency for dirt to collect in the non-overhung grooves on the upper surface, and I would refer Mr. Mills to col. 1 on page 810 of the paper, to my replies to Mr. Langton and Mr. Farrer (pages 846 and 847), and to Fig. O referred to in my reply to Mr. Siviour. Incidentally, when insulators of this form do require cleaning the cleaning of the external corrugations is very easy, and presents a problem very different from that of cleaning the corrugations on the under-sides of standard insulators, especially those nearest the central pin.

HEAT LOSSES DUE TO LOAD CURRENT IN DIRECT-CURRENT ARMATURE WINDINGS.*

By E. A. HANNEY, M.Eng., Associate Member.

(*Paper first received* 18*th August, and in final form* 31*st December*, 1931.)

SUMMARY.

Designers of alternating-current machinery have long been able to make rapid estimates, by means of published curves, of the heating effect due to current displacement in slot-wound conductors. The wave-shape of the current in the windings of direct-current armatures is complex, since it is rich in harmonics. The estimation of the heating effect due to current displacement in direct-current armatures has hitherto necessitated laborious calculation, for each case on its own merits. The busy designer rarely has the time to carry out such a long process, and it is probable that in most cases guesswork is resorted to.

In this paper an attempt is made to provide curves, by the use of which the heating of direct-current armatures may be estimated rapidly. It is believed that results are obtainable with fair accuracy, and with almost the same rapidity as is associated with the estimation of the loss in an alternating-current machine. It is not possible to construct one curve for use in all cases; a "standard" curve is given, which refers to a single-turn full-pitch winding, having 15 slots per pole and 45 commutator segments per pole. Two additional curves give coefficients which enable other full-pitch single-turn windings to be dealt with. The heating ratios so obtained do not differ from those obtained from individual calculations by more than 2 per cent in any practical case. Curves are also given for windings which differ from the standard winding in having (*a*) two turns per coil, (*b*) three turns per coil, (*c*) chording. The question of the critical height of conductor, and the question of the use of unequal heights for the two layers in a slot, are also touched upon.

It is, perhaps, not generally realized that current displacement is present at all times in a direct-current armature winding; it is not confined to the period of commutation. A set of current-distribution curves has been calculated for one case, to show this.

The author hopes to deal with the problem of the rotary convertor, and the problem of unusual winding arrangements designed to reduce heating losses, in a subsequent paper.

LIST OF SYMBOLS.

f = frequency of a periodic function, cycles per second.
h = height of one conductor, cm (see Fig. 6).
I_c = maximum current (amperes) in one conductor of a direct-current armature winding.
$\mathbf{I}_1$ = vector notation of a sinusoidal current component, of amplitude I_1.
i_b, I_b, $\mathbf{I}_b$ = total current flowing in a slot below the conductor in question.
K = ratio between the heat loss due to a sinusoidal alternating current, and the loss which would occur if the current were uniformly distributed throughout the conductor.
K_n = K when specifically applied to the nth harmonic of the trapezoidal current [see Fig. 2(*b*)] of maximum value I_c.
K'_n = ratio between the heat loss due to the nth harmonic of the trapezoidal current of maximum value I_c, and that due to a steady current I_c (see Section 4).
K_0 = ratio between the heat loss due to the trapezoidal current of maximum value I_c, and that due to a steady current I_c. $K_0 = \Sigma K'_n$.
l = buried length of one conductor, in cm.
l_1 = total length of one conductor, i.e. active length + length of end connection.

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

List of Symbols—*continued.*

$\mathbf{M} = ah \coth ah = M_r + jM_x$ (see Section 4).
$\mathbf{N} = 2ah \tanh \frac{1}{2}ah = N_r + jN_x$ (see Section 4).
n = order of harmonic.
n_a = number of coil-sides side by side in a layer in one slot (see Fig. 1).
p = the number of a conductor in one coil-side of a layer, counting from the bottom of the layer (see Fig. 1).
s = number of turns per coil in the winding, i.e. conductors in series per coil-side (see Fig. 1).
t = time, in seconds.
w_c = total width of conducting material in one layer across the width of the slot, in cm ($w_c = n_a \times$ width of one conductor).
w_s = width of slot, in cm (see Fig. 6).
x = height of a level in a conductor, measured from the boundary of the conductor remote from the slot mouth (see Fig. 6).
a = a "semi-imaginary" quantity; $a = |a|\underline{/45°}$ (see Section 3). Except where expressly stated in Section (3), a is calculated for the fundamental, of angular velocity ω.
$|a|$ = numerical value of a; a function of f, w_c, w_s, ρ (see Section 3).
2β = angular width of commutating zone for one coil; an electrical angle based on the pole-pitch as angle π (see Fig. 2).
Δ = instantaneous current density, amperes per cm^2.
Δ_x = vector notation of sinusoidal component of current density, at height x in a conductor.
θ = phase angle ωt.
ρ = resistivity of the conductor material in C.G.S. units.
ϕ = phase angle between two sinusoidal currents, of the same frequency, in corresponding coil-sides of the two layers in a slot. (ϕ = zero for full-pitch windings.)
2ψ = electrical angle between adjacent currents in two neighbouring coil-sides of a layer in one slot, based on the pole-pitch as angle π (i.e. electrical angle between two commutator segments).
ω = angular velocity of the fundamental component of the current wave of maximum value I_c, in radians per second.

Introduction.

Whenever the current in a conductor is varying, a displacement takes place so that the distribution of current in the conductor is no longer uniform. The heat for which a non-uniform current is responsible is greater than that which accompanies the same current if the distribution is rendered uniform.

The heat loss which takes place in the buried conductors of a winding carrying a sinusoidal alternating current was first investigated by A. B. Field,* whose results have been of great use to designers.

The fact that a somewhat similar current displacement takes place in the armature conductors of a direct-current machine has for some time been appreciated.* The investigation of individual cases has, however, necessitated very laborious calculations.

In this paper the author has endeavoured to present data from which the effective resistance of the buried portion of the armature winding of any normal direct-current machine can be predicted with an accuracy sufficient for engineering purposes. The method of presenting the data is such that results should be obtainable with no more labour than is associated with similar calculations for the alternating-current case.

The general method of computing the total loss in a conductor carrying a non-sinusoidal alternating current which flows in a direct-current armature is as follows:—

The wave-shape of current is replaced by a Fourier series and the loss due to each harmonic is determined separately. (The above Fourier series is infinite, but the resultant loss series has fairly rapid convergency in normal cases.) The justification for the separate treatment of the harmonics, and the summation of the terms of the resultant loss series, is capable of rigid proof.

In general it is unlikely that the heat loss due to the displaced current of a loaded direct-current armature can be predicted as closely as that of an alternating-current armature. Three important causes militate against accurate predetermination. They are:—

(1) Uncertainty of current wave-form, which may be influenced by brush contacts, interpole adjustment, brush position, etc. This matter is considered in Section (1).

(2) Phase difference between neighbouring currents in one layer of a slot. This is considered in Section (2) below.

(3) Doubtful accuracy of calculations for harmonics of high order. This arises from the phase difference between neighbouring currents (see the preceding cause), and to the uncertainty regarding tooth saturation and tooth eddy losses at the higher frequencies.

It must be noted that the fundamental and the lower harmonics always contribute an overwhelming proportion of the total loss. It will be seen below that the uncertainties referred to above appear to exist in a marked degree only in the case of harmonics which are negligible, in their contribution to the total loss.

Definition of Terms applied to Windings.

There is no standard nomenclature applied to the windings of dynamo-electric machines. It is therefore necessary to define the terms used in this paper in regard to the windings of direct-current machines.

A direct-current armature winding, as ordinarily arranged, is regarded as being of the *two-layer type*. The layer nearer the mouth of the slot is referred to as the *upper* layer; that near the bottom of the slot is referred to as the *lower* layer. The conductors in one layer in one slot are all taped together to form one *taped-up coil*; one side of a taped-up coil constitutes the upper layer in some slot, and the other side of the same taped-up coil constitutes the lower layer in some other slot. But one taped-up coil usually consists of several exactly similar coils, arranged side by side in the taped-up coil; corresponding ends of neighbouring coils are con-

* See Bibliography, (1).

* See Bibliography, (34) to (43); also part of (2), and (10) (Part III).

nected to neighbouring commutator segments. Each coil may have a number of turns, arranged one above the other; the conductors of the several turns of one coil constitute a *coil-side*.

The symbol n_a is used for the number of coil-sides side by side in one taped-up coil. A multi-turn coil is described as having s turns. The turns are always counted from the bottom of a layer towards the mouth of a slot, and reference is made to the pth turn. The value of p applied to any one conductor applies only in

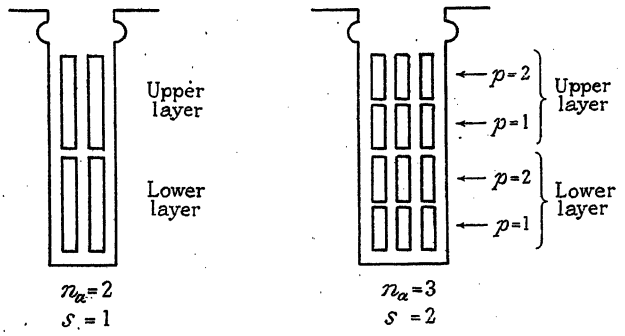

FIG. 1.—Examples of arrangements of windings in slots.

the slot under consideration (thus one side of one turn may be the top turn in the upper layer of one slot, whilst the other side of the same turn is the bottom turn of the lower layer of another slot).

Examples of arrangements of windings in slots, showing the application of the nomenclature, are given in Fig. 1.

(1) THE CURRENT WAVE-SHAPE AND ITS HARMONICS.

The simplest assumption regarding the wave-shape of the current in the conductors of a direct-current armature is a rectangular wave, in which the current has its

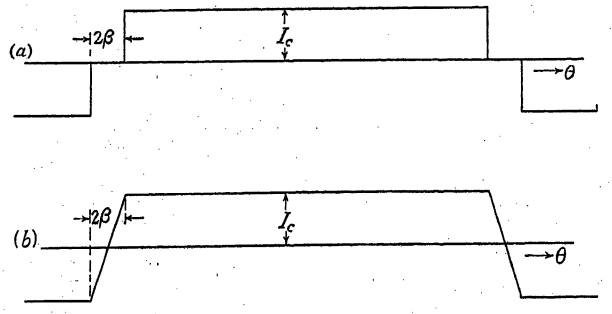

FIG. 2.

maximum value for a complete half-period, the reversal being instantaneous.

Another approximation is to assume zero current during the time interval in which the coil undergoing commutation is short-circuited. This is shown in Fig. 2(*a*).*

A further simple wave-form is that in which the current changes during the time of commutation according to a straight line (Fig. 2*b*).

* This wave-shape is included since it is the basic form from which other wave-shapes are derived by adding a wave representing the behaviour during commutation. Also this wave-shape is stated by W. V. Lyon [see Bibliography, (41)] to be the one on which the nominal resistance loss should be computed, according to the Standardization Rules of the American I.E.E.

In practice the way in which the current changes during the period of commutation is uncertain. It is greatly influenced by the design of the interpole, and is likely to be different for the various coil-sides of a layer. The actual wave-form always consists of that of Fig. 2(*a*), plus a wave-form in which the current is zero except during an interval 2β in the half period. Thus the behaviour of the current during the period of commutation cannot greatly affect the amplitudes of the lower harmonics in any practical case.

An investigation has been carried out on several simple wave-forms. These include the rectangular wave-form, those of Fig. 2, and forms in which the current changes during the period of commutation according to a half-period cosine wave, and to quarter-period sine waves representing accelerated and retarded commutation. In all waves except the rectangular one it was assumed that $2\beta = 12$ fundamental electrical degrees (i.e. a commutation period occupying 1/15th of the half period). Excluding the rectangular wave, and that of Fig. 2(*a*), the amplitudes of the higher harmonics differ, as between the several wave-forms, by amounts which do not exceed about 1 per cent of the fundamental.

The heating effects due to given harmonics are proportional to the squares of the amplitudes. It is therefore clear that the type of commutation on which calculations are based is not of much moment. At the same time, the rectangular wave-form, and that of Fig. 2(*a*), are extreme cases which bear no relation to practice.

The author therefore decided to base all calculations on straight-line commutation (Fig. 2*b*).

(2) THE PHASE DISPLACEMENT BETWEEN NEIGHBOURING CURRENTS IN A LAYER.

The fact that there is a phase displacement between the currents in neighbouring coil-sides in a layer complicates the distribution of magnetic flux within the slot. It will now be shown that the effect of ignoring this complication cannot introduce a large error in any practical case.

If straight-line commutation is assumed, the current in one coil-side varies according to Fig. 3, in which the angles correspond to the fundamental. Thus 2β is the angular width of the commutating zone for one coil, and I_c is the maximum value of current per conductor.

Mathematically this current may be represented by

$$i_1 = \frac{4}{\pi} I_c \left[\frac{\sin\beta}{\beta} \sin\theta + \frac{1}{3} \frac{\sin 3\beta}{3\beta} \sin 3\theta + \ldots \right]$$

The current in an adjacent coil-side in the same layer is

$$i_2 = \frac{4}{\pi} I_c \left[\frac{\sin\beta}{\beta} \sin(\theta - 2\psi) + \frac{1}{3} \frac{\sin 3\beta}{3\beta} \sin 3(\theta - 2\psi) + \ldots \right]$$

where 2ψ = the fundamental angle between two neighbouring coil-sides or commutator segments.

If there are n_a coil-sides per layer in one slot, the fundamental phase angle between two limiting coil-sides in a layer is $2\psi(n_a - 1)$. The corresponding angle for the nth harmonic is $2\psi n(n_a - 1)$.

When a sinusoidal current of frequency n times that of the fundamental, and of amplitude $\left(\frac{4}{\pi} I_c \frac{1}{n} \frac{\sin n\beta}{n\beta}\right)$, traverses each of the n_a coil-sides of a layer, with a phase displacement 2ψ between two neighbouring coil-sides, the resultant current of the layer is

$$\frac{4}{\pi} I_c n_a s \left(\frac{1}{n} \frac{\sin n\beta}{n\beta}\right) \left(\frac{\sin n_a \psi n}{n_a \sin \psi n}\right)$$

where there are s turns per coil.

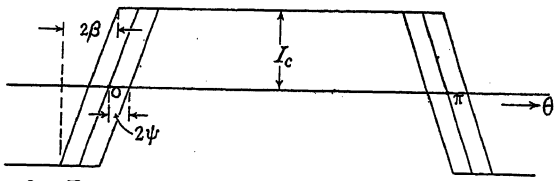

FIG. 3.—Trapezoidal current wave-forms in adjacent coil-sides.

Both the quantities within brackets decrease for increasing values of n. (They both decrease to zero and become negative, but this occurs at stages which, for the general practical case, are beyond the significant limits.)

The "Transverse" and "Radial" M.M.F.'s of a Layer.

The resultant current of a layer in one slot gives a magnetomotive force which is directed across the slot. This "transverse" m.m.f. tends to produce a flux which is normal to the sides of the slot.

The components of the individual sinusoidal currents which are in time quadrature with the sinusoidal

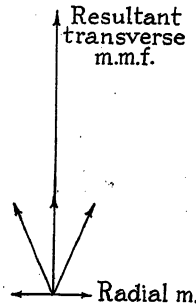

FIG. 4.—Individual, resultant transverse, and resultant radial m.m.f.'s due to a harmonic of the currents in the coil-sides of a layer in one slot ($n_a = 3$).

resultant, cancel one another. But these components have an actual existence on the two sides of the centre-line of a slot. The sum of these components on one side of the centre-line of a slot gives the current which produces the "radial" m.m.f. acting along that centre-line. (It is at once evident that, in any given slot, or layer in some slot, in a direct-current armature, "radial" m.m.f. can only exist whilst commutation is taking place within the given region, for at all other instants all coil-sides within the region carry the same current. Thus the "radial" m.m.f.'s due to sinusoidal components of the total current cancel one another except during brief intervals. This is further considered below.)

The simple case of three coil-sides per layer in one slot, carrying sinusoidal currents which differ in phase (as in the case of a harmonic of the currents in a direct-current winding), is illustrated vectorially in Fig. 4. The figure shows the transverse and radial m.m.f.'s.

One of the most important premises* in the investigations first carried out by A. B. Field is not observed in a winding where a radial m.m.f. is able to upset the field normal to the sides of the slot. It is therefore necessary to make some attempt to assess the influence of this radial m.m.f. in practical cases.

The Magnitude of the Radial M.M.F.

It is of interest to examine a case in which the radial m.m.f. is unusually large. Such a case is furnished by a slot containing only two coil-sides per layer, when the fundamental phase angle between them, and the width of the commutating zone, are both relatively large. The radial m.m.f. along the centre-line of the slot in this case is greater than that in any other arrangement in which the same current per layer is divided amongst more than two coil-sides, with the angular slot-pitch unchanged. The transverse and radial m.m.f.'s are respectively obtained from the sum of, and half the difference between, the two currents, as shown in Fig. 5.

From this figure it is clear that the effect of ignoring the radial m.m.f. is not likely to be important in any practical case.

But the radial m.m.f. exists precisely at the time when the displacement of current is very great (see Section 3). The above conclusion may, however, be confirmed analytically as follows.

For the nth harmonic, the magnitude of the current giving the radial m.m.f. is, for one layer,

$$\frac{4}{\pi} I_c \frac{1}{n} \frac{\sin n\beta}{n\beta} [\sin \psi n(n_a - 1) + \sin \psi n(n_a - 3) + \ldots]$$

In this series the last term refers to the $\frac{1}{2}(n_a - 1)$th coil-side if n_a is odd, and to the $\frac{1}{2}n_a$th coil-side if n_a is even.

The summation reduces to

$$\frac{4}{\pi} I_c \frac{1}{n} \frac{\sin n\beta}{n\beta} \left[\frac{\sin \left\{\frac{1}{2}(n_a - 1)\psi n\right\} \sin \left\{\frac{1}{2}(n_a + 1)\psi n\right\}}{\sin \psi n}\right]$$

when n_a is odd; and

$$\frac{4}{\pi} I_c \frac{1}{n} \frac{\sin n\beta}{n\beta} \left[\frac{\sin \left\{\frac{1}{2}n_a \psi n\right\} \sin \left\{\frac{1}{2}n_a \psi n\right\}}{\sin \psi n}\right]$$

when n_a is even.

In practice n_a varies from 1 to 6, and for these values the expression within the brackets above becomes:—

For $n_a = 1$	0
$n_a = 2$	$\sin \psi n$
$n_a = 3$	$\sin 2\psi n$
$n_a = 4$	$\frac{\sin^2 2\psi n}{\sin \psi n}$
$n_a = 5$	$\frac{\sin 2\psi n \sin 3\psi n}{\sin \psi n}$
$n_a = 6$	$\frac{\sin^2 3\psi n}{\sin \psi n}$

* These premises are reproduced in Section (3).

Now with increasing order of harmonic, the transverse m.m.f. of a layer decreases, and the radial m.m.f. acting along the centre-line of a slot increases. The investigation of a large number of cases, ranging over the whole normal design field, has brought to light the following facts:—

The series representing separate heating ratios for the odd harmonics from 1 upwards is extinguished (for practical purposes) at or before the stage at which the centre-line radial m.m.f. for a harmonic becomes equal to the transverse m.m.f. for the same harmonic. It is to be noted that this radial m.m.f. varies from zero at the outer boundary of the limiting conductor to a maximum at the centre-line of the slot; that it acts on a relatively long air path; and that it is only important for harmonics which make but a small contribution to the heating. The conclusion is therefore justified that a method which entirely ignores the effect of the radial m.m.f. is yet a distinct improvement on purely empirical methods.

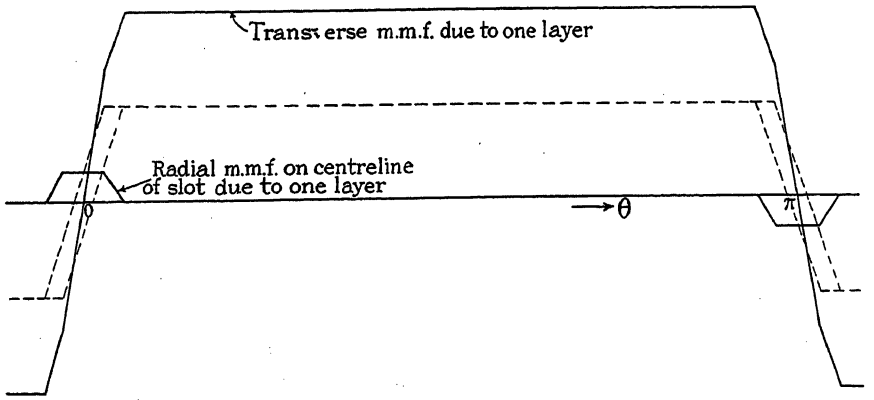

FIG. 5.—Wave-forms of radial and transverse m.m.f.'s due to one layer in one slot, with $n_a = 2$.
18 slots per pole, 2 coil-sides per layer; $2\psi = 5°$, $2\beta = 16°$.

(3) THE DISTRIBUTION OF CURRENT IN THE ARMATURE CONDUCTORS.

When the current of an armature conductor is reversed during the commutating period, the distribution of the current throughout the section of the conductor is changed so that the current is driven towards the mouth of the slot. The end of the period of commutation finds the current non-uniform, and during the interval which elapses before the next commutation the current gradually settles down towards a state of uniform distribution.

The current distribution in conductors which are buried in slots formed in laminated sheet-steel structures was first investigated analytically by A. B. Field.* The following assumptions were made by Field, and by other writers at later dates:—

(1) Rectangular conductors are buried in rectangular slots. (The shape of the slot mouth is immaterial.)

(2) The flux produced by an element of current in a conductor is uniform, normal to the sides of the slot, and is all through or above the element.

(3) The current density along a plane perpendicular to the sides of the slot is constant in one conductor.

(4) The conductor material has uniform resistivity in spite of non-uniform heat production. (The temperature gradients in copper are probably small.)

(5) The reluctance of the magnetic paths through the iron is negligible.

(6) The current distribution is uniform in the end-windings.

Subsequent experience has shown that the discrepancies between test-results and results calculated on the above assumptions are not of engineering importance in alternating-current machines.*

No experimental data are available concerning the losses which occur due to current displacement in direct-current armatures, but Messrs. Lyon, Wayne, and Henderson† have made tests on a model in which current was reversed 120 times per second in a conductor 1 in. deep. The measured current distribution, and that computed after making the assumptions outlined above, were in close agreement.

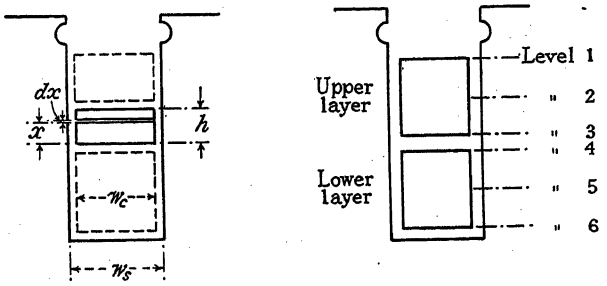

FIG. 6.

The differential equation for the current distribution in a conductor of height h cm, at a level x cm above the bottom of the conductor (see Fig. 6), is

$$\rho\frac{\partial\Delta}{\partial x} - \frac{4\pi}{10^9 w_s}\left[\int_0^x w_c\frac{\partial\Delta}{\partial t}\,dx + \frac{\partial}{\partial t}i_b\right] = 0‡$$

* See Bibliography, (1).

* See Bibliography, (2), (6), (7), (9), (16, discussion), (19), (30), (31), (33).
† *Ibid.*, (41).
‡ This equation is well known, and is developed in several papers. A step-by-step development is given by W. V. Lyon [see Bibliography, (16)].

In this expression, ρ is the resistivity of the conductor material; Δ is the instantaneous current density at the level x; w_s is the width of the slot; w_c is the total width of conducting material in the layer; and i_b is the instantaneous sum of currents in all conductors below the one in question. C.G.S. units are used throughout.

The equation assumes that the currents in the n_a conductors of a layer are in phase, and that the instantaneous value of Δ is the same at all points having the same level.

The solution of this equation is well known for the case in which the current densities are sinusoidal functions in time. In the case of the periodic functions which represent the current in the conductors of a direct-current armature, it is necessary to obtain a Fourier series. This series is solved for each harmonic separately, and the results are added. The results are obtained in a series of fairly rapid convergency.

With regard to the method of solving the above equation for any one harmonic, F. W. Carter* has treated the matter in detail, developing the method from first principles. The author has, however, preferred to use the symbolic treatment due to W. V. Lyon.† This method leads to relatively easy computation, with the aid of Prof. Kennelly's "Tables of Complex Hyperbolic and Circular Functions." In its general application the treatment has the additional advantage that equivalent reactances due to current displacement may be investigated from the same expressions.

In symbolic form, the current density Δ_x at level x, due to a sinusoidal component of amplitude I_1 and frequency f (with current $\mathbf{I}_b$, of the same frequency, flowing in the slot below the conductor in question), is

$$\Delta_x = \frac{\alpha}{w_c}\left[\mathbf{I}_b \sinh \alpha x + \mathbf{I}_1 \frac{\cosh \alpha x}{\sinh \alpha h} - \mathbf{I}_b \cosh \alpha x \tanh \tfrac{1}{2}\alpha h\right]$$

where $\alpha^2 = \dfrac{8\pi^2 f w_c}{10^9 \rho w_s}\sqrt{(-1)}$, or $\alpha = \sqrt{\left[\dfrac{8\pi^2 f w_c}{10^9 \rho w_s}\right]}\underline{/45°}$‡

For a clear deduction of this equation the reader is referred to Item (16) in the Bibliography.

Consider the case of a normal single-turn winding with several conductors side by side in a layer in one slot. It has been shown in Section (2) that for practical purposes the currents in the conductors of a layer may be combined vectorially, and the resultant current used in calculations. (This procedure is equivalent to the replacement of the winding by one having only two conductors per slot, each conductor carrying the resultant current of the layer.) Then, for sinusoidal currents, the expressions for the current density at the top, at the middle, and at the bottom of a layer are:—

$$\text{(Top)} \qquad \Delta_h = \frac{\alpha}{w_c}[\mathbf{I}_1 \coth \alpha h + \mathbf{I}_b \tanh \tfrac{1}{2}\alpha h]$$

$$\text{(Middle)} \qquad \Delta_{\frac{1}{2}h} = \frac{\alpha}{w_c}[\mathbf{I}_1 \tfrac{1}{2} \operatorname{cosech} \tfrac{1}{2}\alpha h]$$

$$\text{(Bottom)} \qquad \Delta_0 = \frac{\alpha}{w_c}[\mathbf{I}_1 \operatorname{cosech} \alpha h - \mathbf{I}_b \tanh \tfrac{1}{2}\alpha h]$$

In the special, though quite common, case of a full-pitch single-turn winding, $\mathbf{I}_1$ and $\mathbf{I}_b$ are equal and in phase for the upper layer; and $\mathbf{I}_b$ is zero for the lower layer. Thus at the six levels in the slot representing the top, middle, and bottom of each of the two layers (see Fig. 6), expressions giving the ratio between the actual current density and the nominal current density which would result from uniform distribution are:—

Level (1):—$\alpha h(\coth \alpha h + \tanh \tfrac{1}{2}\alpha h)$
Level (2):—$\alpha h(\tfrac{1}{2} \operatorname{cosech} \tfrac{1}{2}\alpha h)$
Level (3):—$\alpha h(\operatorname{cosech} \alpha h - \tanh \tfrac{1}{2}\alpha h)$
Level (4):—$\alpha h(\coth \alpha h)$
Level (5):—$\alpha h(\tfrac{1}{2} \operatorname{cosech} \tfrac{1}{2}\alpha h)$
Level (6):—$\alpha h(\operatorname{cosech} \alpha h)$

In the above expressions α has the value corresponding to the harmonic under consideration. Thus for the nth harmonic, α is $\sqrt{n}$ times the value of α for the fundamental.

If straight-line commutation is assumed, with a commutating zone of angular width 2β (as in Fig. 2*b*), and with a maximum current $n_a I_c$ in the layer, the nominal current density for the nth harmonic is, in real terms,

$$\frac{4}{\pi}\frac{n_a I_c}{w_c h}\frac{\sin n\beta}{n^2\beta}\sin n\omega t^*$$

Since the harmonic components of the current in the layer are all in phase, the six expressions giving the actual current density in terms of the density $(n_a I_c)/(w_c h)$, and giving their phases relative to that of the harmonics of the nominal current density, are:—

Level (1):—$\dfrac{4}{\pi}\cdot\dfrac{\sin n\beta}{n^2\beta}\sqrt{nah}(\coth \alpha h + \tanh \tfrac{1}{2}\alpha h)$

Level (2):—$\dfrac{4}{\pi}\cdot\dfrac{\sin n\beta}{n^2\beta}\sqrt{nah}(\tfrac{1}{2} \operatorname{cosech} \tfrac{1}{2}\alpha h)$

Level (3):—$\dfrac{4}{\pi}\cdot\dfrac{\sin n\beta}{n^2\beta}\sqrt{nah}(\operatorname{cosech} \alpha h - \tanh \tfrac{1}{2}\alpha h)$

Level (4):—$\dfrac{4}{\pi}\cdot\dfrac{\sin n\beta}{n^2\beta}\sqrt{nah}(\coth \alpha h)$

Level (5):—$\dfrac{4}{\pi}\cdot\dfrac{\sin n\beta}{n^2\beta}\sqrt{nah}(\tfrac{1}{2} \operatorname{cosech} \tfrac{1}{2}\alpha h)$

Level (6):—$\dfrac{4}{\pi}\cdot\dfrac{\sin n\beta}{n^2\beta}\sqrt{nah}(\operatorname{cosech} \alpha h)$

In these expressions (and subsequently) the value of α is that calculated for the fundamental.

* See Bibliography, (40).
† Developed in "Heat Losses in the Conductors of A.C. Machines" [see Bibliography, (16)].
‡ If $|\alpha|$ is the modulus, or numerical value of α, then $|\alpha| = m\sqrt{2}$, where m is the quantity used by A. B. Field. For a copper winding, the expression for $|\alpha|$ reduces to:—

$|\alpha| = 3{\cdot}42\sqrt{\left[\dfrac{fw_c}{w_s(234{\cdot}5+x°\,\mathrm{C})}\right]}$ at $x°$ C; $|\alpha| = 0{\cdot}193\sqrt{\left[\dfrac{fw_c}{w_s}\right]}$ at 80° C.;

$|\alpha| = 0{\cdot}205\sqrt{\left[\dfrac{fw_c}{w_s}\right]}$ at 45° C.; $|\alpha| = 0{\cdot}187\sqrt{\left[\dfrac{fw_c}{w_s}\right]}$ at 100° C.

* In the case of a winding having s turns per coil, the expression is still correct, since the maximum current per layer is $(n_a s I_c)$, and the section of the layer is $(w_c s h)$, where h is the height of the conductor.

An Example of the Current Distribution.

To illustrate the manner in which the current is distributed in the slot windings of a direct-current armature, an example has been completely calculated over one half-period of the fundamental. The case illustrated is that of a full-pitch winding with only one conductor per layer in one slot.

The calculation has been carried out up to, and including, the 21st harmonic, with a value of $|a\hbar|$ equal to 1·5, and a commutating zone of 12° fundamental angular width. These values are fairly representative of modern practice.

The diagrams shown in Fig. 7 demonstrate the values, at the six levels, of the current densities due to individual harmonics. Fig. 7(*a*) refers to the fundamental; 7(*b*) to the fifth harmonic; 7(*c*) to the eleventh; and 7(*d*) to the twenty-first. The densities are shown relative in magnitude to the nominal density $(n_a I_c)/(w_c h)$; the vectors also show their phases relative to the sinusoidal components of the nominal-current-density function, whose vectors would be drawn horizontally towards the right.

The total current density at the six levels, calculated from moment to moment over one half-period of the fundamental, is shown in Fig. 8, relative to the nominal density $(n_a I_c)/(w_c h)$. It is noteworthy that the current does not appear to have settled down until an interval has elapsed corresponding to fully five times the period of commutation.

The method of calculating the vectors in Fig. 7, and the calculation of one point on each of two curves in Fig. 8, are shown in Appendix I.

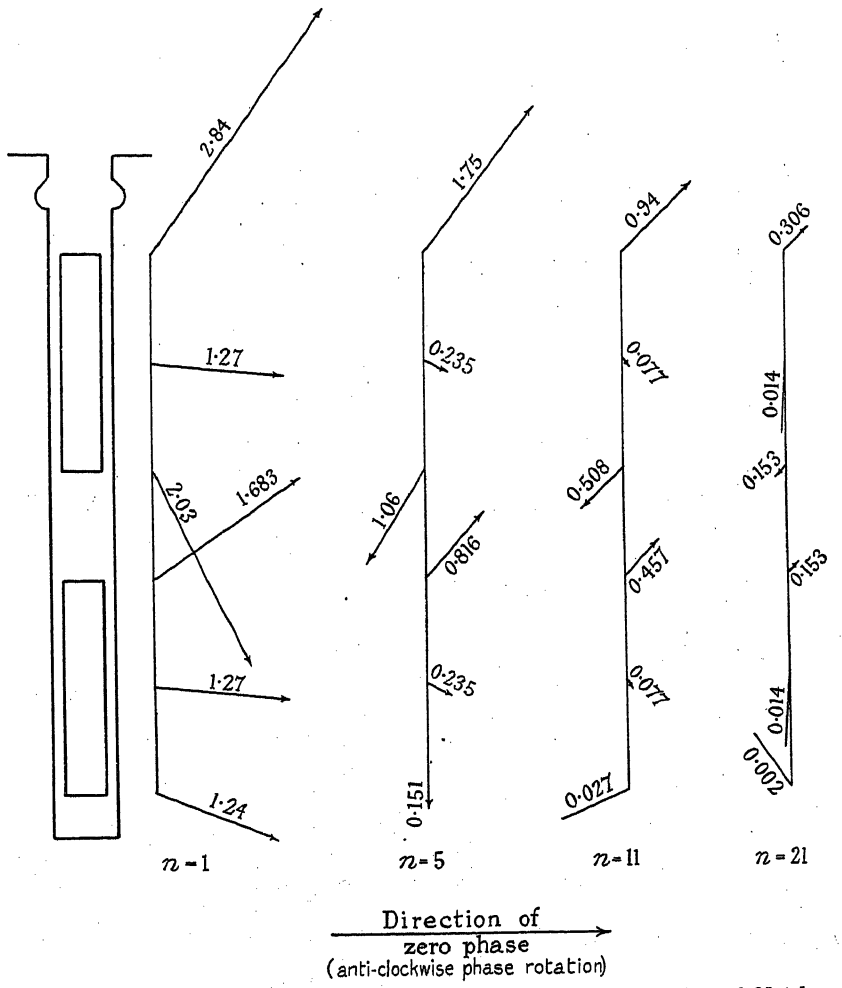

FIG. 7.—Magnitude and phase of the current density due to the 1st, 5th, 11th, and 21st harmonics, at the six levels shown in Fig. 6.

Current wave-form as in Fig. 2(*b*). The figures are amplitudes of current-density components relative to the density $[n_a I_c/(w_c h)]$.

(4) THE METHOD OF CALCULATION OF THE HEAT LOSS.

An expression has been given in Section (3) for the current density at a level x in a conductor, in terms of the conductor dimensions, the quantity α, and the currents $\mathbf{I}_1$ and $\mathbf{I}_b$ in the conductor and below the conductor respectively.

By expressing the loss in an element, and integrating, the loss in one turn of a layer, in a whole layer, or in a whole slot, may be determined.

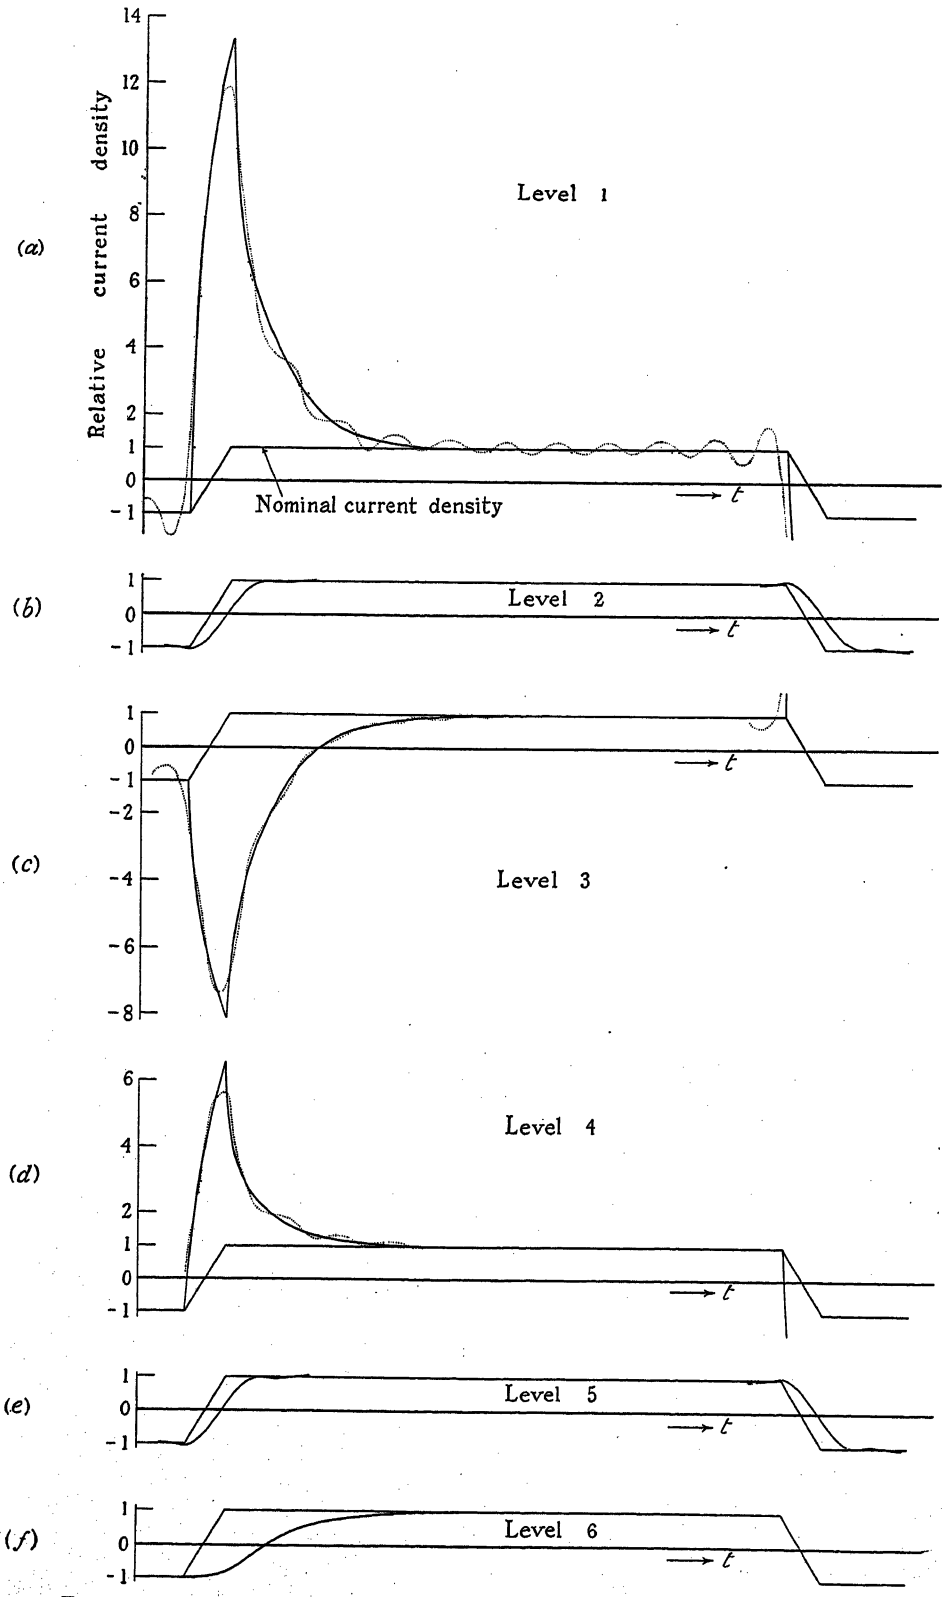

FIG. 8.—Curves of current density against time at different levels in the slot.

The dotted curves of (*a*), (*c*), and (*d*), and the full-line curves of (*b*), (*e*), and (*f*) are as actually calculated. The full-line curves of (*a*), (*c*), and (*d*) are made to correspond as nearly as possible to the values which would be obtained by calculating further members of the series. The position of each level is defined in Fig. 6.

W. V. Lyon* has shown that heating ratios, and reactive power ratios in the various cases can all be expressed as functions of **M** and **N** where

$$\mathbf{M} = ah \coth ah = M_r + jM_x$$
$$\mathbf{N} = 2ah \tanh \tfrac{1}{2}ah = N_r + jN_x$$

In these expressions, M_x and N_x are only needed in calculations of reactive power. Thus in considering the ratio between actual heating and that which would occur with uniform current distribution, the functions M_r and N_r are needed. A table of calculated values of the functions M_r and N_r over a range sufficient to cover practical needs is given in Appendix II.

The windings of direct-current armatures are almost invariably of the two-layer type, with one or more coil-sides side by side in a layer, and one or more conductors per coil-side (or turns per coil). Lamination of the conductors is not resorted to; the mechanical difficulties associated with such a feature in rotating two-layer windings appear to be too great, so that laminated windings are not considered here.

If a sinusoidal current of amplitude I_1 flows in a conductor, and current of amplitude I_b flows in the slot below this conductor with a phase angle ϕ between them, then the ratio of the actual loss to the loss which would occur with uniform current distribution, is K, where

$$K = M_r + \left(\frac{I_b^2}{I_1^2} + \frac{I_b}{I_1}\cos\phi\right)N_r$$

Applying this to standard cases:—

(1) A one-layer-per-slot winding, or the lower layer of a two-layer winding.

$$K = M_r + (p^2 - p)N_r$$

for the pth conductor (counting from the bottom of the layer) and

$$K = M_r + \tfrac{1}{3}(s^2 - 1)N_r$$

for the whole layer in an s-turn winding.

(2) The upper layer of a two-layer winding, with s turns per layer, where all conductors of both layers are of the same size and carry the same current, but where the two layers differ in phase by angle ϕ.

$$K = M_r + \left[p^2 - p + s^2 + (2p - 1)s\cos\phi\right]N_r$$

for the pth conductor; and

$$K = M_r + \left[\tfrac{1}{3}(4s^2 - 1) + s^2\cos\phi\right]N_r$$

for the whole layer.

(3) The average ratio for the slot containing a two-layer winding, the currents in the two layers differing in phase by angle ϕ, is obtained from the cases above, and is

$$K = M_r + \left[\tfrac{1}{3}(5s^2 - 2) + \tfrac{1}{2}s^2\cos\phi\right]N_r$$

These may be applied to two-layer windings, having one, two, or three turns, with all conductors the same size, whether full-pitch or chorded windings. The resultant values of K are given in Table 1.

* See Bibliography, (16), for this, and for the loss-ratio expressions which follow.

TABLE 1.

Values of K in Standard Two-Layer Windings. All Conductors Same Size.

	$\phi \neq 0$	$\phi = 0$
	Single-Turn Windings.	
Slot ..	$M_r + \frac{1}{2}N_r(1 + \cos\phi)$	$M_r + N_r$
Upper layer	$M_r + N_r(1 + \cos\phi)$	$M_r + 2N_r$
Lower layer	M_r	M_r
	Two-Turn Windings.	
Slot ..	$M_r + N_r(3 + 2\cos\phi)$	$M_r + 5N_r$
Upper layer	$M_r + N_r(5 + 4\cos\phi)$	$M_r + 9N_r$
Second turn	$M_r + 6N_r(1 + \cos\phi)$	$M_r + 12N_r$
First turn..	$M_r + N_r(4 + 2\cos\phi)$	$M_r + 6N_s$
Lower layer	$M_r + N_r$	$M_r + N_r$
Second turn	$M_r + 2N_r$	$M_r + 2N_r$
First turn..	M_r	M_r
	Three-Turn Windings.	
Slot ..	$M_r + N_r(\frac{4}{6}\frac{3}{3} + \frac{3}{2}\cos\phi)$	$M_r + \frac{7}{6}\frac{0}{0}N_r$
Upper layer	$M_r + N_r(\frac{3}{3}\frac{5}{3} + 9\cos\phi)$	$M_r + \frac{6}{3}\frac{3}{3}N_r$
Third turn	$M_r + 15N_r(1 + \cos\phi)$	$M_r + 30N_r$
Second turn	$M_r + N_r(11 + 9\cos\phi)$	$M_r + 20N_r$
First turn..	$M_r + N_r(9 + 3\cos\phi)$	$M_r + 12N_r$
Lower layer	$M_r + \frac{8}{3}N_r$	$M_r + \frac{8}{3}N_r$
Third turn	$M_r + 6N_r$	$M_r + 6N_r$
Second turn	$M_r + 2N_r$	$M_r + 2N_r$
First turn..	M_r	M_r

The above expressions are in order even if the conductors are not of the same height in the two layers, so long as the current is the same in magnitude for each layer. But it must be remembered that $|ah|$ is not the same for both layers, whence M_r and N_r will not be the same throughout the slot.

Now the actual loss in a conductor of resistance R ohms, carrying a sinusoidal current of amplitude I_1 amperes, is

$$\tfrac{1}{2}KI_1^2R \text{ watts}$$

If the value of K computed for the nth harmonic of the current of trapezoidal wave-shape is denoted by K_n, then the loss in one layer due to this harmonic is

$$\tfrac{1}{2}K_nR\left[\frac{4}{\pi}(I_c n_a s)\left(\frac{1}{n}\frac{\sin n\beta}{n\beta}\right)\left(\frac{\sin n_a\psi n}{n_a \sin\psi n}\right)\right]^2$$

The expression in the bracket is the resultant nth harmonic current of one layer, if I_c is the maximum value of the current in one conductor (see Section 2).

The simplest method of estimating the loss in a winding due to uniformly distributed current is to obtain the product of the resistance between brushes and the square of the steady direct current. This method forms a convenient basis for the loss ratio of the direct-current armature. On this basis the loss ratio in the buried portion of the winding is, for the nth harmonic,

$$K_n' = \frac{8}{\pi^2}\left(\frac{1}{n}\frac{\sin n\beta}{n\beta}\right)^2\left(\frac{\sin n_a\psi n}{n_a \sin\psi n}\right)^2 K_n$$

where K_n is obtained from Table 1, in terms of M_r and N_r. The value of $|\alpha h|$ used in finding M_r and N_r (see Table 7 in Appendix II) is $\sqrt{n}$ times that calculated for the fundamental.

The heating ratio for the buried winding is given by the sum of the values of K'_n for the various harmonics.

An example illustrating the method is given in Table 2, Section (5).

(5) The Heat Loss in Single-Turn Full-Pitch Windings.

If the two layers, one above the other in a slot, have conductors of equal height, and carry currents which have no phase difference between them, the relevant values of K are given in Table 1. For a full-pitch single-turn winding, K is equal to $(M_r + N_r)$ for the whole slot.

To illustrate the method of calculating the heating ratio of the buried portion of a winding, an example is detailed in Table 2.*

It is clear from Table 2 that the calculation of the heating ratio is laborious. Attempts have therefore been made to reduce the labour involved, by making a very large number of calculations with the object of plotting a standard curve, and determining coefficients for use in conjunction with the standard curve in non-standard cases. Since the heating ratio depends upon $|\alpha h|$, n_a, β, and ψ, it is not possible to plot all the variables continuously. It was decided to investigate three angular widths of commutating zone, viz. 8°, 12° (standard), and 16° (counting the pole-pitch 180°). For each of these values calculations were made over a range of values of $|\alpha h|$ from 1 to 2, and over the usual practical range of values of coil-sides per layer (n_a) and commutating bars per pole.

An armature having 15 slots per pole and 45 commutator segments per pole, with a 12° commutating zone, has been adopted as a standard. The heating ratios for this case are given in Fig. 9.

For fixed values of slots per pole and coil-sides per layer (i.e. fixed values of n_a and ψ), the change in the heating ratio when changing from a commutating zone of 12° to one of 8° or 16° varies slightly with the value of $|\alpha h|$. This latter variation is so slight that mean values, weighted in favour of the commonest values of $|\alpha h|$, viz. 1·4 to 1·6, have been chosen and are given as coefficients in Fig. 11.

Heating ratio for slot $= K_0 = 2{\cdot}64 \times 8/\pi^2 =$ 2·14

The change in the heating ratio K_0, made by a given change in the values of n_a or ψ, is also small, and varies over the practical range between + 6 per cent and − 8 per cent approximately. Here again the change depends slightly on the value of $|\alpha h|$, and mean values, weighted in favour of the commonest values of $|\alpha h|$, have been chosen and are given as coefficients in Fig. 10.

A selection of the values of K_0 which have been calculated for full-pitch single-turn windings is given in Appendix III. It should be noted that these values do not appear in Figs. 9, 10, and 11. They are given to afford information of the extent to which the mean values adopted as coefficients in Figs. 10 and 11 are in error.

By the use of Figs. 9, 10, and 11, it is possible to find K_0, for any ordinary case, within 2 per cent of the computed value. In the more usual cases the error is generally much less than this. Two examples of the use of these curves are given below.

Whilst there is apparently no justification for highly accurate computations according to this method, since

* Reference should be made to the expression for K'_n at the end of Section (4).

† 15 slots per pole; 30 commutator segments per pole; 25 cycles; commutating zone 1/15th of pole-pitch; full-pitch single-turn winding. $h = 1{\cdot}9$ cm; $w_c/w_s = 0{\cdot}72$; $|\alpha| = 0{\cdot}193\sqrt{[25\times 0{\cdot}72]}$; hence $|\alpha h| = 1{\cdot}56$; $n_a = 2$; $2\psi = 6°$; $2\beta = 12°$.

the divergence from the truth may be appreciable, it is felt that the graphs of coefficients in Figs 10 and 11 are justifiable, on the ground that comparisons between alternative designs are possible. The degree of accuracy in comparison is probably very high relative to the degree of accuracy in absolute predetermination.

Examples of the Use of Figs. 9, 10, 11.

The buried winding investigated in Table 2 has a loss ratio of 2·14. To find the loss ratio from the curves in Figs. 9, 10, and 11, it is necessary to find a ratio from Fig. 9 and to multiply it by coefficients found from Figs. 10 and 11. Thus for $|\alpha h| = 1{\cdot}56$ the heating ratio $= 2{\cdot}112 \times 1{\cdot}014 \times 1 = 2{\cdot}14$.

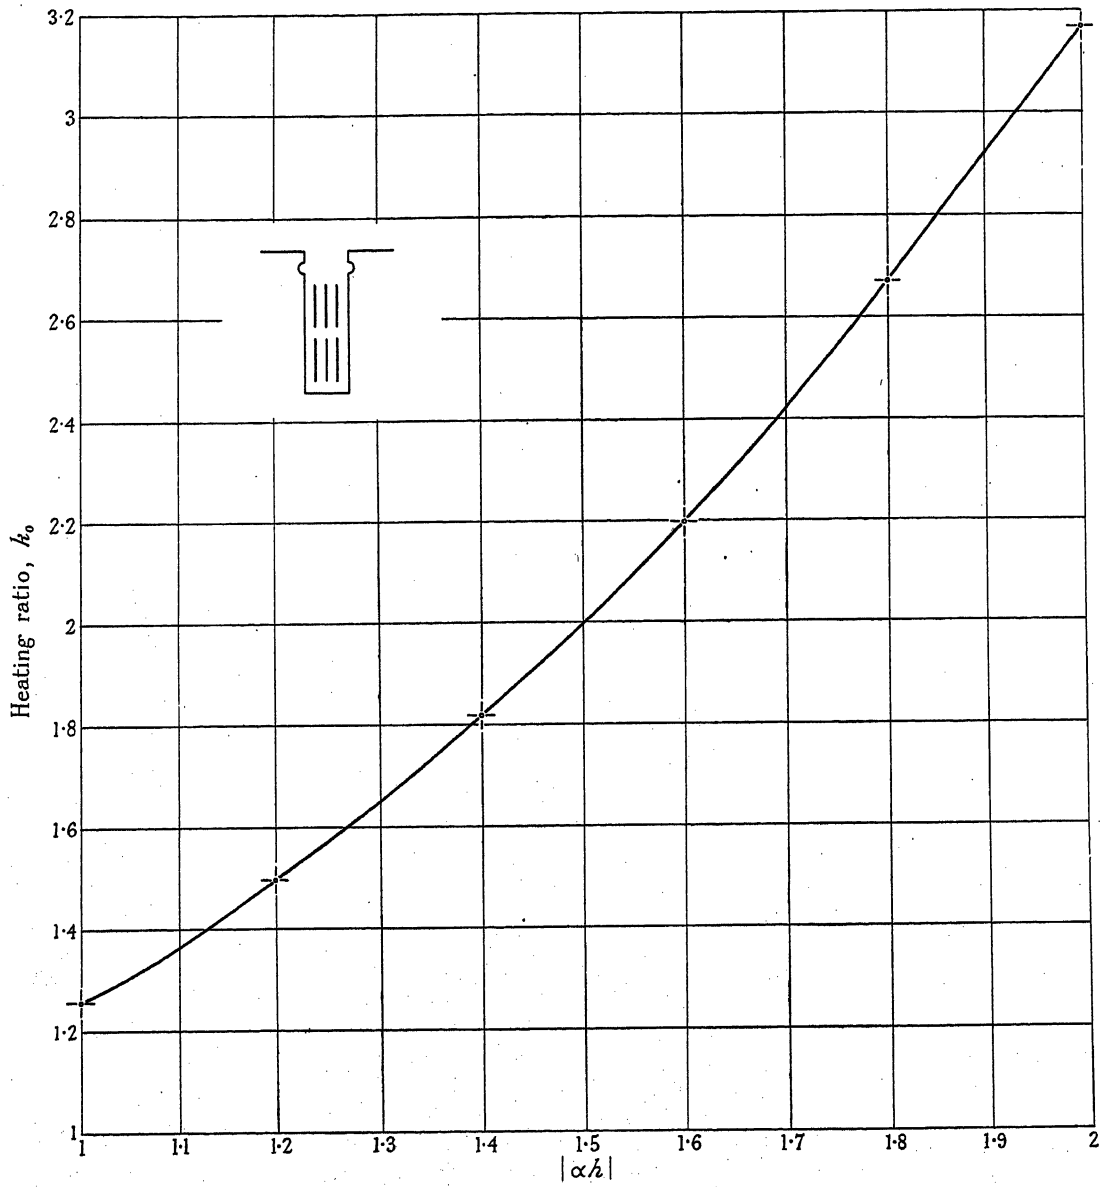

FIG. 9.—Heating ratio for the buried portion of the standard winding.

This curve applies to a full-pitch single-turn winding with 15 slots per pole, 3 coil-sides per layer, and a commutating zone 1/15th of the pole-pitch in width. For windings which differ from this, if still full-pitch and single-turn, multiply ratio by coefficients from Figs. 10 and 11.

$$|\alpha| = \sqrt{[8\pi^2 f w_c/(10^9 \rho w_s)]}$$

For copper $|\alpha| = a\sqrt{[f w_c/w_s]}$

where $a = 0{\cdot}193$ at 80° C.
$= 0{\cdot}187$ at 100° C.
$= 8{\cdot}42/\sqrt{(234{\cdot}5 + x^\circ \text{ C.})}$ at x° C.

As a further example, suppose it is desired to investigate a full-pitch single-turn winding having 12 slots per pole and 60 commutator bars per pole. Suppose the angular width of the commutating zone is 10°, and that $|\alpha h| = 1{\cdot}6$. Fig. 9 gives a ratio 2·198 for $|\alpha h| = 1{\cdot}6$; Fig. 10 gives 0·972; Fig. 11 gives, as an approximate

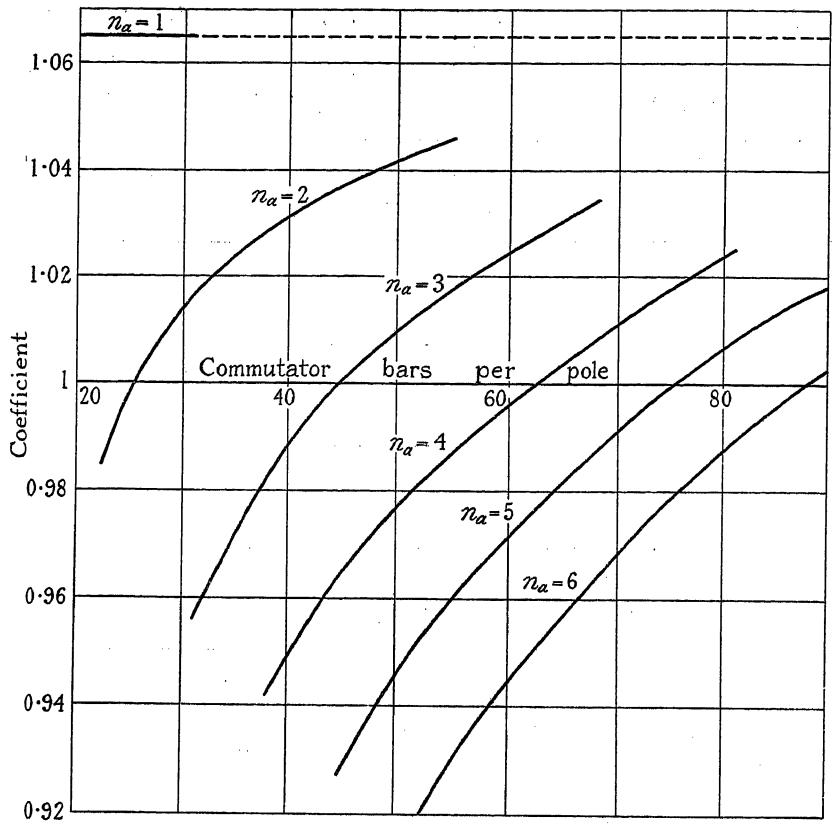

FIG. 10.—Coefficients to cover a change of n_a and commutator bars per pole from the standard of $n_a = 3$, and 45 bars per pole, i.e. 15 slots per pole.

Curves calculated for 12° commutating zone. For other zones multiply coefficient by one obtained with the aid of Fig. 11.

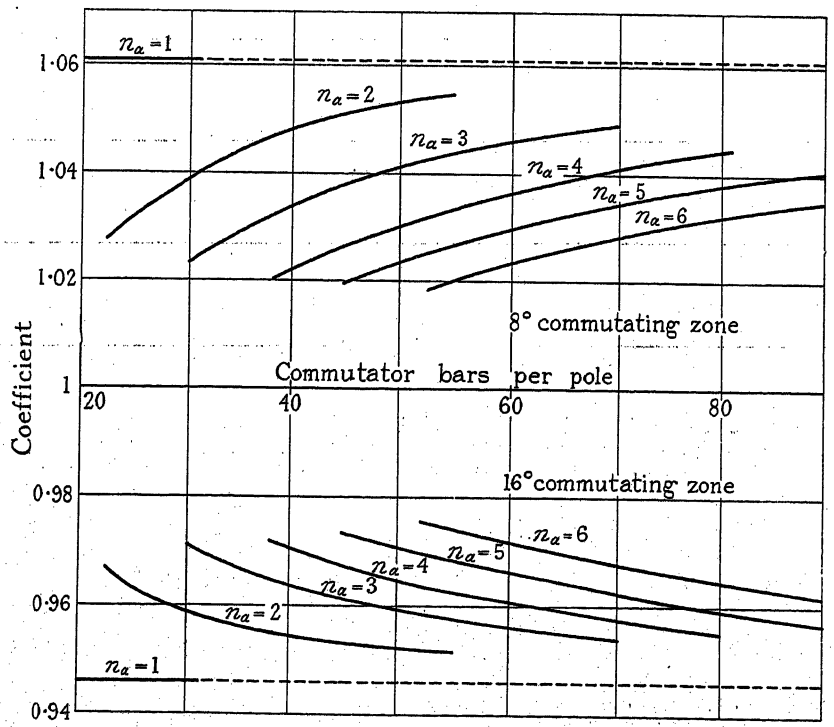

FIG. 11.—Coefficients to cover a change of commutating zone from the standard of 12°, to 8° and 16°.

interpolation, 1·015. The required ratio is thus 2·198 × 0·972 × 1·015 = 2·17. Detailed computation gives 2·16.

The Unequal Heating of Upper and Lower Layers in Single-Turn Windings.

As shown in Section (4), the heating of the lower layer of a single-turn winding depends on the function M_r, and that of the upper layer (if the winding has full-pitch) on the function $(M_r + 2N_r)$. The ratios already given are for mean slot heating, which depends on the function $(M_r + N_r)$, when all the conductors have the same size and carry the same current.

In any given case the calculations may be repeated, using values of the new functions, to obtain heating ratios for the two layers separately. This has been carried out for the standard case (15 slots per pole, 45 commutator bars per pole, commutating zone 1/15th of the pole-pitch), over the range $|ah| = 1$ to $|ah| = 2$, and a graph of the results is given in Fig. 12.

The graph shows that heating in the upper layer may

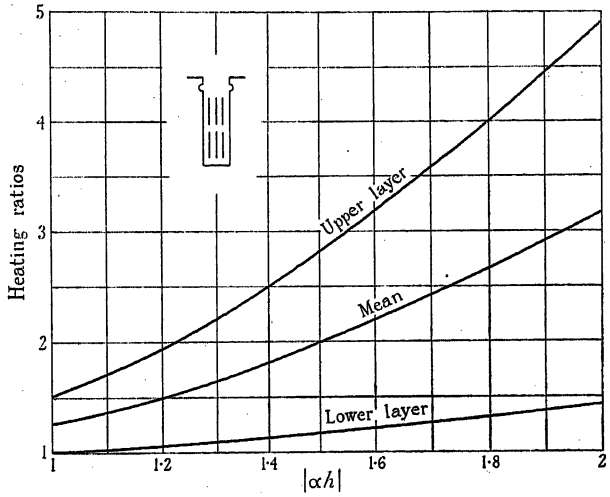

FIG. 12.—Heating ratios for the two layers separately, in the standard full-pitch single-turn winding.

Ratios calculated for a full-pitch single-turn winding, with 15 slots per pole, 3 coil-sides per layer, and a commutating zone 1/15th of the pole-pitch in width. The ratios differ slightly with differences in windings.

be severe, whilst that in the lower layer is never very much higher than that for uniform current distribution.

(6) The Heat Loss in Two-Turn Full-Pitch Windings.

The standard armature with 15 slots per pole, 45 commutator bars per pole, and a commutating zone of 1/15th of the pole-pitch, has been investigated for two-turn windings, over a range of $|ah| = 0·6$ to $|ah| = 1·2$. The results are given in Fig. 13, for each turn, for each layer, and for the whole slot.

The heating ratio for the top turn in the slot is high, and the extra heating for the whole of the buried winding is by no means negligible.

It will be observed that the heating ratios tend to values which fall below unity as $|ah|$ decreases. This depends on two causes. Firstly, a trapezoidal current wave is being calculated in terms of a uniformly distributed current of rectangular wave-form; thus, in the entire absence of any current displacement, the heating ratio would be $\left[1 - \frac{2}{3}(2\beta/\pi)\right]$, which is 0·9735, 0·9556, and 0·9408 for $2\beta = 8°$, 12°, 16° respectively. Secondly, the radial m.m.f. current component has been ignored; the heating due to this component is unknown, but in this treatment even the nominal loss due to it is omitted. The precise effect of the second cause is ascertainable in

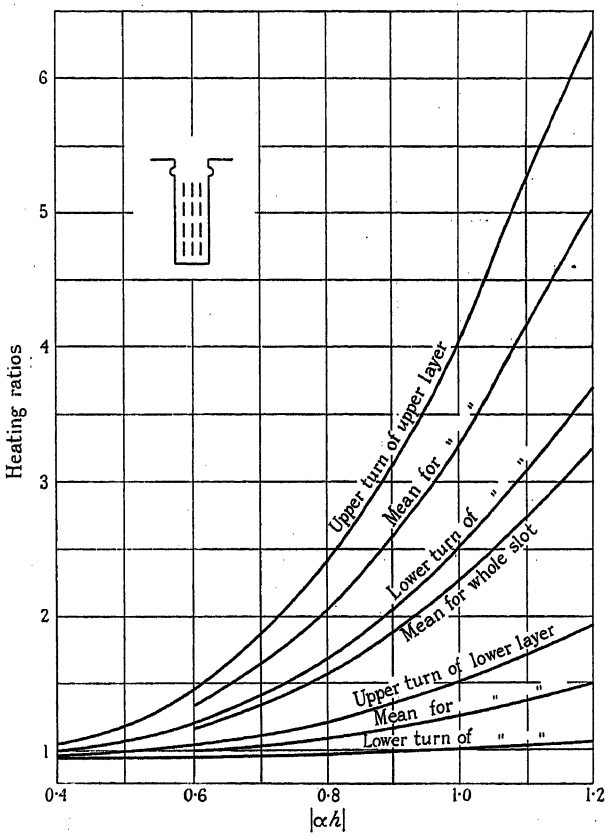

FIG. 13.—Heating ratios for the turns and layers separately, in the standard full-pitch two-turn winding.

Heating ratios for buried windings, calculated for a full-pitch 2-turn winding, with 15 slots per pole, 3 coil-sides per layer, and a commutating zone 1/15th of the pole-pitch in width. The ratios differ slightly with differences in windings.

any given case by repeating the calculation with only one coil-side per layer. This latter calculation in any case gives the maximum value of the heating ratio, and the true ratio must lie between the computed one and the maximum. That the maximum possible error is never more than a small one may be inferred from a study of Fig. 10.

The curve for the heating in the top turn shows a point of inflection, which is really a faint echo of the inflexion in the curve of the function N_r, since the former curve is a function of $(M_r + 12N_r)$.

(7) The Heat Loss in Three-Turn Full-Pitch Windings.

The armature which has been adopted as standard has again been investigated for three-turn full-pitch windings, over a range of $|ah| = 0·4$ to $|ah| = 0·7$. The

results are given in Fig. 14, for the top turn, for each layer, and for the whole slot.

Again the heating ratio for the top turn is high, and the extra heating for the whole of the buried winding is in no practical case negligible.

Single-, Two-, and Three-Turn Windings Compared.

If comparisons are made between single-, two-, and three-turn windings, with the same *total* depth of conducting material in the slot, there is certainly less extra loss the more the number of turns, over the practical range of $|\alpha h|$. The *extra* loss is very roughly inversely proportional to the number of turns.*

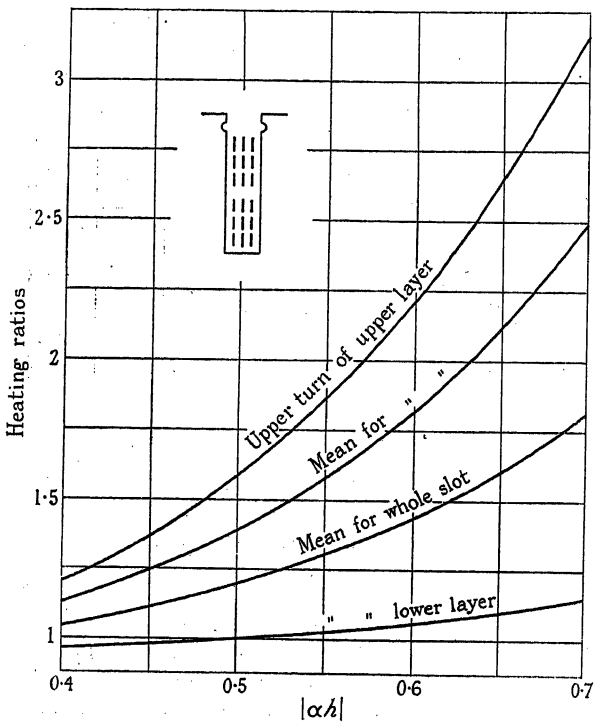

FIG. 14.—Heating ratios for the topmost turn and the two layers separately, in the standard full-pitch 3-turn winding.

Heating ratios for buried windings, calculated for a full-pitch 3-turn winding with 15 slots per pole, 3 coil-sides per layer, and a commutating zone 1/15th of the pole pitch in width. The ratios differ slightly with differences in windings.

(8) THE HEAT LOSS IN CHORDED WINDINGS.

The effect of chording a winding is to reduce the amount of extra heating due to current displacement. It will be seen from the expressions given in Section (4) that a difference in phase between two layers in a slot does not affect the heating of the lower layer, but reduces that of the upper layer.

Calculations have been made in the case of the standard armature with a single-turn winding, assuming three degrees of chording, viz. ½-slot, 1-slot, and 1½-slot chording. It is hoped that the results, which are given in Fig. 15, will afford some guide as to the effect of chording in the general case. The results are given in the form of percentage reductions of the heating ratio, in terms of the corresponding full-pitch winding.

(9) MINIMUM LOSS AND MINIMUM TEMPERATURE-RISE IN DIRECT-CURRENT WINDINGS.

Minimum Loss.

It is well known that in the case of windings which carry a sinusoidal current there is in every case a value of $|\alpha h|$ which results in the minimum loss in the buried portion of the winding. Thus if $|\alpha|$ is kept constant, and the height of the conductors is varied, there is a "critical conductor height" resulting in the minimum loss. Greater values of conductor height result in smaller nominal current densities, but disproportionately greater loss due to current displacement. The same phenomenon occurs in the windings of direct-current armatures.

If a direct-current armature winding is assumed to carry a given current, and the loss in the buried portion of the winding is investigated over a range of values of $|\alpha h|$, the minimum loss occurs when K_0/h is a minimum.* Assuming that $|\alpha|$ is not varied, the minimum loss occurs when $K_0/|\alpha h|$ is a minimum. In the case of the standard full-pitch single-turn winding (see Fig. 9) this occurs when $|\alpha h|$ is approximately equal to 1·1.

A more useful criterion, however, is the total loss. Assuming that the current displacement in the end windings is negligible, then for a ratio l_1/l of total length of winding to length of buried portion, the minimum total loss occurs when $\left[\left(\frac{l_1}{l}-1\right)+K_0\right]\Big/|\alpha h|$ is a minimum. The results given in Fig. 9 for the standard full-pitch single-turn winding have been used to find the value of $|\alpha h|$ corresponding to minimum loss, for various values of l_1/l. Fig. 16 shows the relation between the ratio l_1/l and the value of $|\alpha h|$ which gives minimum total loss. It should be observed that in all cases the "critical" value of $|\alpha h|$ is not very critical; a variation up to, say, 10 per cent does not, in general, increase the loss by more than a very small amount. Thus if l_1/l is 2·5, the minimum total loss occurs at $|\alpha h| = 1{\cdot}7$; at $|\alpha h| = 1{\cdot}5$ or 1·95 the total loss is only 1 per cent more than the minimum; at $|\alpha h| = 1{\cdot}2$ the total loss is 8 per cent more than the minimum, whilst the buried loss has almost its minimum value.

The data given in Figs. 12, 13, and 14 may similarly be used to find the condition for minimum buried loss or minimum total loss in the whole winding, or the upper layer, or the upper turn of the upper layer, in single-turn, two-turn, or three-turn windings.

In general, the most usual values of $|\alpha h|$ for modern direct-current machines are greater than those which give minimum *buried* loss, particularly in the windings near the mouths of the slots. The usual values of $|\alpha h|$ tend to be such that the total loss is not much greater than the minimum.

* On the basis of the above comparisons, it may be observed that the curves for mean heating in the slot tend to converge at high values of $|\alpha h|$. It can be shown that at values much above the normal practical limit, the single-turn arrangement actually gives *least* heating. The same phenomenon can, of course, be shown in the case of the alternating-current machine.

* The actual loss in one slot is $2K_0I_c^2n_c^2s_0l/(w_ch)$, where K_0 is the loss ratio for the slot, and l is the active length.

Minimum Temperature-Rise.

Just as there is a critical height of conductor for every winding, there is a height which gives a minimum temperature-rise in the buried winding. There is, in general, no connection between the two, and the height which corresponds to minimum temperature-rise is difficult to determine owing to uncertainty regarding the heat paths. The following approximations are put forward for what they are worth.

Assuming that all heat passes through the sides of a coil, and none through the top and the bottom and the ends, the temperature-rise is proportional to the watts dissipated per unit area of these surfaces, i.e. to K_0/h^2. If, in a given design, h is varied, the minimum temperature-rise occurs when $K_0/|\alpha h|^2$ is a minimum. In the case of the standard full-pitch single-turn winding this occurs at a high value of $|\alpha h|$ somewhat beyond the limit of the curve ($|\alpha h| = 2$). If an attempt is made to allow for other heat paths, it is probable that end conduction is roughly proportional to K_0 and so will have little effect on the optimum point; and the top and bottom paths can be approximately allowed for in a given normal case by adding a constant allowance. It is found that in this case the optimum value of $|\alpha h|$ is slightly less than that calculated on the first assumption, and appears to be in the neighbourhood of $|\alpha h| = 1 \cdot 8$ to 2 (depending on the allowance made for top and bottom heat paths, i.e. on the width of conductor material in the slot). Whilst it is clear that an appreciable variation of $|\alpha h|$ from the optimum value would not increase the temperature-rise to a marked degree, it is probable that an investigation based on more complete knowledge of the problem would result in theoretical optimum values corresponding to the usual practical values of $|\alpha h|$.*

(10) The Use of Unequal Sections in the Conductors of the Upper and Lower Layers.

It is not practicable to use different heights of conductor in the two layers of multi-turn windings. In single-turn windings, however, there are two methods of arranging this:—

(1) A bar of the larger section is used, and the active portion of the upper layer of each coil is milled to a smaller height. This method results in a large section in the end-connections.

(2) Each coil is jointed at the end remote from the commutator, the two halves of the coil having different conductor heights. This method allows fractional-slot chording, but increases the heating in one half of the end-windings.

Whichever method is used, the heat produced in the space available for conductor material within the slot is

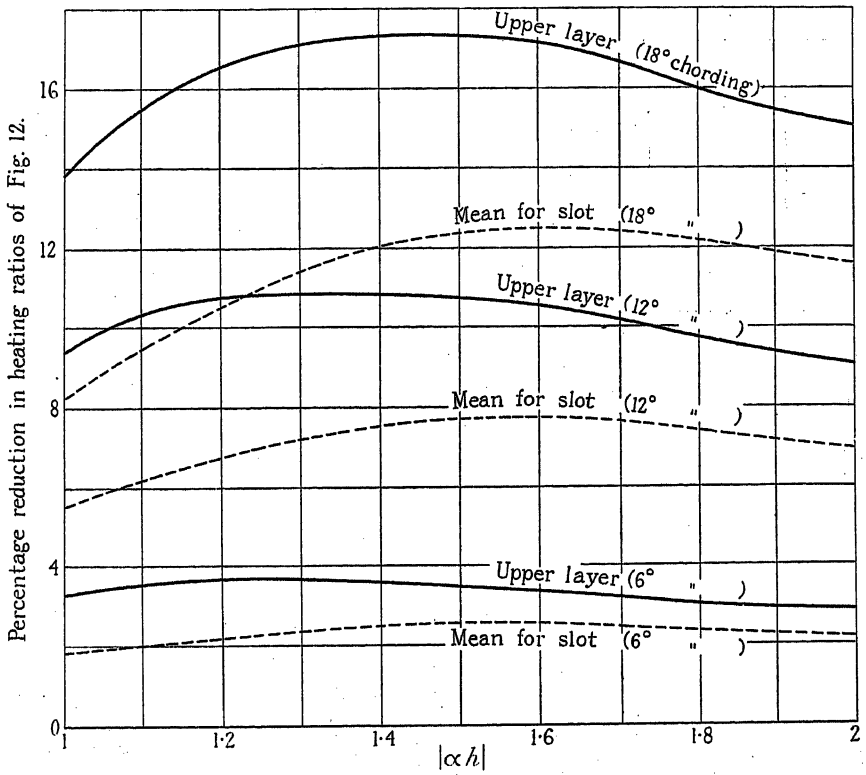

Fig. 15.—Effect of chording the standard single-turn winding by ½, 1, and 1½ slots, in terms of the corresponding full-pitch winding.

Effect of chording the standard single-turn winding (15 slots per pole, 3 coil-sides per payer, commutating zone 1/15th of the pole-pitch in width). Upper layer heating reduced; lower layer not affected.

* An analysis of a number of modern machines with single-turn windings reveals that the value of $|\alpha h|$ is usually in the neighbourhood of 1·5 to 1·6. There are, however, a few examples of values up to 2.

reduced by using a small conductor height for the upper layer, and a large one for the lower layer.

If various arrangements are tried in a fixed available space, it is found that the total heat produced in the slot is gradually reduced as the height of the lower layer is increased at the expense of the upper layer. This is illustrated by the example worked out in Table 3; the case chosen is a full-pitch single-turn winding with two conductors per slot, each conductor being initially 1·9 cm high, with $|\alpha h| = 1{\cdot}6$. The heights are varied, keeping the height of both layers together at 3·8 cm; that is, the mean value of $|\alpha h|$ remains at 1·6. Heating ratios are read from Fig. 12; the heating relative to the nominal I_c^2R loss in a conductor 1·9 cm high is obtained by multiplying each heating ratio by (1·9 ÷ new height). All heating ratios are given to two figures.

If it is assumed that, instead of a reduction in heating, the rating is increased so as to keep the total buried heating loss constant, the effect of varying the conductor heights is shown in Table 4.

TABLE 3.

Effect on the Heating of Variation in Height of Layers, the Total Height being kept Constant at 3·8 cm.

Lower layer				Upper layer				Mean relative heating
Depth	$\lvert\alpha h\rvert$	Heating ratio	Relative heating*	Depth	$\lvert\alpha h\rvert$	Heating ratio	Relative heating*	
cm				cm				
1·9	1·6	1·22	1·22	1·9	1·6	3·18	3·18	2·20
2·0	1·685	1·26	1·20	1·8	1·515	2·88	3·04	2·12
2·1	1·769	1·3	1·18	1·7	1·431	2·60	2·91	2·04
2·2	1·853	1·35	1·17	1·6	1·348	2·33	2·77	1·97
2·3	1·938	1·41	1·16	1·5	1·263	2·10	2·66	1·91
2·4	2·021	1·45	1·15	1·4	1·179	1·89	2·57	1·86
2·5	2·105	1·5	1·14	1·3	1·094	1·70	2·49	1·81
2·6	2·188	1·55	1·13	1·2	1·01	1·53	2·42	1·77

* Relative heating = heating ratio × (1·9 ÷ new height).

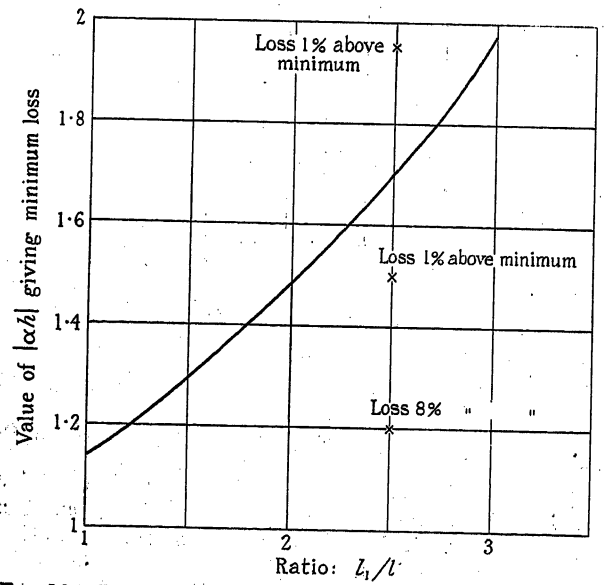

FIG. 16.—Relation between l_1/l (total length ÷ active length) and the value of $|\alpha h|$ which gives the minimum total loss. Based on the standard full-pitch single-turn winding (see Fig. 9).

There is normally a considerable disparity between the heat produced per unit height of conductor in the two layers. Table 4 shows that this disparity is increased when the conductor space is re-divided in an attempt to increase the rating. It is clear that an increase in temperature-rise is inevitable in the upper layer, except in so far as heat can flow to the cooler lower layer, or out to the end-connections. It is therefore essential to investigate the conditions in the end connections.

TABLE 4.

Effect on the Rating of Variation in Height of Layers, the Total Height being kept Constant at 3·8 cm, and the Total Buried Loss being also Constant.

Distance of division between layers above normal position	Lower layer		Upper layer		Rating
	Depth	Relative heating	Depth	Relative heating	
mm	cm		cm		
0	1·9	1·22	1·9	3·18	1·0
1	2·0	1·24	1·8	3·15	1·018
2	2·1	1·26	1·7	3·11	1·035
3	2·2	1·30	1·6	3·08	1·055
4	2·3	1·33	1·5	3·06	1·07
5	2·4	1·36	1·4	3·03	1·085
6	2·5	1·38	1·3	3·01	1·1
7	2·6	1·4	1·2	3·0	1·11

The above case has been investigated in regard to the end connections, but details are not given here. The following facts emerge, assuming constant total buried loss:—

(1) The method which involves the use of bars of large

section, milled down in part, enables the rating to be increased, whilst the total loss actually decreases slightly. The low current densities in the end windings facilitate the flow of heat from the buried windings. The *extra* weight of conductor material needed for a given winding is relatively greater than the increased rating obtainable, in practical cases.

(2) The method involving the use of end connections of the same section as the bars in the slots results in higher current densities in the windings connected to the upper layer. This restricts the flow of heat from the slots, and may, unless the end windings are normally very cool, reduce or nullify the possible increase in rating. The total loss is increased almost to the same extent as the rating, i.e. the loss in the end windings is considerably increased.

It would appear that, apart from the question of cost, the use of different conductor heights in the two layers and the end windings (by butt-welding of bars) is necessary in order to secure maximum rating and maximum economy of material.*

ACKNOWLEDGMENT.

The author desires to record his indebtedness to Dr. A. E. Clayton, Member. This paper is the outcome of a conversation in which Dr. Clayton suggested the usefulness of such an investigation. He has followed its progress, and has from time to time made a number of valuable suggestions.

BIBLIOGRAPHY.

It is believed that the following bibliography is fairly complete to the end of 1930.† All the papers, known to the author, which deal with the phenomenon of current displacement in slot-wound conductors at power frequencies, are included. The first and larger section comprises matter which is wholly or mainly concerned with sinusoidal current wave-forms. The second section comprises matter which deals with the problem of the direct-current machine.

Kennelly's "Tables of Complex Hyperbolic and Circular Functions," being obtained in the form $a\angle\theta$. The resultants of the expressions in brackets are obtained in the same form, for each of the eleven harmonics considered. Each value is then multiplied by the appropriate value of $\left(\frac{4}{\pi}\cdot\frac{\sin n\beta}{n^2\beta}\sqrt{nah}\right)$, giving the quantities shown in Table 5.

To compute the current density at any level, and at any instant relative to the instant of zero nominal current density, necessitates the summation of the instantaneous current densities for the various harmonics. Each of these latter is obtained by multiplying the argument given in Table 5 by the sine of the angle $(n\theta + \phi_5)$, where ϕ_5 is taken from Table 5, and θ is the angle representing the chosen instant (see Fig. 8). Table 6 shows the calculation of the current density for the instant $\theta = 3°$ for levels 1 and 6 (see Figs. 6 and 8).

APPENDIX II.

Calculated Values of M_r and N_r.

In Section (4) it is stated that heating ratios and reactive power ratios can be expressed as functions of **M** and **N**, where

$$\mathbf{M} = ah\coth ah = M_r + jM_x$$
$$\mathbf{N} = 2ah\tanh \tfrac{1}{2}ah = N_r + jN_x$$

The coth and tanh functions of so-called "semi-imaginaries" are tabled in Kennelly's "Tables of Complex Hyperbolic and Circular Functions" and from these **M** and **N** may be derived in the form $a\angle\theta$. The real parts of these values are values of M_r and N_r. Table 7

Table 7.

Values of M_r and N_r (see Section 4).

$\lvert ah\rvert$	M_r	N_r	$\lvert ah\rvert$	M_r	N_r

	1·6	2·283	2·227	2·152	2·198	2·088	2·12	2·036
	1·8	2·76	2·698	2·605	2·67	2·534	2·574	2·47
	2	3·274	3·199	3·107	3·168	3·02	3·07	2·947
$2\beta = 16°$	1	1·247	1·227	1·198	1·213	1·175	1·188	1·15
	1·2	1·489	1·461	1·425	1·44	1·39	1·409	1·36
	1·4	1·789	1·75	1·708	1·741	1·661	1·687	1·625
	1·6	2·178	2·135	2·082	2·107	2·026	2·056	1·984
	1·8	2·633	2·59	2·525	2·572	2·463	2·497	2·413
	2	3·139	3·084	3·012	3·058	2·941	2·98	2·892

Each value has been calculated according to the method demonstrated in Table 2. The calculations were carried out until the terms in the last column of Table 2 dwindled to less than 0·001, this stage being variously reached at from the 13th to the 27th harmonic.

The values of K_0 obtained by using Fig. 9, and the mean coefficients given in Figs. 10 and 11, do not correspond to the calculated values of K_0. The divergence is never great, and a study of these values, in conjunction with results obtained from the curves, will show that the method of adopting mean coefficients is justifiable.

The term "bars per pole" in Table 8 refers to the number of commutator bars or segments between adjacent brush arms.

INSTITUTION NOTES.

Nominations for Election to the Council.

In addition to those members nominated by the Council (see page 143) the following have been nominated for ballot as Ordinary Members of Council:—

A. P. M. FLEMING, C.B.E., M.Sc. [Nominated by B. A. G. Churcher, A. G. Ellis, G. A. Juhlin, H. C. Lamb, H. Pearce, B.Sc.(Eng.), J. S. Peck, J. A. Robertson, Prof. S. Parker Smith, D.Sc., Prof. Miles Walker, D.Sc., F.R.S., and E. B. Wedmore.]

Sir ARNOLD B. GRIDLEY, K.B.E. (Nominated by C. O. Brettelle, Sir James Devonshire, K.B.E., H. Hobson, W. W. Lackie, C.B.E., J. Leggat, Colonel B. C. Lockhart-Jervis, D.S.O., R.E., Colonel T. H. Minshall, D.S.O., R. Nelson, A. M. Sillar, and Johnstone Wright.)

J. W. THOMAS, LL.B., B.Sc.Tech. (Nominated by E. Fawssett, J. Frith, M.Sc., P. B. Hall, T. E. Herbert, A. B. Mallinson, J. H. Parker, G. G. L. Preece, G. F. Sills, H. C. Turner, and J. N. Waite.)

Proceedings of the Wireless Section.

96TH MEETING OF THE WIRELESS SECTION, 24TH FEBRUARY, 1932.

Col. A. S. Angwin, D.S.O., M.C., B.Sc.(Eng.), Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting held on the 3rd February, 1932, were taken as read and were confirmed and signed.

A general discussion took place on the subject of "The Selectivity of Broadcast Receivers" (see page 103), with an introductory paper (see page 102) by Prof. C. L. Fortescue, O.B.E., M.A.

The meeting terminated at 8.35 p.m. with a vote of thanks to Prof. Fortescue for his introductory remarks, which was moved by the chairman and carried with acclamation.

97TH MEETING OF THE WIRELESS SECTION, 2ND MARCH, 1932.

Mr. L. B. Turner, M.A., Vice-Chairman of the Section, took the chair at 6 p.m.

The minutes of the meeting held on the 24th February, 1932, were taken as read and were confirmed and signed.

A paper by Mr. H. A. Thomas, M.Sc., Associate Member, entitled "Developments in the Testing of Radio Receivers" (see page 114), was read and discussed.

The meeting terminated at 7.45 p.m. with a vote of thanks to the author, which was moved by the chairman and carried with acclamation.

Elections and Transfers of Members.

At the Ordinary Meeting held on the 17th March, 1932, the following elections and transfers were effected:—

ELECTIONS.

Associate Members.

Bingham, John Merton.
Booth, Charles Frederick.
Clark, John, B.Sc.
Foster, Joseph Edward.
Smithers, Fred Aubrey.
Sweetlove, James Arthur, B.Sc.Tech.

Companion.

Haslett, Caroline Harriett (Miss), C.B.E.

Associates.

Armstrong, William Thos.
Brack, Herbert Marson.
Branson, James Watson.
Hall, Harold.
Large, Arthur Leslie.
MacKellar, Clifford Edmond, Major, R.A.(T.A.).
Young, James Alexander.

Graduates.

Blackwell, Alfred.
Boag, David James W.
Bray, Victor Henry.
Burch, James Thomas.
Douglas, Archibald Perry, B.E., B.Sc.
Douglas, Thomas Armitage.
Emanuel, Maurice Ranald, B.E., B.Sc.
Evans, Emlyn Rees, B.Sc.
Gale, William Edward J. R. B.
Green, Cecil.
Hammerton, Herbert Reginald.
Hancock, Jeffrey.
Hancox, Leonard John.
Haslewood, Francis Dering.
Jones, Philo Lawton.
Lewis, Norman William J., B.Sc. (Eng.).
Lonsdale, Robert.
Lugg, John Victor.
Marsh, Thomas Eric Eaton.
Perkins, Brian Lea, B.Sc. (Eng.).
Pringle, Robert William.
Probert, Gilbert Ambrose.
Rafi, Mian Mohammad.
Rowe, Alan Henry R.
Stott, Arnold.
Tappin, Launcelot Ponton, M.Sc.

Graduates—continued.

Thomas, Evan David, B.Sc.
Thurston, Albert Peter, D.Sc.
Waine, Ian Leslie.
Wakefield, Kevin Stuart.
Weir, William, B.A.
Whitwam, Thomas Cotton.

Students.

Woodforde, John.

METAL-CLAD SWITCHGEAR, AUTOMATIC PROTECTION, AND REMOTE CONTROL, WITH PARTICULAR REFERENCE TO DEVELOPMENTS DURING THE LAST SEVEN YEARS.

By H. W. CLOTHIER, Member.

(*Paper first received 2nd November, and in final form 19th December,* 1931; *read before* THE INSTITUTION *25th February and 3rd March, before the* TEES-SIDE-SUB-CENTRE *17th February, before the* NORTH-EASTERN CENTRE *22nd February, before the* NORTH-WESTERN CENTRE *23rd February, and before the* DUNDEE SUB-CENTRE *10th March,* 1932.)

SUMMARY.

This paper outlines a picture of the progress during the last seven years in the field it deals with, and also sets out the problems of to-day and the lines of possible future practice. The period under review has seen a change of national policy in Great Britain, which practically puts an end to isolated plants for public service, and enhances the scope for economy by the running of the largest plants with interconnections between them and all other plants and loads. New conditions therefore arise, demanding a reconsideration of the problems dealt with by the author in their earlier form in 1925.

The construction of the various types of metal-clad switchgear is diagrammatically represented by illustrations brought up to date and concluding with a forecast of the full application of the principle of complete enclosure and immersion of all conductors and insulators for all voltages as the means of safeguarding life and property, and securing continuity of supply.

Certain basic constructional features are dealt with more fully. These are, in general, typical of changes, some brought about by research and practical experience, and others evolved in the quest by designers for something "different" in a period of intensified competition. An attempt is made to classify the prevalent forms of arcing contacts and busbar enclosures, and to state the effects of such details, particularly of the latter, on the general lay-out of the whole switching equipment.

The use of metal-clad switchgear has of itself effected such economy in buildings that outdoor switchgear has not been widely used in Great Britain; but reasons are given in favour of outdoor construction.

A review is given of the present position of rating, performance, and selection of circuit breakers, in order to lead up to a better understanding of the interpretation of these terms, and in view of the need for an international agreement on standard conditions for assessing ratings. Results of tests in a British 1 500 000-kVA testing station are recorded as examples.

The need for economy is accepted as a fundamental object for the designer, but it should be effected by the reduction of components rather than by lowering the quality of details. Some ways and means of effecting economy along these lines are therefore proposed.

The automatic isolation of faults has a particular bearing on the protection of property and supply; in the latter its performance in procuring stability is considered to be of paramount importance, and in the former its speed of operation is a criterion of equal merit. In the light of these principles the known protective systems are reviewed, and some new developments are mentioned. This study is in the main a history of the quest of the ideal, which, for the sake of economy alone, excludes the pilot cables of the earlier systems, and thus an opening occurs for the use of telephone pairs. Some original research is recorded for the avoidance of interference with the other uses of such telephone conductors arising from accidents on main lines. Further, the resistance of heavy arcs has been experimentally ascertained, with a view to making clear the necessity of using reactance instead of impedance as the true means of measuring distance for the accurate location and discrimination of faults in the distance types of protection.

The evolution of automatic and remote-control systems is traced from the earlier power-station control-room to the present-day design of regional control from a central room, and the forecast for the future favours the increasing application of mechanical principles, which in the first place tends to avoid errors, and in the second place takes over the responsibility of action in an emergency.

TABLE OF CONTENTS.

(1) Introduction.
(2) Switchgear Construction.
- (i) General.
- (ii) Classification.
- (iii) Innovations.

Appendix III. Reactance versus Impedance Measurements for Distance Relays.

Appendix IV. The Safeguarding of Post-Office Pilots associated with Power Networks.

(1) INTRODUCTION.

In a paper read by the author before the Institution in 1925, an attempt was made to record the then established state of the design of metal-clad enclosure, protective systems, and control, especially in relation to the avoidance of shock and fire, and the maintenance of continuity of supply. It is proposed now to review the present position (thus completing a continuous series* —1902, 1910, 1925, 1932), with particular reference to the developments during the last seven years, under three main headings, namely:—

Switchgear Construction.
Automatic Isolation of Faults.
Remote and Automatic Control.

(2) SWITCHGEAR CONSTRUCTION.

(i) *General.*

An increasing demand, accelerated by the Electricity Act of 1926, has given an impetus to initiative in design. New service conditions have brought about the evolution of units of larger capacity to work at higher

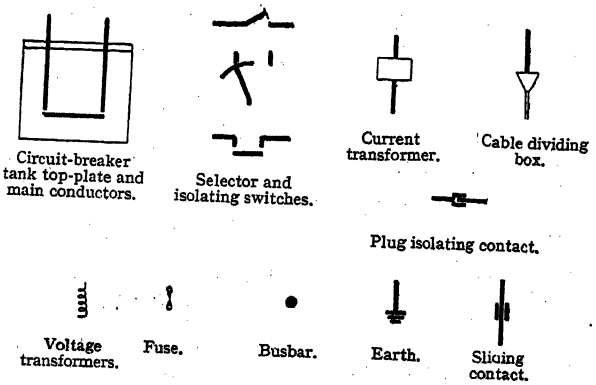

FIG. 1.—Symbols for component parts of diagrams.

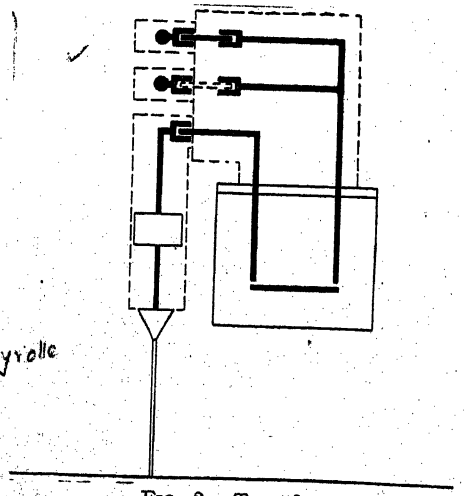

FIG. 2.—Type 1*a*.

In 1925, metal-clad practice was well established in Great Britain; now it is accepted as the normal rule. It is advancing in America, and has obtained a foothold on the Continent.

The need for the avoidance of all chance of the spreading of arcs and consequent fire, leading to possible failures of supply, has brought about an enlarged demand for high quality in constructional details. This

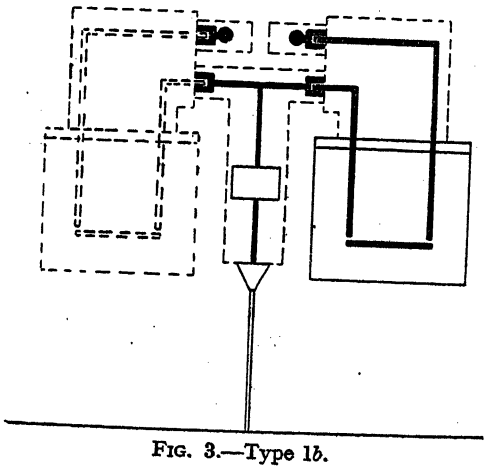

FIG. 3.—Type 1*b*.

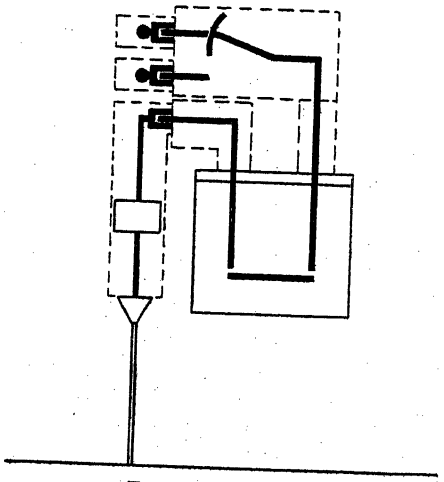

FIG. 4.—Type 1*c*.

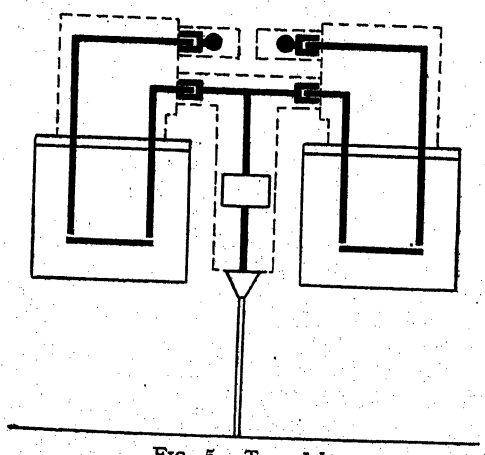

FIG. 5.—Type 1*d*.

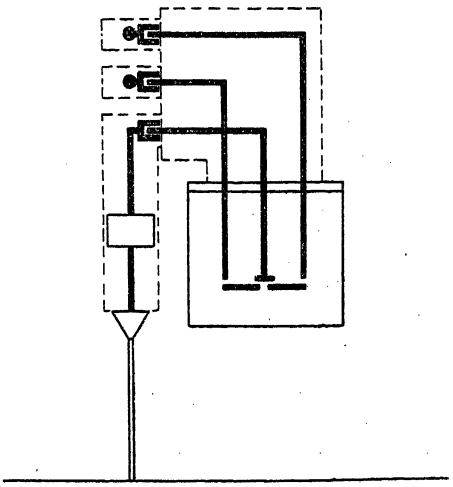

FIG. 6.—Type 1*e*.

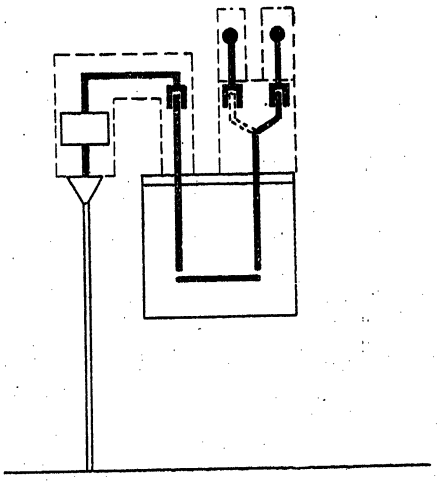

FIG. 7.—Type 2*a* (Railing and Garrard).

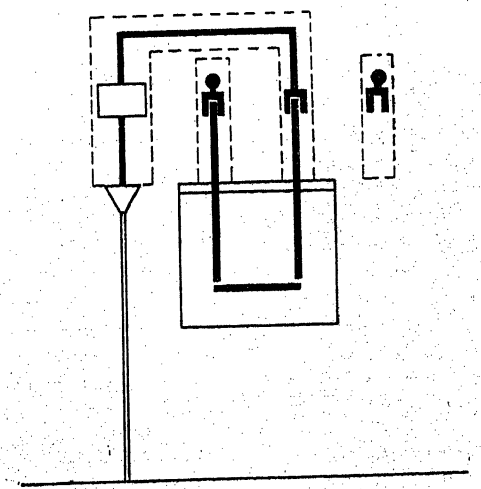

FIG. 8.—Type 2*b*.

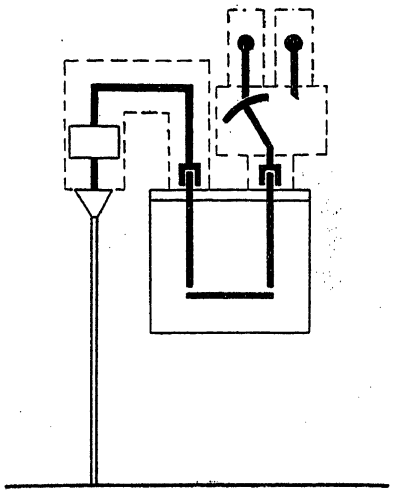

FIG. 9.—Type 2*c*.

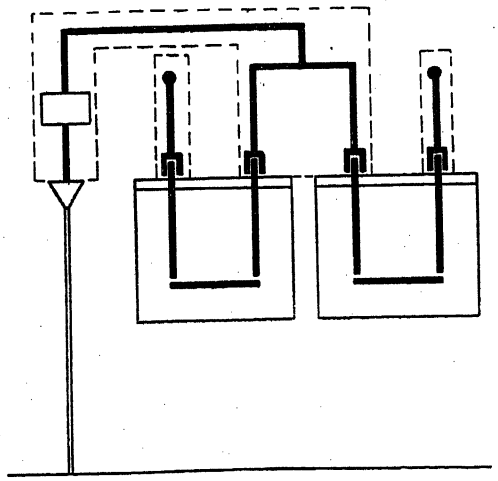

FIG. 10.—Type 2*d*.

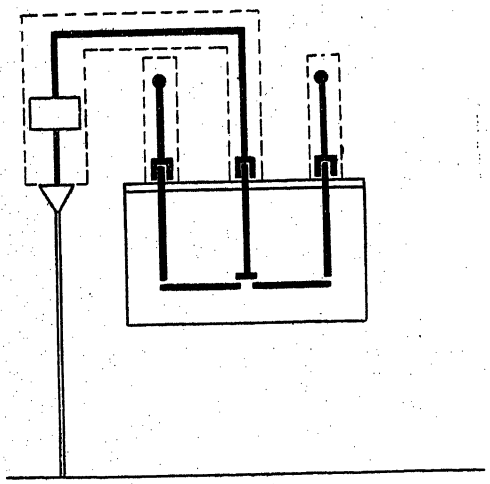

FIG. 11.—Type 2*e* (Ferguson, Pailin Ltd.).

in general has given designers more scope for competition in solidity, and has helped to establish a policy of economy-in-the-long-run in preference to cheeseparing in the initial cost of plant. Economy has been sought in floor space and in housing, rather than in crucial circuit-breaking components.

(ii) Classification.

Figs. 1 to 15 indicate the variety of arrangements, and give a comparative view of the disposition of the main

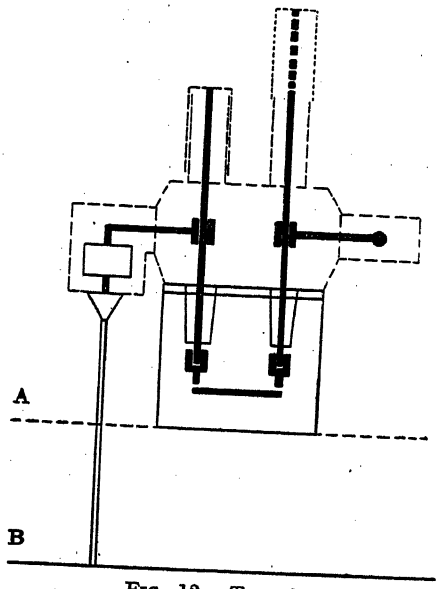

FIG. 12.—Type 3*a*.
A and B.—Alternative floor-levels.

components, namely, busbars (single and duplicate), circuit breakers, current transformers, isolating and selector devices, and cable sealing boxes. The several types of metal-clad switchgear may be divided into three

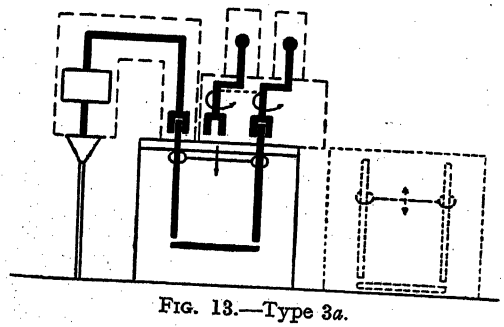

FIG. 13.—Type 3*a*.

generic classes, according to the method of isolation, namely:—

(1) Horizontal draw-out.
(2) Vertical drop-down.
(3) Internal switch and/or internal plug.

Isolation is effected in the first two classes by the drawing-out and the dropping-down respectively of the circuit breaker, but in the third there are separate isolating devices, and the removable portion need only be moved for inspection or maintenance.

These three classes are capable of subdivision into types, according to the method of busbar selection, as follows:—

(*a*) Change-over plugs.
(*b*) Circuit-breaker transference.
(*c*) Change-over switch.
(*d*) Duplicate circuit-breaker.
(*e*) Double-contact circuit-breaker.

(iii) Innovations.

The line diagrams are intended to outline all the varieties of metal-clad switchgear in an elementary way. They are arranged in order of types within the three classes, and it may be useful to point out some of the innovations.

The proposal to use the upward vertical movement of

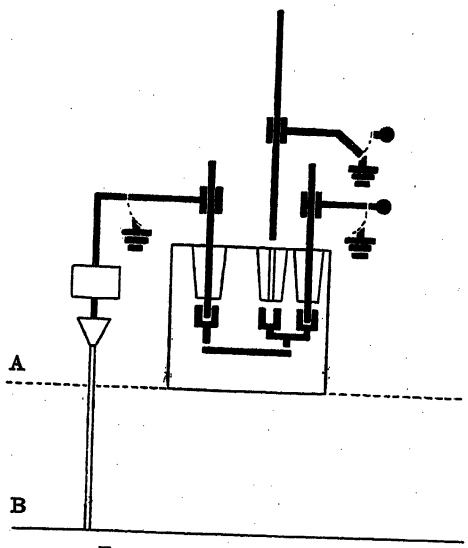

FIG. 14.—Type 3 (*a* and *c*).
A and B.—Alternative floor-levels.

a central fitting for isolating is not new. Its origin was for heavy high-voltage switchgear, in which the circuit breaker was to be stationary* (Fig. 12, Type 3*a*); but it has now been developed in a form† shown diagrammatically in Fig. 13 (Type 3*a*), and in more detail in Fig. 16, wherein the vertical movement is downwards. It has been used in this way for small units in combination with some of the draw-out characteristics of both the horizontal and the vertical metal-clad forms. The circuit breaker itself may rest on the ground and be removed horizontally for inspection. On the other hand, the fixed orifice insulators are vertical, and isolation is effected by a downward movement within the tank of a framework carrying the entire circuit-breaker terminals and contacts. It has, therefore, the advantage over the usual vertical drop-down switchgear that there is no lifting and lowering of a heavy weight for isolating; but the design is such that the top has to be hinged or otherwise lifted for inspection of oil and contacts. Fig. 44 also shows a variety of this means of isolating, in

* The author. † Whitehead (Switchgear and Cowans, Ltd.).

which the isolating contacts automatically open with the opening of the main contacts.

Fig. 10 shows a drop-down development (Type 2*d*) that has been used in British and American practice for large installations. In Great Britain also the same type has been installed for 66 000-volt service (Fig. 17). It will be

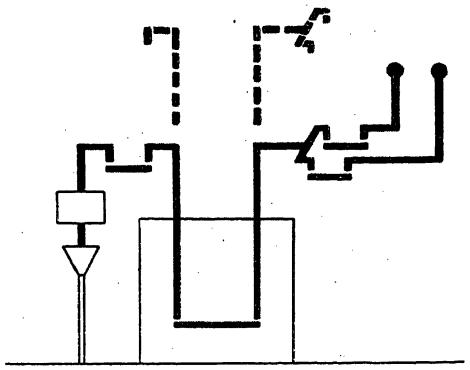

FIG. 15.—Type 3*c*.

referred to again in Section (2)(x), which deals with disposition of busbars and phase separation.

Fig. 18 shows an alternative method in which the circuit is changed over to a transfer busbar in order to avoid the use of a duplicate circuit-breaker for each unit. The connection to the transfer busbar is effected by means of a switch in an oil tank, which also encloses the earthing contacts. This method has been used* in

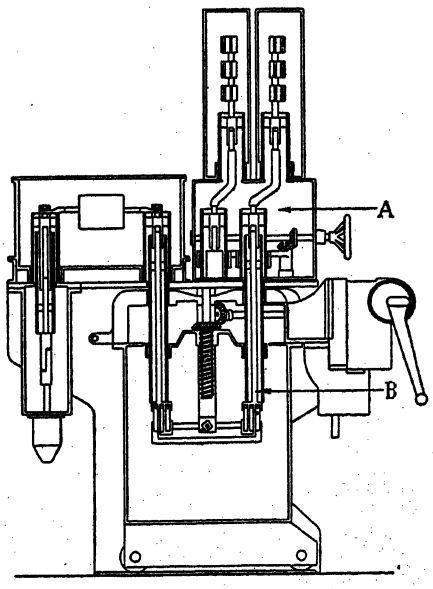

FIG. 16.

A.—Change-over plug receptacles.
B.—Central fitting, movable downwards with circuit breaker open.

switchgear designed and laid down in the factory in 1927–28 for 37 000 volts, and with a breaking capacity of 1 000 000 kVA. The actual processes of isolating and transporting the circuit breakers are facilitated by the use of motor-operated portable trucks.

Fig. 19 illustrates the principle as applied to the

* Allis-Chalmers/Reyrolle.

smaller horizontal-draw-out classes of switchgear. An alternative (Fig. 20), which has been applied for Scandinavian practice, occupies less floor space and indicates another way of earthing the feeder.

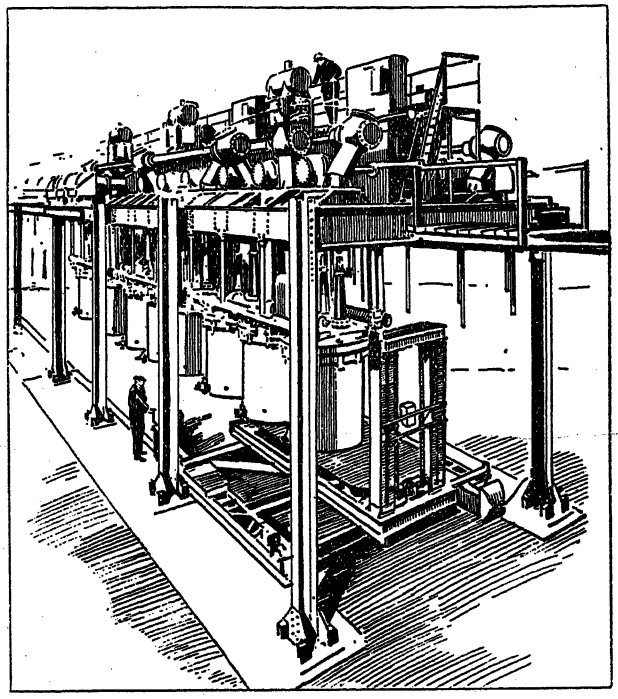

FIG. 17.

Figs. 14 and 21 [Type 3(*a* and *c*)] show a further development* of Fig. 12 for 66 000-volt designs, opening the way to the metal-clad enclosure of even heavier switchgear.

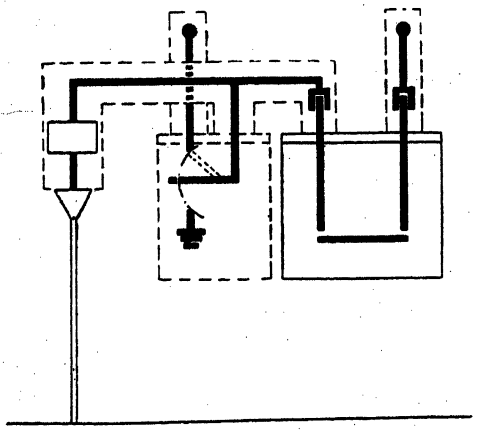

FIG. 18.—Type 2*c* Special (transfer busbar).

(*iv*) *Oil-tight Joints.*

Figs. 19 and 20 show an example of a change in a detail of construction. The creepage of oil through the smallest conceivable opening made it formerly a maxim of good practice to avoid joints under oil. For instance,

* The author, Allan, and Christie.

in the ordinary tank-type circuit breaker the conductors passed into the oil from the top. Modern requirements produce situations in an assembly where conductors and

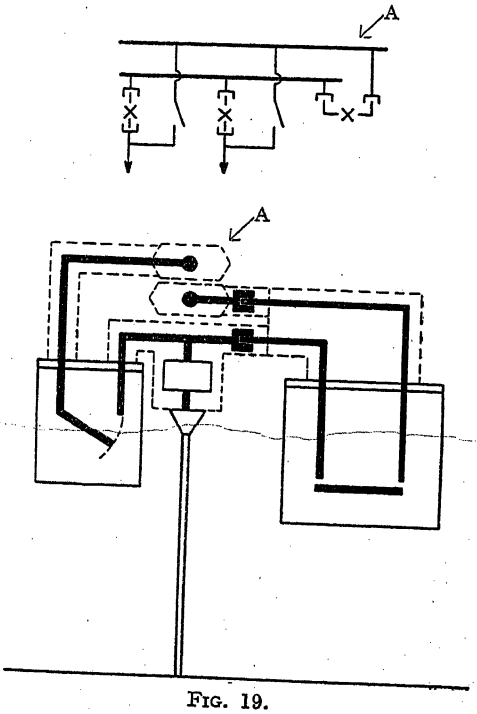

FIG. 19.
A.—Transfer busbar.

insulators must pass through the sides or bottoms of oil-filled enclosures. Cements fail owing to constant changes in the relative dimensions of conducting and

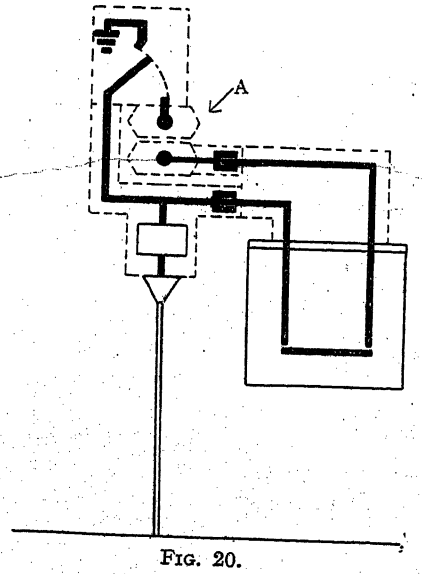

FIG. 20.
A.—Transfer busbar.

insulating materials caused by the differences between the expansion and contraction of the several materials with temperature variations. Moreover, most cements are apt to deteriorate either from contact with oil or from being subjected to high temperature. For these reasons the mechanical joint has of recent years found a more prominent place as an essential detail for securing high quality. Fig. 19 shows the oil-immersed transfer-switch with conductors passing through the top, whereas Fig. 20 illustrates the corresponding conductors passing through the bottom. The mechanical method of securing the oil, and the joint between a porcelain

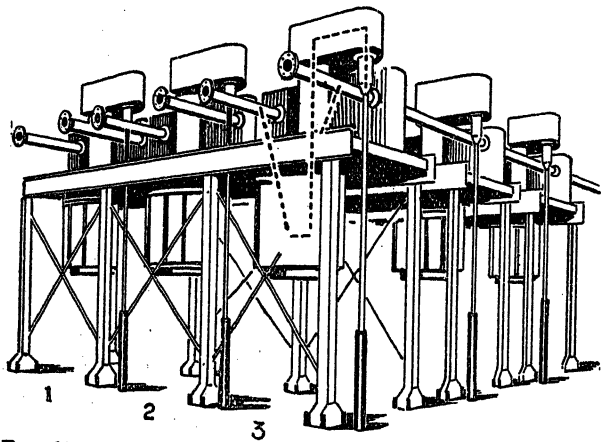

FIG. 21.—Type 3 (*a* and *c*), with switches for isolating, earthing, and change-over, and with vertical removal of circuit breaker.

insulator on the one hand, and the conductor and the metal enclosure on the other, are shown in Fig. 22. When bakelite insulators are used, it is equally necessary to take precautions by appropriate means against leakage.

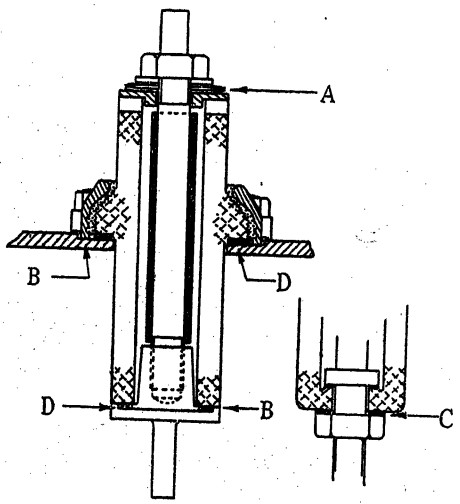

FIG. 22.
A.—Spring washer compensating for expansion
B.—Machined surfaces.
C.—Alternative joint.
D.—Packing.

(*v*) *Transformer Accessibility.*

Compound-filled transformer chambers are the most economical and durable, but when they are used the transformers are not readily accessible or easily removable to the test house for meter-testing. Chambers filled with oil or liquid compound are the alternative, and have

come into wider use. They have large doors, and thus allow access to the terminals and the entire removal of the transformers.

Fig. 23 shows diagrammatically a method devised in Germany. The current-transformer chamber is plugged-in between the circuit breaker and the fixed portion, and the same carriage carries the voltage transformer.

(*vi*) *Horizontal or Vertical.*

There has been some controversy on the relative merits of the original horizontal draw-out and the later vertical drop-down, the outcome being that both types have progressed in size and demand; and each has had its representatives among the new makes evolved during the period under review.

The main claims for the horizontal type are that the removable portion, rolling on a level plane, requires a comparatively small manual effort to isolate it. On mechanical principles, the construction is simple and the disposition of the parts makes the interlocking of the circuit-breaker position with the racking-out components

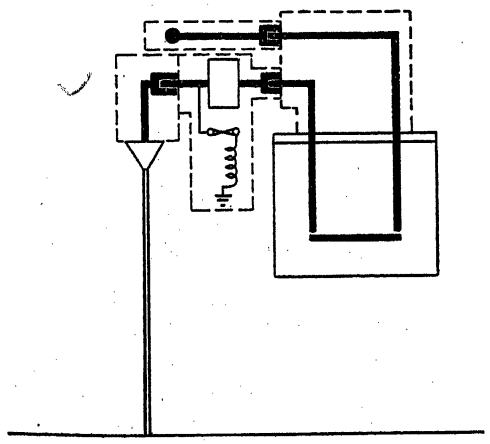

FIG. 23.

very easy. The problems of alignment and co-operation between the moving and the fixed portions are greatly simplified by the use of a true horizontal plane of relation. In contrast with this, the vertical movement involves lowering and raising the heavy removable portion, an operation that for small sizes means much manual effort, and for medium and large sizes necessitates a motor and much incidental gearing, as well as additional means of vertical and horizontal location by guides with such mechanical clearances in all directions as will avoid jamming and ensure true engagement between the fixed and moving contacts and their surrounding parts. On the other hand, the vertical type does economize in floor width, chiefly because less gangway is required for manipulation.

For outdoor use, the roof formed by the busbar chamber when placed above the circuit breakers serves to protect the orifices from the weather, and the vertical orifice not only makes for better clearance of dirt and drainage of moisture from the surface of the insulators, but also lends itself to oil-filling, which is advantageous for very high voltages.

For indoor use, however, the additional height of the one type must be set against the additional floor width of the other when calculating building costs; and, taking everything into account, on the basis of the usual British practice of using single circuit-breakers in preference to duplicate circuit-breakers, and particularly on the score of easy design and accessibility and general convenience in operation, the author's conclusion is in favour of the horizontal type, up to the point at which oil-filling of orifices becomes necessary on account of voltage. Figs. 24A and 24B show a comparison of examples of the two types used in practice on the basis of plans prepared in the same drawing-office.

(*vii*) *Arcing-Contact Classification.*

Known forms of arcing contacts may be classified, as distinct from circuit-breaker classification, as follows: (*a*) Plain; (*b*) Boxed; (*c*) Blast.

(*a*) *Plain Contacts.*—With contacts of this class, the arc is controlled by the general body of oil in the tank, and is subject to deflexion only by magnetic induction from neighbouring current-paths. This class includes all types of arcing contacts that have been in practical service from the beginning, such as sliding, butt, and roller contacts.

With the object of keeping the amount of vaporized metal comparatively small, metals vaporizing at high temperatures have been tried as arcing contacts. Provided suitable means are available for the avoidance of welding, it has been found that the use of steel in this way has the obvious advantage of tending to increase the contact grip by magnetic attraction, thus reducing chattering and arcing when closing on short-circuits. A solenoid-grip contact has been used abroad for the same purpose. In another design, where greater speed of separation was the object, acceleration of the break has been obtained by " flicker " contacts in oil, thus reverting to the principle of the early Ferranti design of high-voltage air-break and oil-break switches. The idea of using separate arcing contacts for making circuit, at closer centres than those for breaking, has been tried for the purpose of reducing the electromagnetic forces when closing the circuit. These " making " contacts have been so arranged, by dash-pot and spring action, that they separate first when opening the circuit. In order to reduce the pneumatic forces tending to push off the circuit breaker, arising from sudden evolution of high-pressure gas between the contact surfaces, several methods have been tried, including the use of small-diameter, spring-loaded, butt-type arcing contacts of tubular form.

(*b*) *Boxed Contacts.*—In a boxed contact, the arc is cloaked by an insulated enclosure, which restricts for a while the expansion of the gas formed by the arc, the outlets controlling the direction of the arc and the gas forces. For example, in the explosion-pot device the gas pressure is confined at the beginning of the stroke. Difficulties have been experienced in making the pots capable of withstanding the high electric and mechanical stresses to which the interiors are subjected when circuit breakers are closed or opened under heavy-current conditions. The old practice of using an insulating lining in a steel container has been largely abandoned in favour

of a chamber constructed entirely of very strong bakelite insulating material.

In America, the "de-ion" device of the air-break type has been developed, in which the arc is split up into a large number of short lengths, reacting to a series of magnetic fields; but relevant discussions there* acknowledge that progress must spring from the crevice and is thus swept through gas escaping from the crevice in the opposite direction.

Contemporary research in Great Britain has set before itself the similar basic aim of achieving peaceful arc-rupturing in oil.

(c) *Blast Contacts.*—All contacts have some form of blast set up around them when operating on short-circuit,

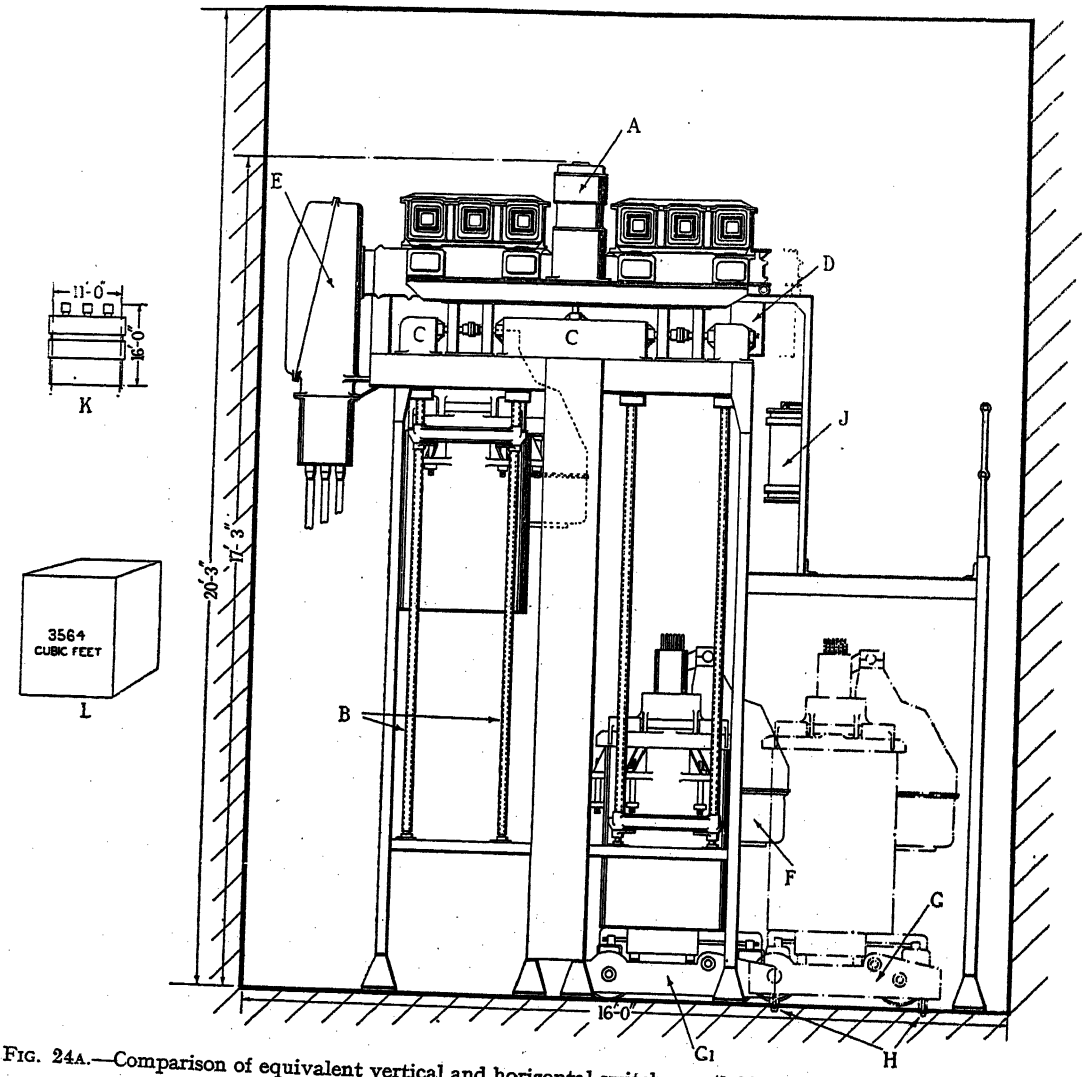

FIG. 24A.—Comparison of equivalent vertical and horizontal switchgear (1 000 000 kVA) (see also Fig. 24B).

fundamental present-day practice of using metal-enclosure and oil-immersion. As a result, the oil-break "de-ion" contact has been evolved, in which the arc is drawn between single electrodes within a vertical crevice cut in an insulated box made of horizontal laminations in which horseshoe iron plates are embedded. The arc is moved by a magnetic field towards the closed side of the

* B. P. BAKER and H. M. WILCOX: "The Use of Oil in Arc Rupture," *Transactions of the American I.E.E.*, 1930, vol. 49, p. 431.

because of the gas formed by the arc; but in those called "blast contacts" for the purpose of the present discussion the blast is accentuated by subjecting the arc-path to some additional pressure artificially produced, as, for example, by a flow of oil or other insulating medium.

In one form, which has been applied to a contactor, the path of the arc is crossed by a blast of air created by a piston incorporated in the mechanism. In the air-blast or gas-blast circuit breaker the path is cut and the arc

is guided into a tube by an artificial blast of air or inert gas. The principle has been very fully explored experimentally by the British Electrical Research Association, and in the meantime a type of somewhat similar construction has been put into practice in Germany. The so-called "expansion" switch, which has followed it there, may be considered as belonging to this class. In the other. It is exemplified in the American oil-blast circuit breaker, in which there are two butt-contacts in series, one of which forms an arc before the other. The first arc creates a pressure, which forces oil and gas across the path of the second arc.* This seems to be a natural outcome of experience of the sudden expansion of materials in contact with the arc; but although it was

it the arc creates steam or other vapour, which is allowed to expand in a secondary chamber through which the arc has to pass. This type may be regarded as a lineal descendant of the water-break devices of 35 years ago;* and it is also reminiscent of the liquid resistances once thought necessary for charging cables.

In another type of this class, two arcs are formed in a box or chamber, one generating a blast which acts upon

* L. ANDREWS: *Journal I.E.E.*, 1898, vol. 27, p. 487.

known several years ago† it has only recently become available in practice.

Whatever may be the merits of the three classes, the ideal, unobtainable so far, would appear to be an arcing contact in such a simple form that it would eliminate all parts apt to be distorted under mechanical stress,

* R. M. SPURCK and H. F. STRANG: "Circuit-Breaker Field Tests on Standard and Oil-Blast Explosion-Chamber Oil Circuit-Breakers," Paper read at the American I.E.E. Winter Convention, January 1931.

† HILLIARD: U.S. Patent No. 1548799—1925, filed 10th August 1921.

and would have a contact-grip capable of mastering the situation completely; that is to say, it should be so strong as to prevent any serious burning or arcing as the current rises and falls in the cycle, but also, when the current is at or about zero, it should instantly release, and the re-establishment of the arc should be prevented either by the high speed of withdrawal of the contact or by some other adequate means. The form that lends itself best to complete enclosure of the whole circuit breaker, and is not dependent upon some external agency that might itself fail at the critical moment, is the one most likely to survive the long ordeal of tests and practical service that will be necessary before universal standardization can be achieved.

(viii) Electrostatic Stress Distribution.

Corona discharge in orifice insulators, and at the base of pin-and-plug insulators, may not be detected during preliminary testing or from observations under normal working conditions; but occurrences after continuous use on systems operating at 33 000 volts and over have proved the advantage of uniform electrostatic stress along the whole surface of each insulator. Porcelain is

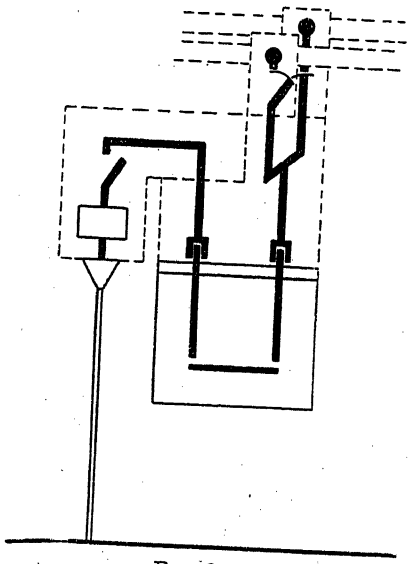

FIG. 25.

effective as a surface insulator, and as such is the best protection from weather and dirt; but it cannot be conveniently shaped to give the full economy in space characteristic of metal-clad switchgear except at the expense of stressing some parts of its surface considerably more than the average. The ideal insulator, therefore, as now required for very high voltages, is one having a surface with the properties of porcelain, and a graded condenser interior.

(ix) Oil-Filled Isolating-Orifices.

From the standpoint of insulation, the isolating-contact orifice is usually the weakest part of the average design, since it is a place where, on account of the contact between the fixed and the removable portion, the fittings are generally in air; and sometimes the clearances have been none too good, particularly when the reduction during the withdrawal or plugging-in of the removable portion is taken into account. Moreover, the orifice introduces an exception to the principle of complete immersion; and, in spite of locking-off doors, men have

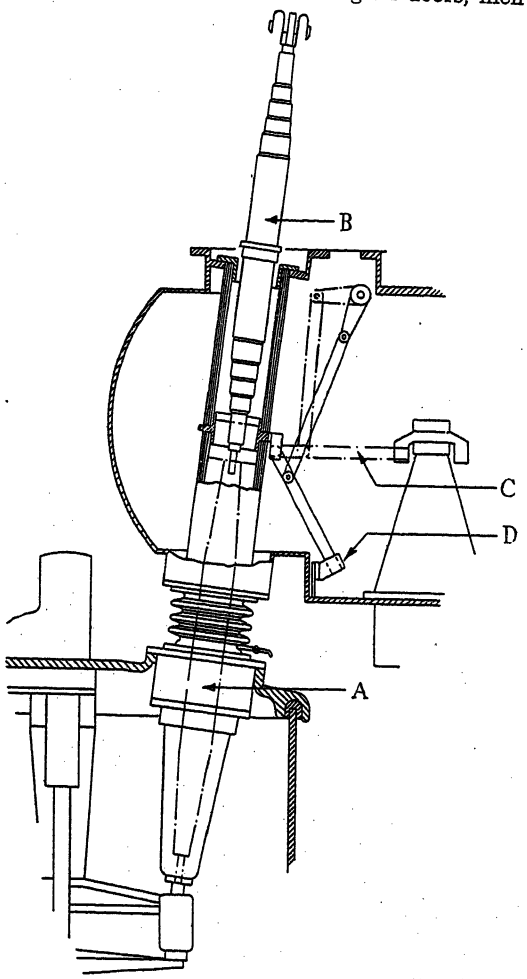

FIG. 26.

A.—Central fitting in circuit and interlocked with earthing switch in open position C.
B.—Central fitting in withdrawn position and interlocked with earthing switch in earthed position D.

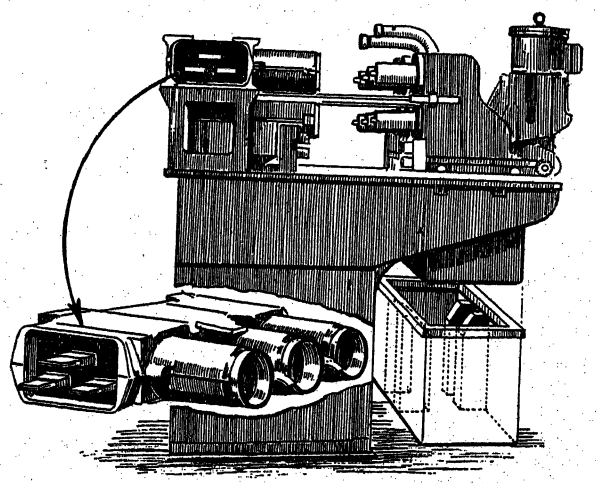

FIG. 27.

been known to put their hands in and make contact with live parts.

Attempts were made as long ago as 1911 to obtain an oil-immersed isolating chamber, and in a measure it was secured in the way illustrated in the author's 1925 paper* (see also Fig. 15, Type 3*c*, of the present paper). In the detail of this design the orifice is contained in the top-plate of an oil-immersed isolating-switch.

Another application† of this principle combined

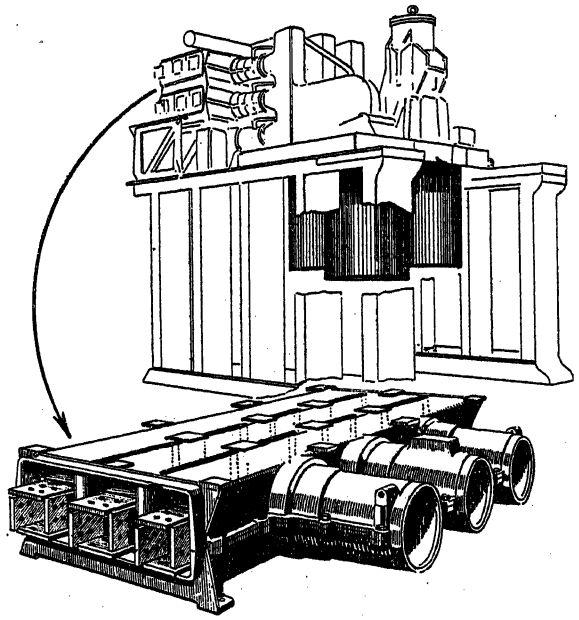

FIG. 28.

Classes (2) and (3), as shown in Fig. 25. The orifice is oil-filled, and has to be emptied before the circuit breaker is withdrawn; but withdrawal is not essential to isolation, and cannot be effected until the conductors in the orifice chamber are isolated on the busbar and feeder sides, and in addition are earthed. By this means the orifice can never be alive when exposed to the air.

A further step in design, Type 3(*a* and *c*), is shown diagrammatically in Fig. 14 already referred to, and in more detail in Fig. 26. After the separation of the central plug contacts, the circuit breaker may be detached from the fixed portion, or, alternatively, it may be examined with safety in its normal position after the oil has been drained from the tank and the manhole covers have been removed. The new development includes the earlier principle of oil-immersed isolation and orifice insulation, and so provides complete oil-immersion of all insulators and fixed conductors, and ensures their inaccessibility when not earthed. Further, since it is compatible with the design requirements of very large apparatus, it makes the construction of self-contained switchgear units for the highest voltages practical for the first time.

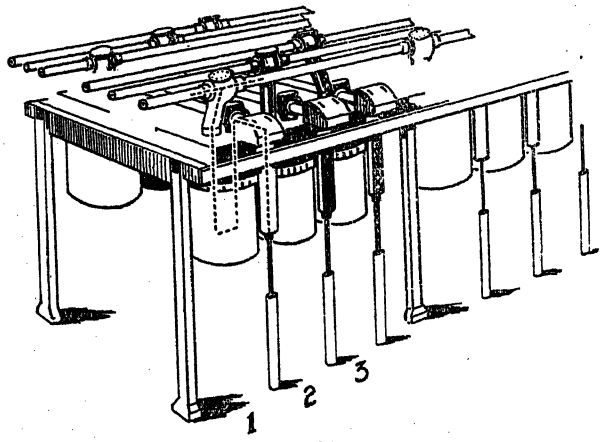

FIG. 29.

(*x*) *Disposition of Busbars and Phase Separation.*

The enclosure of busbars in metal-clad switchgear is a feature bound up with general design, and is an important controlling factor in construction. The earlier methods of enclosing each set of 3-phase busbars, extensively used in actual service, are:—

(*a*) *Three-phase enclosure.*—A single metal chamber, with only insulation between phases: compound-filled (Fig. 27).

(*b*) *Metallic phase-separation.*—A single metal chamber, with metal divisions between phases: compound-filled (Fig. 28).

* *Journal I.E.E.*, 1925, vol. 63, p. 429, Fig. 7.
† British Patent No. 238952: Application date 28th May, 1924.

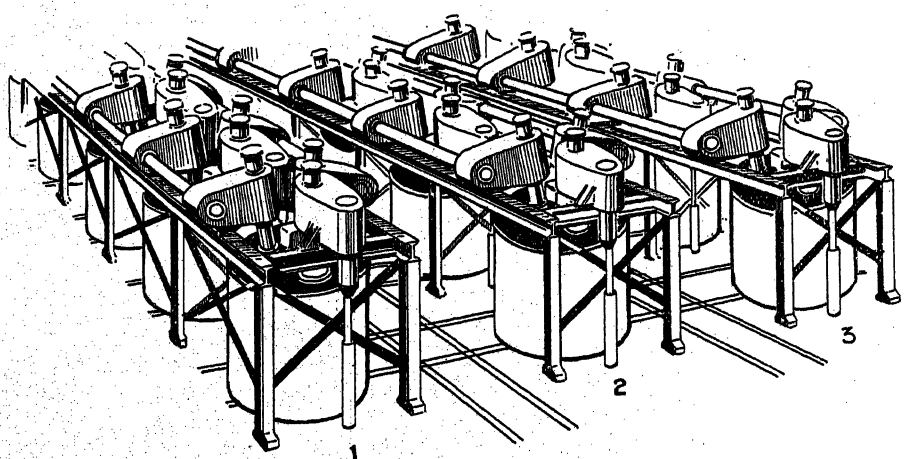

FIG. 30.

The later methods are:—

(*c*) *Single-phase enclosure.*—A group of three adjacent tubular chambers, one chamber for each phase, with the circuit breakers arranged in 3-phase groups, all in one line in the same direction as the busbars: compound-filled or oil-filled (Fig. 29).

(*d*) *Complete spatial phase-separation.*—A tubular chamber for each phase, with the circuit breakers arranged in three single-phase rows, each row in a separate line in the same direction as the corresponding busbar: generally oil-filled (Fig. 30).

In general practice, 3-phase compound enclosure (Method *a*) is used for sizes up to 750 000 kVA and 33 000 volts, and the circuit-breaker phases are wholly or partially separated by partitions in a common tank.

For larger breaking capacities, 3-phase busbars with metal divisions between phases [Method (*b*)] have been adopted in the largest power stations for breaking capacities up to 1 500 000 kVA and 33 000 volts. The associated circuit breakers have a separate tank for each phase, and there is thus complete phase-separation by earthed metal in every part of the switchgear units.

Single-phase enclosure on a large scale with tubular oil-filled busbar chambers [Method (*c*)] was first applied on a trial unit in the form referred to above (Fig. 25); but the practical progress of this system is best known on account of the State Line power-station* installation in America. The original equipment of this was planned on the basis of building-up a casing on site from a number of standard parts, into which the conductors were threaded, but owing to the high cost of "field" work the component parts of later equipments have been produced in "factory-group" construction; that is to say, the bulk of the detail assembly is done in the factory,

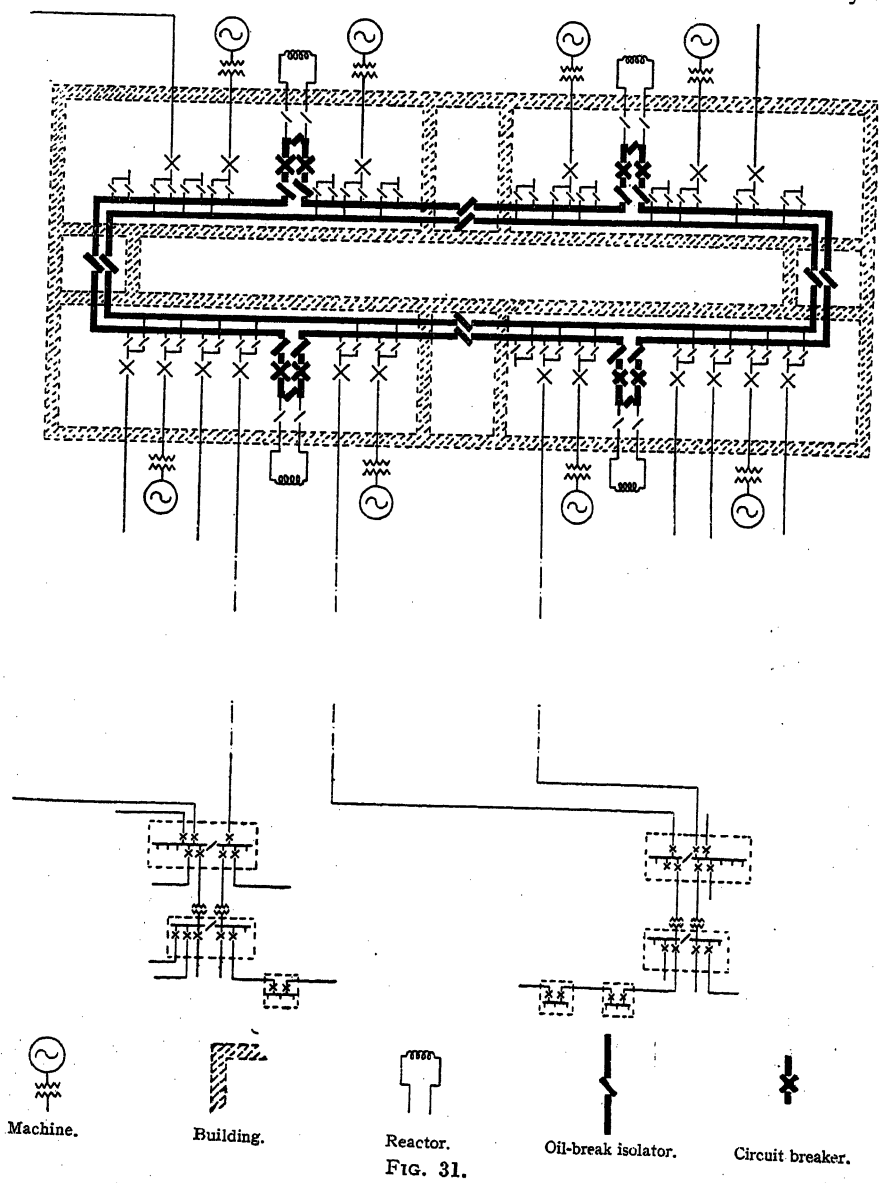

FIG. 31.

* A. M. ROSSMAN: "The Metal-Clad Switchgear at State Line Station," *Transactions of the American I.E.E.*, 1930, vol. 49, p. 397.

the dimensions of individual groups being limited only by transport facilities. In Great Britain, the factory-group system, which was applied to large switchgear in 1918, is now being used for switchgear up to 66 000 volts.

Complete phase-separation for the purpose of ensuring freedom from short-circuits between phases has long had practical application in America for open-type switchgear, as exemplified in those stations in which the phases are actually contained in separate horizontal or vertical sections of buildings; but in metal-clad switchgear of moderate dimensions earthed metal between phases is an equally effective barrier against the spread of faults. Economy in space is secured by it, and since with modern insulation busbar faults are a remote risk, and with metal barriers between phases can only be single-phase faults to earth, which are limited in intensity by neutral-earthing resistors, there seems to be no good reason for greater separation. The case is different in designs for very high voltages, and in exceptionally large constructions,

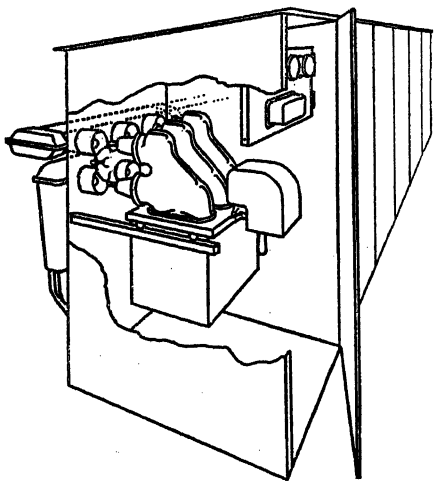

FIG. 32.

because it is desirable to avoid crossing busbars over trunk connections and the like, which is apt to lead to tortuous details. The requisite neatness is secured by spatial separation, in which a straight, clear gangway is provided between phases; and Method (*d*) therefore emerges in the course of the elimination of the complicated.

(*xi*) *Busbars and Building Lay-out.*

Where comparatively weak circuit-breaker enclosures are prevalent, there is much concern about the risk of oil fires and explosions. This has revived the search for oil-less equipment, but in general British practice the saving in space by using oil or compound as an insulating medium, and the general acceptance of metal-clad construction, have secured the retention of oil-immersed circuit breakers characterized by strong enclosures. The occurrence of a few fires, however, has forewarned designers of the possibility that flaming oil or explosive gas may be liberated because of some flaw in construction or operation, such as sustained arcing inside a circuit breaker caused by a failure of insulation. To avoid spreading the damage to adjacent panels, the external enclosure has been made completely fireproof down to that of the smallest secondary connection. It is also preferable that the lay-out of the building should provide for the ready drainage of stray oil. As one form of additional safeguard, the whole equipment has been subdivided into groups of panels, each group contained in a separate switch room, with oil-immersed isolating switches, also in separate rooms, between adjacent groups. Each subsidiary distributing point takes its supply from panels in more than one room, the aim being to lay out the whole of the distribution from the power station in such a way that the complete putting out of action of any room by fire or by hostile attack would not prejudice the supply to any part of the network. The building division in a large power station lay-out is shown diagrammatically in Fig. 31, from which it will be seen that each busbar section extends

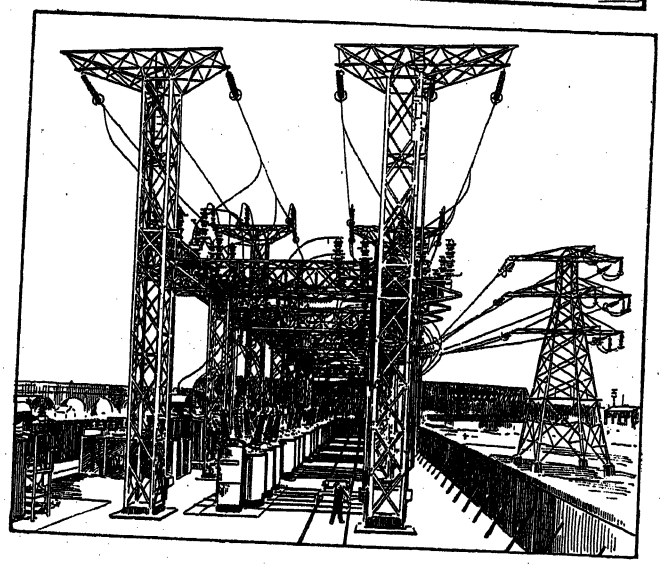
through three distinct rooms. In practice, the building takes the form of an **H**, with the busbar junctions and room-isolating switches situated in the cross-junction.



(*xii*) *Outdoor Switchgear.*

Until recently, large outdoor equipments have not been encouraged by British operating engineers, owing probably to fear of having to do maintenance work in inclement weather. Another justification has lain in the fact that indoor metal-clad construction of itself effects ample economy by its large reduction of building costs. In the author's opinion there is much to be said for installing large switchgear out of doors; it has had to be done, because of size, for the 132 000-volt British grid. It is to be expected that the high standard of design now attainable in the metal-clad type with proper care will keep the necessary maintenance work within reasonable limits. The chief gains with this type lie in saving the cost of erecting and maintaining buildings, and in the protection of conductors and insulators from the effects

Metal-clad.

Key diagram.

FIG. 34.

Switches at A (key diagram) in the existing open-type substation bypass the circuit breaker for one busbar, enabling the feeder to be used with the circuit breaker out of commission. This bypass is not included in the metal-clad lay-out. The metal-clad covering of insulators makes it unnecessary, since it is for maintenance purposes only, to enable insulators to be cleaned and the steelwork painted, etc. On the other hand, the metal-clad lay-out includes isolators and earthing switches at B that are not included in the open lay-out.

of exposure to dirt, water, and lightning. With open-type switchgear, the space factor has become of increasing importance because of the necessity of avoiding accidental contact with live conductors in one section by an operator working on an earthed section or walking near live conductors while carrying metal. The complete covering of all conductors obviates the compulsory provision of large clearance distances. In addition, the splitting-up of the sections of switchgear into fireproof compartments is avoided, and so the whole of the equipment can be seen at a glance. Moreover, remote as the likelihood of

an explosion may be, if one does occur there is less risk to men who may be working on the switchgear, since they can make their escape more easily. With metal-clad switchgear, whether indoors or out of doors, the primary effects of a fault are local, and the remainder of the switchgear is unaffected. The secondary effects in a building, however, such as smoke and gas, may hinder the speedy restoration of supply; but this would not be so out of doors. Metal and compound or oil are better for the defence and preservation of conductors and insulation than brick walls and roofs. It is common practice to put large transformers outside, and the case for similar treatment of well-protected switchgear is equally strong.

As a half-way measure, switchgear of the smaller sizes is housed in metal kiosks or close-fitting weather-proof protection. A unit, partly housed on these lines and partly outdoor, has been proposed* as indicated in Fig. 32.

(*xiii*) 132 000-*Volt Metal-Clad Switchgear.*

A recent American application of metal-clad principles to 132 000-volt service in the United States includes the use of ordinary circuit breakers having enclosed terminals connected up with metal-covered cables to cable busbars through isolating devices of the type shown in Fig. 33.

It is opportune here to discuss a possible alternative to the existing types of British grid lay-out. Cables are already included in populous districts, where overhead lines are ruled out on account of first cost and danger. The maintenance cost of overhead lines is an item not to be overlooked. It has already been shown (Fig. 30) how metal-clad connections can be marshalled in the substations, and since these are generally situated in industrial or residential districts it is logical to suppose that at some future time the requirements of safety will call for the covering of all conductors in the neighbourhood of the substation. In such districts, also, land is generally increasing in value.

Fig. 34 illustrates, in plan view and in small-scale elevation, a comparison between the open-type "low" and "high" substations and the possible metal-clad arrangement. The last-named occupies about 20 per cent of the ground area of the "low" structure, and about 45 per cent of that of the "high" structure. The reduction of head-room in the substations would avoid any objections on æsthetic grounds to obtrusive overhead structures.

Fig. 35 indicates the prospective further progress of Type 3(*a* and *c*) (Fig. 14) on a large scale. The framework and the tank and circuit-breaker lowering mechanism, usually convenient up to 66 000 volts, are too bulky and heavy for higher voltages. The proposal therefore is to give access through manhole doors for normal inspection after isolating and earthing all conductors, and to provide for complete removal of the circuit-breaker portion with the aid of portable bogies only. The drawing shows a cross-section in the plane at right angles to the line of busbars in order to illustrate the operation of changing over from one busbar to the other. The ground space occupied by the complete unit panel is very little more than is required for the now familiar grid circuit-breakers, and the necessity for large clearances is avoided by the immersion of all conductors and insulators in oil. The general lay-out has already been referred to (Fig. 30).

(*xiv*) *Voltage Measurement.*

Progress has been made in the development of condenser couplers (Figs. 36 and 55) with the object of substituting them for the usual voltage transformers in very-high-voltage circuits. The high-voltage windings of the transformers have always been a possible source of weakness, necessitating high-voltage isolating devices and fuses. Condenser couplers eliminate fuses because they have no high-voltage primary windings; and in

* Allis-Chalmers Manufacturing Co.

electric strength they are equal to or better than any other main insulator.

(xv) Busbars.

The increase in current ratings has entailed research to ascertain the best construction of busbars and to enable the correct current densities to be selected to avoid overstepping accepted temperature-rises. Fig. 37 shows the average current densities that have been found necessary in practice to limit hot-spot temperatures to 50 deg. C. rise. The values are based on the results of tests of different sizes and arrangements of busbars with thermo-couples in contact with the copper in several positions. In the past it was the practice for users to specify busbar sections, or current densities, or both, but in metal-clad switchgear it is the ultimate temperature alone that matters, and the permissible maximum densities may vary considerably with the design and the ambient conditions. The ideals of complete enclosure and of keeping down temperature conflict with one another, but one objective is common to both, namely, to keep the insulation permanently perfect. The maximum internal temperature is the criterion of endurance, and it is therefore this, as has

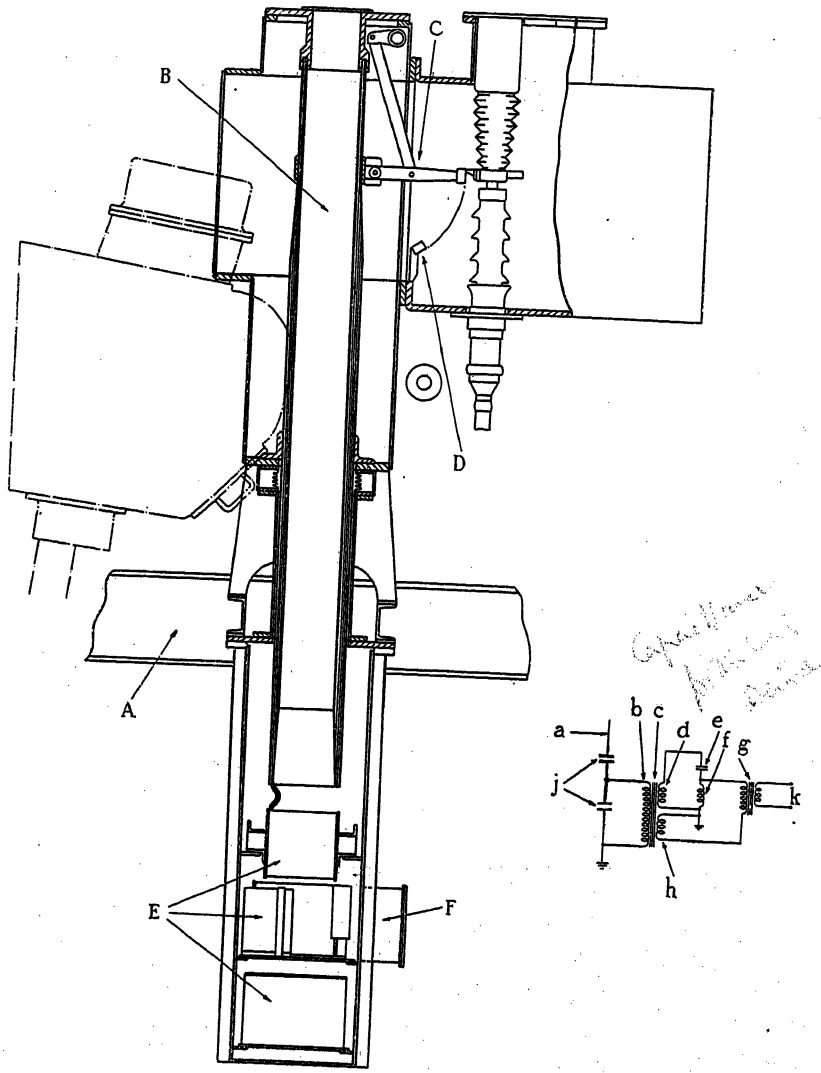

FIG. 36.

k.—Secondary terminals.

been said, rather than the temperature-rise, that matters most. Hence it is necessary to determine the maximum permissible temperatures for all the materials used. Insulating materials are the most vulnerable, and 80° C. is a reasonable limit for procurable qualities of those in common use in switchgear to-day; the permissible temperature-rise is therefore the difference between 80° C. and the ambient temperature. Although it has been the standard practice to permit a rise of 30 deg. C. for currents up to 2 000 amperes, and of 40 deg. C. for currents above this value, there appears to be no longer any reason for this distinction. It is true that it is more difficult to keep the temperature down in metal-clad switchgear at the heavier currents, but, since it is mainly a question of durability of insulation, the requirements should be the same for low-current ratings as for high-current ratings. The curve shows that ratings of 2 500 amperes and over necessitate abnormal sections of copper, or special arrangements of busbars, in order to keep the temperature within safe limits. This, together with the abnormal stresses set up when short-circuit currents are carried or broken, determines a

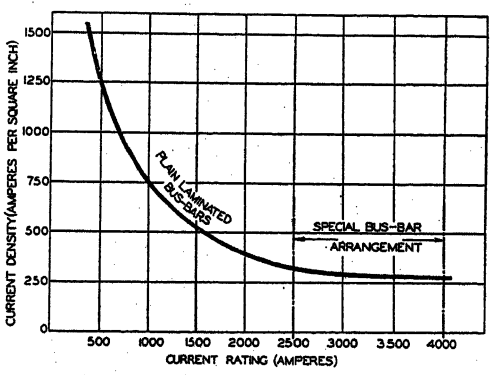

FIG. 37.

practical limit for the current rating of main power-station panels.

This limitation of current raises the question of the suitable working voltage for the switchgear of a generating station of any given size, particularly in view of the present tendency towards a need for greater breaking capacities. Obviously, since for a given breaking capacity the current is inversely proportional to the voltage, a voltage chosen too low for conditions involving some definite breaking capacity must lead to very difficult problems arising out of too high current values. Hence, speaking generally, there is a best (or at least an advisable minimum) voltage for any given breaking capacity. It is difficult to establish a rule for a problem into which so many variables enter; but a very rough approximation might be that for a 3-phase circuit breaker, within the range of present standard ratings, namely up to 1 500 000 kVA, the numerical value of the minimum working voltage of switchgear should be, say, something of the general order of the 1/125th part of the numerical value of its breaking capacity in kVA.

(*xvi*) *Switching Capacity.*

"Switching capacity" is the term used here to describe the operating ability of a circuit breaker as a protective device for making and breaking current. In practice as it stands to-day, there is need to clarify the idea associated with the terms "rating," "performance," and "selection," when used in relation to making and breaking under short-circuit conditions.

Ratings have been established in B.S.S. No. 116–1929, Clause 46 of which specifies that the standard kVA ratings of Table III shall be based on a schedule of currents given in Table IV and on the line voltages given in Table I. In the standard conditions for determining making capacity and breaking capacity, whereas a power factor of 0·1 lagging and the duty-cycle are included, recovery voltage is not prescribed. Recovery voltage is also a condition of severity, and therefore the present specification of standard conditions, under which the rating is assigned, is incomplete.

Previously manufacturers had established certain dimensions of circuit-breaker enclosures based upon the experience of practical service. These were checked from time to time with available data; but in the absence of large test plant the data had to be derived from tests on plant of a size small in comparison with the range of ratings that had to be declared. It is not surprising, therefore, that some of the designs made to the old empirical ratings have required revision in respect of strength of detail components.

Performance is the proved ability of the circuit breaker under test conditions, and, like rating, should be based on the current broken and the severity of the other conditions of the circuit in which the test is made. The conditions include the size and the electrical and mechanical characteristics of the generator, and the internal and external impedance of the circuit, which control both the power factor during the arcing period, and the value and rate of growth of the recovery voltage on the extinction of the arc.

Selection is the choice of circuit-breaker rating for a given service condition, and must be in accordance with the recovery voltage and power factor of the short-circuit in the vicinity of the circuit breaker on the system, and the margin for safety required, having regard to the relative importance of the position. For a given fault current the demand upon the circuit breaker is greatest with low power factor and high recovery voltage. This occurs when the fault current is restricted by reactance, as in a fault on the secondary circuit of a transformer near to a large generating station. The demand is least when the power factor is high and the recovery voltage is low; but this seldom occurs in practice. Between these two extremes comes relative easement by low recovery voltage or by high power factor. An example of low recovery voltage conditions is a fault near isolated generating plant, which stores up little electro-mechanical energy and has a large voltage decrement. High power factor is associated with a remote fault, in which the current is small in comparison with the capacity of the plant, and the circuit, in the absence of transformers, is mainly non-inductive.

An international method of interpreting short-circuit oscillograms has yet to be determined. In the author's opinion, rated breaking capacity should be based upon performance under some clearly-defined standard test-

conditions. A suggestion for discussion, intended to assist in the establishment of a suitable standard circuit, is included in Appendix I. The effect of departure from test conditions must be very clearly understood. For instance, let it be supposed that a circuit breaker has had some definite rating assigned to it under the standard conditions; then, if the same circuit breaker is used in a situation where, other things being equal, the power factor and the recovery voltage depart from the standard, the performance may be expected to differ also, and it may in fact become necessary to select a circuit breaker of a larger or smaller rating, as the case may be.

In spite of doubts that have been expressed about the consistency of oil-break circuit-breaker operation, given a correct understanding of the conditions typical British commercial oil-break circuit breakers will break short-circuits with reasonable consistency well above the rating assigned to them in accordance with B.S.S. No. 116—1929, at a recovery voltage in accordance with the

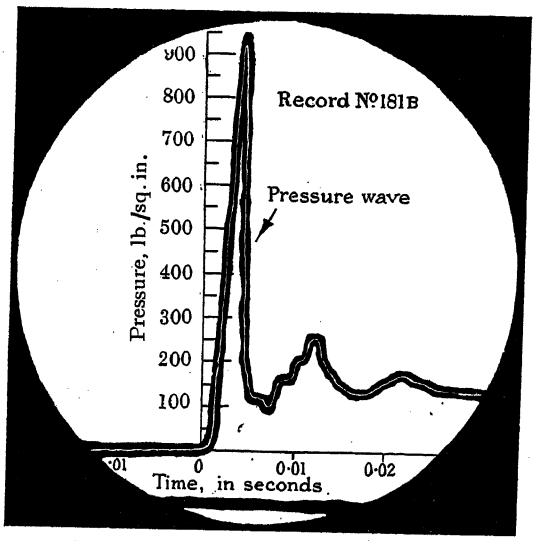

FIG. 38.

service conditions of an interconnected network. (This is shown in Appendix II.) These conclusions are based on experience with circuit breakers having satisfactory mechanical construction and insulation. Obviously, the circumstances may be entirely different if there are such defects as sticking of a circuit breaker, a tendency to reclose when opening, pumping at the contacts when closing, or failure of insulation, any of which may cause sustained arcing, which, even if of short length and of only a few seconds' duration, may entirely alter the stress within the enclosure. An excessive succession of arc impulses may build up stresses that venting devices are incapable of relieving with sufficient rapidity, and such stresses will exceed many times that of the maximum gas explosion. On the other hand, it must be remembered that enclosures which pass heavy and steady hydraulic pressure tests will withstand impulse shocks of much greater intensity. For example, a tank designed for a steady hydraulic pressure of 150 lb. per sq. in. is shown by a pressure record (Fig. 38) to have withstood an impulse pressure of 950 lb. per sq. in., and experience proves that impulse pressures up to 10 times the steady hydraulic pressure can be withstood satisfactorily.

Closing on short-circuit is perhaps so rare that in the past it has not been required of circuit breakers in standard specifications. It has been a debatable point whether the circuit breaker should trip free, or go right home first. A trip-free circuit breaker that does not close completely may destroy itself in pumping caused by the pull of the closing solenoid or of the motor yielding to the repelling forces before the trip has time to operate; and even without pumping there remains the chance that the circuit breaker may attempt to break at the maximum wave of the short-circuit transient without having the full benefit of the quick-break mechanism. A further argument in favour of ability to go right home lies in the fact that the service duty of any circuit breaker is to isolate the section controlled by it; and therefore, if a circuit breaker is closed on a "through" fault, another circuit breaker, namely, the one controlling the faulty section, is the one that should open, and not the one that is being closed.

It is possible that currents on the closing of circuit breakers on a short-circuit may sometimes be so large, and closing right home so difficult to achieve, that a less expensive alternative may be sought; for example, the addition of some discriminating device that will actually prevent the attempt when the circuit condition is such that these heavy currents would be encountered.

(xvii) Stress Limitation.

The first requirement of a circuit breaker is that it must be capable of withstanding any current or voltage condition within its rating, without establishing an arcing fault in itself. Next in importance is that during the arcing period it shall create the minimum effective stress within its enclosure. The strong tank and top-plate, in contrast with the earlier thin tank, are in themselves a means to this end. The strong walls resist the pressure and restrict the arc-containing bubbles. The turbulent gases at high density, which form the bubbles, help to prevent restoration of the arc after the current has passed through zero. Paradoxical as it may seem, a pressure created within the tank is actually a stress-limiting factor in circuit-breaking.

It is also essential, for stress reduction, to make the contacts sufficiently robust to withstand the mechanical forces due both to the magnetic field and to the thermal effects of the current and consequent arcing. The problems of the circuit breaker may not be entirely solved by the use of intricate arcing contacts, even should tests show promise of stress reduction. Devices of elaborate shapes and constructive features are costly and difficult to inspect and to maintain, when compared with plain arcing contacts separating in oil. If contrivances designed to improve breaking capacity include in themselves additional features, they tend on that account to introduce weakness either mechanically or electrically; and in the event of failure the final defence must depend upon strength of enclosure. Moreover, the elimination of oil does not necessarily give immunity from trouble, since the insulation is more apt to fail because of its exposure, and arcing in air creates stresses

and widespread damage, constituting a danger to persons and a likely source of damage to buildings.

(*xviii*) *Saving Switchgear.*

The elimination of superfluous switchgear tends to increase safety, on the principle that there are fewer parts to go wrong; and for an equal cost the simpler switchgear has better components, and therefore the risks are still further reduced. On step-up units the use of switchgear on the low-voltage side of the transformers only has effected a saving in high-voltage circuit breakers; and the principle can be applied wherever the high-voltage side of the transformers and the line are independent units. Similarly a saving in power-station switchgear is effected by using one circuit breaker to control the generator and its step-up transformer. Incidentally, it has been a great advantage to do this in capital power stations when generating at 6 000 or 12 000 volts, because it avoids the wasteful cost of conductors for very heavy currents.

When other connections come from the line, as happens with tees, parallel feeders, and ring mains, the cost of high-voltage switchgear must be faced. The "single-switch" substation idea, due to Mr. J. R. Beard, has been adopted to good effect on the 132 000-volt grid, three switches serving where five would normally be required for two feeders, two transformers, and a busbar coupler (Fig. 39).

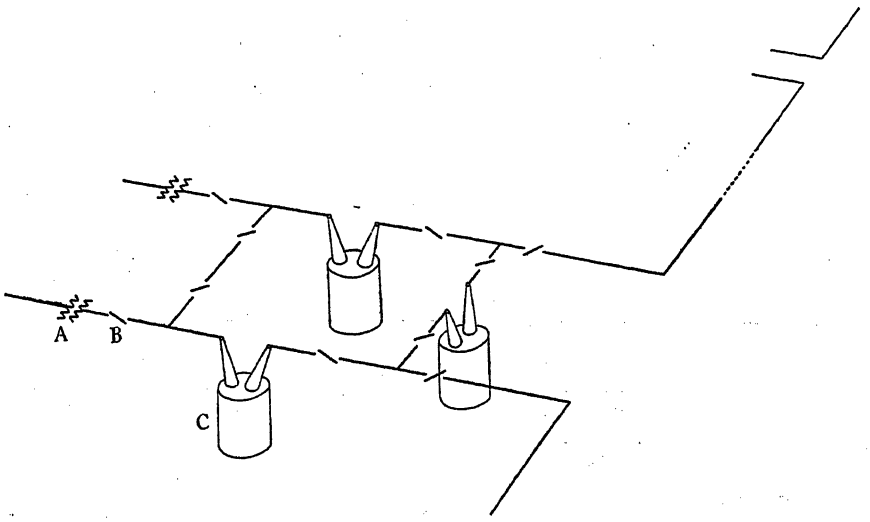

FIG. 39.

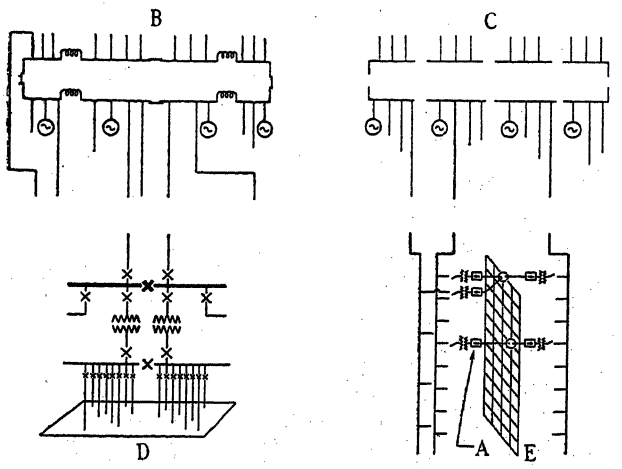

FIG. 40.

A.—Network protectors.
B.—Closed busbar system.
C.—Divided busbar system.
D.—Distribution area as normally used in Great Britain.
E.—Low-voltage network (solid).

The lay-out and connection to the low-voltage distribution may have a material effect on the breaking-capacity demands on the transmission switchgear. For example, the generating plant, when "synchronized at the load"* as an alternative to paralleling at the bus-

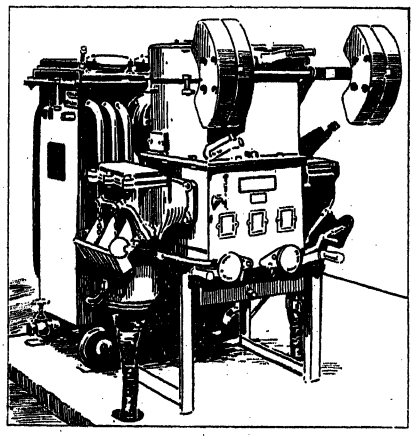

FIG. 41.

Diagram of connections as in Fig. 42, but with overload cut-out in tee-off to consumer's transformer.

* Three papers, "Synchronized at the Load," *Transactions of the American I.E.E.*, 1929, vol. 48, pp. 1079–1107.

bars, utilizes the load transformers and network as impedance. Fig. 40 shows the contrast between the running condition of the closed busbar system and that of the divided busbar. The latter system has introduced into American practice the automatic "network protector," which is a circuit breaker with automatic discrimination in respect to voltage, synchronizing, anti-pumping, and direction of flow of power. The system requires comparatively small circuit breakers near the source of power, since the total capacity is split up into relatively small sections instead of all being tied to one busbar. The reduction in short-circuit fault-current values on the various parts of the system, compared with those obtained in more usual supply and distribution systems, is shown by the following figures, which have been calculated on an assumed symbolic system:

Type of System.

Equipment	"Synchronized at the load" (low-voltage network)	Paralleled at the busbars
	Maximum fault kVA	Maximum fault kVA
Switchgear at source of supply	50 000	150 000
High-voltage circuit breakers near the load	There need be none	131 000
Low-voltage circuit breakers near the load	1 850	31 400
Low-voltage cables designed to burn clear on the occurrence of an "internal" fault	16 000	There are none designed to burn out, since radial feeders are usual, with protection by fuses or circuit breakers

Consumers' outdoor substations can be very simply equipped with oil-immersed isolators in the way indicated in Figs. 41* and 42, when no automatic control of incoming and outgoing feeders is required. An adaptation in a group of three units, illustrated in Fig. 43,

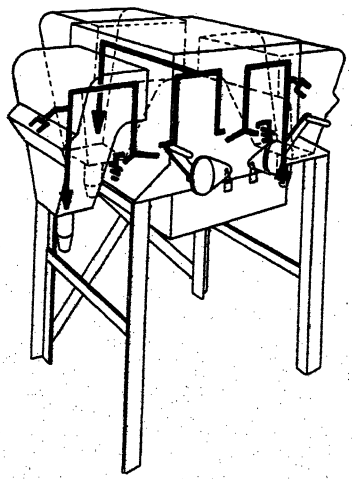

FIG. 42.

allows for the coupling of two pairs of sectionalized feeders, with isolation, earthing, and testing of any of the four cables, and complete isolation of the switching units of either pair of cables; that is to say, it is equivalent to non-automatic 5-panel switchgear.

* Cook and Kingsbury.

Fig. 44 shows a fuse that trips a switch,* and is thus an additional example of combinations of fuses with switches designed to avoid the usual trip coils and current transformers.

Group-switching may be adopted to reduce the dimensions and possible short-circuit conditions of feeder circuit-breakers, where there are a number of feeders branching from one source. The circuits are so arranged that all heavy short-circuits are cleared by the group circuit-breaker before the faulty-feeder circuit-breaker trips. After the latter has opened, the group circuit-breaker recloses, and the healthy feeders continue working.

In one form of the arrangement it is intended that the less severe faults shall be cleared by the feeder circuit-breakers; but the objection to this is that a small fault may grow into a serious short-circuit during the operation of the comparatively small feeder circuit-breaker, which may thus be caused to fail seriously. The alternative is to have all faults cleared by the large group circuit-breaker; and there are two main systems for doing this, one with pilots and the other without them.

The principle of group-switching with pilot wires, shown in Fig. 45, involves simple electrical interlocking between the circuit breakers; and the proposal for

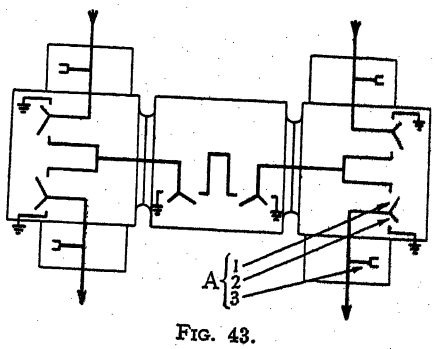

FIG. 43.

A.—Interlock between:—
1. Main switch.

3. Testing plug.

operation without pilots, which has been called "sequential group-switching," is illustrated in Fig. 46, where it is shown that each feeder circuit-breaker has two trip-coils mechanically interlocked in such a way that one is made ready to trip the circuit breaker on the occurrence

* Page and Astbury.

of a fault; but is not allowed actually to do so until it is released by the other, which is an under-current or under-voltage coil. This release does not take place until the

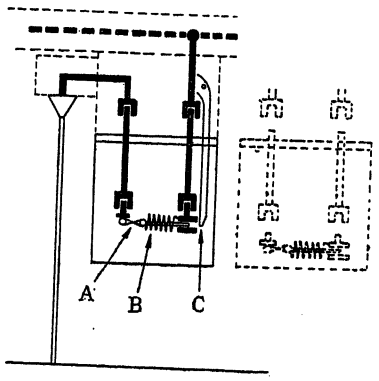

FIG. 44.

B.—Kick-off spring released by fuse blowing. } Mounted on plunger bar of circuit breaker.
C.—Tripping lever.

current in the coil has died away; that is to say, until the group circuit-breaker is open. The group circuit-breaker itself has an over-current or earth-leakage release, and is provided in addition with an automatic reclosing device, which operates in about 0·6 sec., and so restores the load on the remaining healthy feeders. The system, since it requires no pilot, is applicable to a number of remote branch feeders connected by cable to the group circuit breaker.*

* Andrew.

(xix) Safety of Men Working on the Line.

The systems of earthing a cable for the safety of men working on a line,* although they have undergone but little change, have been the subject of much discussion, particularly in respect of their application in mines.

The point has arisen that when the circuit breaker is closed for earthing it must not trip out on any account. Since circuit breakers are generally of the free-handle type, this means the addition of some mechanism to lock-off the tripping-device. Interlocks must be very thorough, to avoid the risk that the lock may be left on at other times when the switch is required to be trip-free.

In regard to the plug type of earthing, complaints have been made that the fitting of the plugs in preparation for earthing is too laborious. One alternative method is shown in Fig. 47. The earthing switch is incorporated in the circuit-breaker tank, and interlocked with the circuit-breaker handle and racking-gear. The main circuit must be open before it is possible to make the earthing contacts, and when they are made the handle is padlocked and the circuit breaker is so locked that it cannot be withdrawn. Therefore the earth cannot be removed by any mischance, the only way being to remove the padlock and to open the earthing contact by hand. It can then be padlocked again in the open position, and the circuit breaker can be used in the ordinary way.

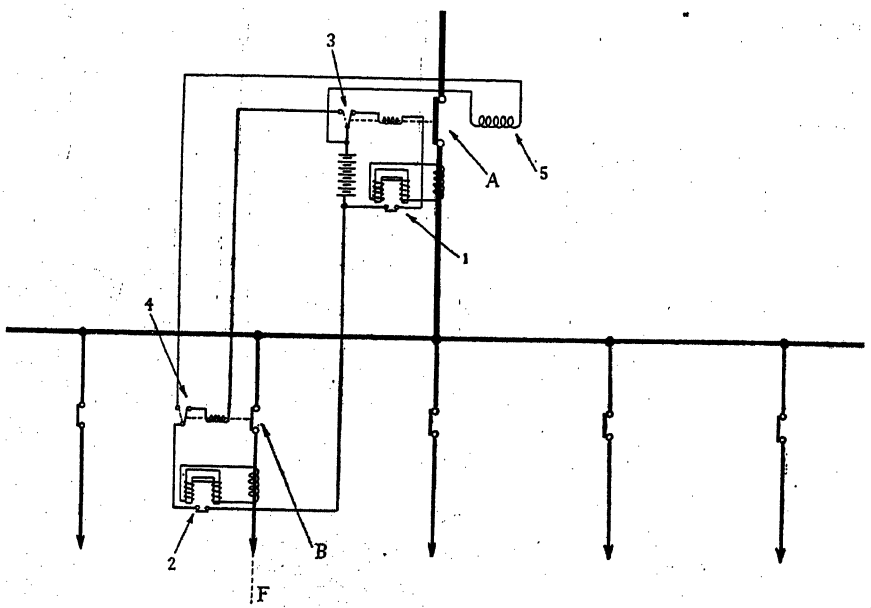

FIG. 45.—Principle of group-switching with pilot connections (necessary time-delay devices and reclosing contactor omitted for simplicity.)

On a fault at F:—
Relay 1 operates, closing trip circuit of group circuit-breaker A.
Relay 2 operates, but does not trip feeder circuit-breaker B until group circuit-breaker A trips, throwing over switch 3 to dotted position.
B trips without load, and throws over switch 4 to dotted position, thus reclosing group circuit-breaker by coil 5.

The same point arises in power-station and substation practice. When a cable is definitely earthed for men working on a line there should be no risk that the circuit breaker will trip out accidentally or by the act of an unauthorized person; and to ensure this the tripping

* *Journal I.E.E.*, 1925, vol. 63, pp. 437 and 438, Figs. 24 and 25.

mechanism must be locked off. This introduces the secondary hazard that the circuit breaker may be racked in erroneously while it is locked in the closed position. Normally a circuit breaker has an interlock between the racking-in and the off position, which automatically trips a closed circuit-breaker during racking-in; but if a part of its mechanism is jammed by an improvised pin or other device foreign to its normal construction, the automatic trip is ineffective. This is not an imaginary danger; it has actually happened that, owing to the insertion of such a pin, a closed circuit-breaker was seriously damaged by arcing at the orifice contacts on being racked in.

Care must therefore be exercised in the selection and use of properly-designed devices for locking-off the tripping mechanism. They must pin down some primary lever, and at the same time positively prevent movement of the racking handle. Such a device, illustrated in Fig. 48, is in the form of a locking bar securely fastened and padlocked into position. The bar has two pins, and the holes are so arranged that only the correct bar, which is made to exact dimensions, will effect the desired purpose. Moreover, the bar is chained to the rest of the earthing equipment.

The system of plug earthing is not always applicable, and, as an alternative, a separate oil-immersed earthing switch has been embodied in the initial design of each unit panel, interlocked with isolating switches, and preferably, in large switchgear, closing on one phase at a time. This phase-by-phase earthing is a precaution reducing the extent of the damage caused in the event of the accidental earthing of a feeder alive from the far end, the resultant damage being then limited to that of a single-phase fault to earth through the earthing resistance.

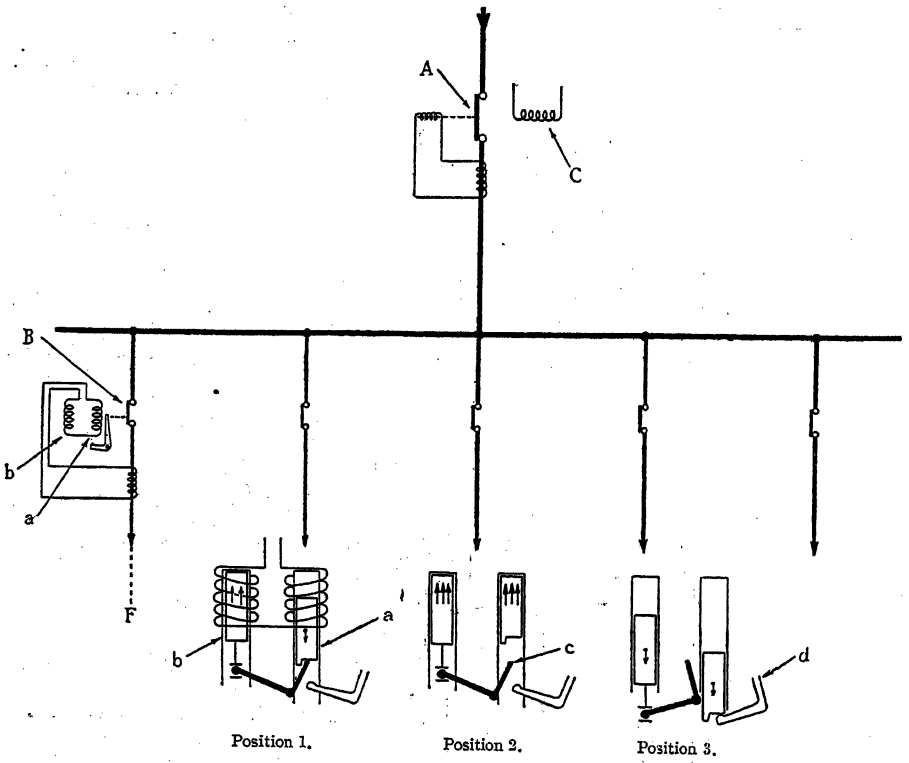

FIG. 46.—Principle of sequential group-switching (necessary time-limit elements omitted for simplicity).

a.—Over-current coil and plunger.
b.—Under-current coil and plunger.
Position 1.—Normal condition. Plungers "a" and "b" are interlocked mechanically.
Position 2.—On a fault at F, plunger "a" is lifted, and both plungers are held up until main fault current ceases, i.e. until group circuit-breaker A opens on self-contained over-current release.
Position 3.—Plunger "b," in falling, removes interlock "c" from path of plunger "a," which falls on tripping-arm "d" and trips feeder circuit-breaker B.
Group circuit-breaker A recloses automatically by coil C after a short interval.
On healthy feeders, plungers "a" and "b" remain interlocked as in position 1.

(xx) Fault-Current Limitation.

The need for care in the lay-out of circuits in its effect on the selection of switchgear has become more and more obvious with the continued growth of systems; and reactors are being used to an increasing extent in order to limit the consequences of short-circuits, and to minimize as far as possible the size of the switchgear required for any given network. To obtain metal-clad construction of reactors, methods have been tried out using windings consisting of single or multi-core cables on a concrete former; but the enclosure of suitably screened coils in oil-filled tanks, following transformer practice, is proving more economical. Fig. 49 illus-

trates a novel combination of switchgear with reactance in feeder circuits. Incidentally, it also shows the

alternative switching method of earthing the feeder cable referred to in the immediately preceding paragraph.

Further, while considering metal-clad auxiliary equipment it is interesting to note the revival of liquid resistors for use in earthing the neutral point of high-voltage systems. The employment of metal-covered cables in this circuit permits the application of metal-clad principles in a simpler manner than is possible with any other form of earthing resistance. The negative temperature-coefficient of the liquid operates in the direction of providing a " current-growing " effect when earth-fault currents are passing.

(xxi) Tripping Batteries.

An advantageous change in the type of battery in common use for substations has been made. Primary batteries of Leclanché cells have been found wanting,

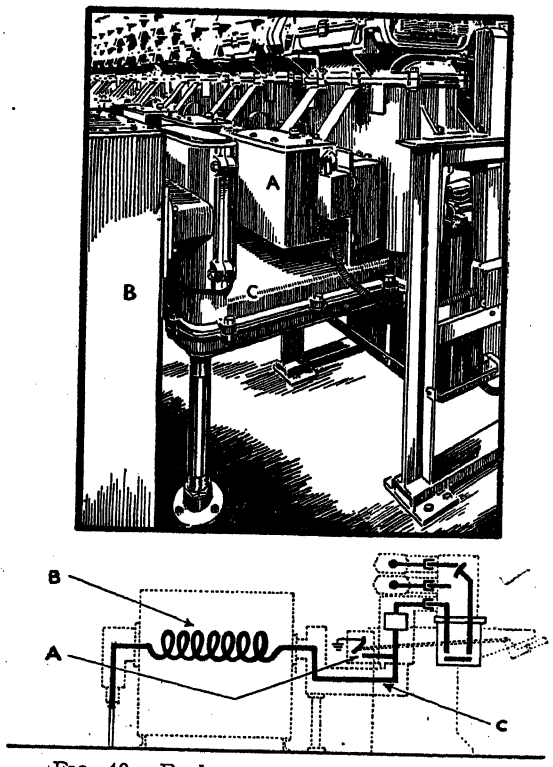

FIG. 49.—Feeder reactance and switchgear.

A.—Earthing switch.
B.—Metal-clad reactance.
C.—Trunking for connections between switchgear and reactance.

owing, for example, to corrosion of terminals requiring excessive maintenance in cleaning, breakage of jars, excessive creepage, and evaporation of the electrolyte. The labour involved in periodic inspection and overhaul has justified a preference for secondary batteries of the nickel-cadmium type, which incidentally are more in conformity with the principles of metal enclosure, and for that reason effect economy in space and maintenance cost. The " trickle " charging of tripping batteries is now a point worthy of attention, particularly for large sizes, which cannot be conveniently transported to a charging station.

(3) AUTOMATIC ISOLATION OF FAULTS.

(i) General.

In no period of the history of automatic protection has the quest for change in design been so active. The

increased length and importance of lines introduced by the British grid have made the need for stability still more pronounced, and the technical difficulties more acute. In the same connection, the reduction in cost of pilots in discriminative feeder-protective systems, or their total elimination, has been insistently called for by the Central Electricity Board in its exercise of economy.

Attention was first paid to the perfecting of the established balance (Merz-Price) systems, and several detail corrections made these acceptable, but only for short lines on account of the high cost of long pilot cables. Then came the time/distance system, with a study of the earlier impedance types and the later reactance types, concentrating upon the reduction of time in operation in order to approach the quality of the balance systems. In the meanwhile, consideration of the possibility of cheapening the pilots for balance systems helped to evolve systems using the inter-operation of relays by means of signals that could be passed over channels used for telephony, or by means of high-frequency currents superimposed on overhead lines. Recent thought has been in the direction of quickening the action of protective gear between the occurrence of a fault and the isolation of the faulty section, on lines of any length, with the use of a practically costless pilot, and without sacrifice of stability.

Protective systems operating in the minimum possible time are referred to as " instantaneous," although the description can never be strictly correct, because a relay requires time even to energize it, apart from the time taken to operate it. It implies that the action of the protective system is such as to start the operation of the trip mechanism of the circuit breaker without deliberate delay. The ideal system would be truly instantaneous, and in addition, to be perfect for universal application, should be a unit system; that is to say, its operation and discrimination on any one section of the network should be independent of the operation and discrimination on any other section, so that the network may be extensible in any way, with tees as well as with loops, without interference with any existing equipment.

The interlinking of power stations and systems is now on so large a scale that a possible reduction of circuit-breaker stresses in dealing with short-circuits has sometimes been suggested by means of automatic sectionalizing prior to the clearance of the line on which the fault exists. Time-limit over-current releases have always been required at power stations and other crucial feeding-points, as a precaution against failure of the switchgear or of the discriminating protective equipment, which constitutes a busbar fault; and the application of these at an additional number of points is preferable to sectionalizing into blocks interconnected by circuit breakers with over-current releases between sections of the network, on account of the dislocation that would be caused by the too frequent unlinking of plant or network, with possible difficulty in subsequent recoupling.

Even with the best of discriminative protective systems, " back-up " protection will always be required, because of the risk of a circuit breaker failing to clear although the protective system has initiated its operation correctly. Moreover, the zone covered by the protective system does not usually include the busbars or the transformers themselves. The transference of operation from one relay to adjacent relays with an additional time-delay in the event of a circuit-breaker emergency has been proposed; and balance or leakage protection has been used to clear all circuits connected to a busbar fault; but neither of these by itself is a complete solution. When complete back-up and busbar-fault protection is regarded as essential, it can be best secured by the addition at all feeding-points of time-limit over-current releases, preferably of the inverse-current type, with low definite minimum time-settings.

Of the classes described in Section (3)(iii) below, the balance class contains the best examples of technically ideal unit systems; the self-balance class also includes unit systems; the unit systems of the direction class have a limitation in respect of adjustments when adding tees to feeders; and the time class, although not completely of the unit type, has the inherent advantage of providing back-up and busbar protection, since operation in adjacent sections overlaps, with time-discrimination.

(ii) Limitation of Damage.

The ideal of instantaneous isolation of faults has been generally accepted. Formerly, long time-limits were adopted in some quarters as a means of discriminating, but now it is realized that the original North-East Coast practice of maximum speed of fault-clearance is essential for restriction of damage as well as for continuity of supply. The tendency is to think in terms of the minimum number of cycles required to clear a fault from its start to the interruption of the arc in the circuit breaker; that is to say, during

(1) The operation of the relay.
(2) The energizing of the trip-coil.
(3) The movement of the circuit-breaker parts up to the point of separation of the sparking contacts.
(4) The arcing period before extinction.

For example, on a 33 000-volt network, with an instantaneous protective system, it should be possible to clear a fault in 8 cycles. The various forms of protection have to be judged by whatever number of cycles their delayed-action characteristic adds to this period.

As a further aid to the limitation of damage by the use of instantaneous protective gear, the operation of the alternator field-switch* is an important addition, the object being to prevent the spread of burning of armature windings and cores after the occurrence of a fault. This has justified the practice of making the field switch (which takes the form of a direct-current circuit breaker) operate instantaneously, without a discharge resistance, immediately after the initial movement of the main circuit-breaker. For similar reasons, the neutral earth-connections are opened automatically by simultaneous operation of the alternator neutral-earthing switch.

(iii) Present-Day Practice.

Selective protective systems for fault isolation may now be divided into four generic classes according to the way in which they provide discrimination, namely:

(1) Balance; (2) Time; (3) Self-balance; (4) Direction.

Systems for generator and transformer protection fall

chiefly into the first class, and have met modern conditions with little, if any, fundamental change. On the other hand, feeder-protective systems have been changed in general character to meet modern requirements of economy, which have already been mentioned, and are dealt with in further detail below.

(1) *Balance.*—All types of balance protection depend upon the use of a pilot or channel of communication used in the form of a pilot cable or a telephone pair, and are derived from the Merz-Price type of protective systems. This widely-used class includes the McColl bias, the "translay," and the split-pilot systems.* The progress in these has been mainly effective in securing greater stability on the occurrence of "through" faults, in the first-mentioned system by bias opposition in the tripping relay, in the second by eliminating the effects of pilot-wire capacitance currents by adjustment of the field in an induction-type rotary relay combined with a transformer (Fig. 50), and in the third by neutralizing the effect of capacitance, vagabond, and other harmful currents by the use of the conductors in the pilot cable on the split-conductor principle of self-balance, thus operating with plain electromagnetic relays (Fig. 51). In the last-mentioned system, further, a tuning arrangement is used to prevent inadvertent operation of the relays by currents of abnormal frequency.

Another system,† starting on new ground, has for its basis the balance, up to certain limits, of current transformers with a low saturation-point (Fig. 52). Tripping is by overload relays interlocked through a pilot wire. The condition for stability on "through" currents in sound sections is that the sum of the currents circulating in the pilot wires operates lock-out relays, which prevent tripping; but in the faulty section the difference of the currents, now in opposition, is insufficient to operate the lock-out relays, and thus the overload relays are allowed to bring about tripping. The advantage of this system is that the pilot voltage is restricted to a low value, and there is a possible saving in first cost on this account.

A proposal‡ has been fully explored to replace the pilot cable with a telephone pair, by which the secondary currents converted into direct currents through small rectifiers at each end of the feeder would be balanced; but since in the conversion the direction of the power flow in the feeder was not reflected by the direct current in the pilot wire, the system was inoperative for a fault fed by equal currents from both ends of the line. In its simplest form it was like the parent Merz-Price system in having no voltage transformer. It also provided instantaneous operation and, in addition, it could be used with a cheaper form of pilot, such as a telephone pair.

For accuracy in operation and minimum time-function, the balance class remains the nearest approach to the present-day ideal for instantaneous operation. Its main virtues are that it functions on current alone, and that it is a simple and flexible unit system.

(2) *Time.*—The types of protective systems in the time class emanate from serial and graded pilotless time-discriminating devices, of which the fuse is a primitive example. During the period under review the types known as distance-relay systems, using restricted time-discrimination aided by a sense both of direction of power flow and of the distance of the fault from the relay, have progressed, mainly on account of the long lines of the British grid, to the extent that now, for 132 000-volt lines of 12 miles in length and over, the characteristics are nearly equal to those of the balance class in speed of operation. The impedance system and the ratio-balance system* are modern systems in this class. Such systems provide discrimination by automatically controlling the time-delay in accordance with the distance of the fault from the relay, as measured, for example, by the impedance of an earth-fault loop in the impedance system, and by the reactance of an earth-fault loop in the ratio-balance system.

Experiments with open arcs have proved that, owing to the inconsistency and variation in the resistance of an arcing fault, impedance measurement may lead to incorrect location of the fault, with consequent isolation of the wrong section, whereas by eliminating the resistance component in the relay design a reactance measurement is obtained by which the risk is removed (see Appendix III). The technical limitations imposed by time-grading put this class at a disadvantage when compared with the balance class; but on the other hand the entire elimination of the pilot compensates liberally for its lack of simplicity, which in essence is due to the addition of a voltage element for direction and distance detection, and other auxiliary selective devices.

(3) *Self-balance.*—In this class, the pairing of cables, or of conductors, provides the means of fault discrimination. Types still in use are split-conductor protection, using two cores for each phase or two separate 3-phase cables or lines in parallel with the conductors grouped in pairs, and 4-core protection, in which only one phase is paired. They depend for operation upon the inequality of current in the conductors of a pair caused by a fault. Where the use of two cables or lines in parallel is not impracticable for other reasons, protection is secured for a negligible extra cost.† The principal problem originally encountered was to ensure tripping at the feed end of the protected line with a fault at the far end. This was solved by using an expensive reactance-type current transformer with an ordinary circuit breaker, and later by using a split-conductor circuit breaker with single-turn current transformers. A recent solution adds a pilot in the form of a telephone pair, which enables an ordinary switch to be used‡ (Fig. 53). The pilot thus takes over the function both of the reactance-type transformers and of the special circuit breaker with split conductors. The use of tees off main cables is frequently a handicap to protective systems. Split-conductor protection can be adapted to a tee-off in the way shown in Fig. 54, in which a differential reactance bridges the splits, and the consumer's load is protected by a switch-fuse. The self-balance class operates only on current, and in this respect ranks with balance protection for simplicity. The systems it includes are also unit systems.

† *Journal I.E.E.*, 1925, vol. 63, p. 443.
‡ Gripper.

(4) *Direction.*—Apart from parallel-feeder protection using directional relays, the entire progress in this class has been recent. A system was proposed at one time* for the protection of an interconnector between two power stations, but since isolation of the fault depended upon fault current being fed from both ends simultaneously, and at that time reverse-power relays were not up to present-day standards of reliability, it made no progress. A lock-out scheme† was proposed long after for overlapping operation on a chain of feeders, but it has not found favour owing to its being a non-unit system. This and other later systems in the direction class obtain discrimination by the transmission of a signal over a pilot.

The interlock‡ system (Fig. 55) was developed to provide unit protection and to enable the signals required for discrimination to be transmitted over any form of pilot. The tripping of the circuit breakers is prevented by the lock-out signal transmitted individually in each section that carries a "through" overload or earth-leakage current, first consideration being given to stability. No signals are sent on the faulty sections, and hence the circuit breakers on these are allowed to operate as soon as the sound sections are stabilized.

To effect further economy, the system was so designed that if, for example, a telephone pair were used normally for telephony or control it could be borrowed momentarily for transmitting the signals during the existence of the fault on the protected feeder, after which it would be restored to its normal use. By this innovation an important step in design was made towards the elimination of a separate pilot for protection alone: an answer was given to the demand for pilot economy by producing a workable system with a practically costless pilot.*

Another variety of this form of protection was subsequently evolved,† in which the relays transmit, in a manner similar to the established duplex telegraphy, dual signals for stabilizing the lines carrying "through" fault currents, whereas the balance of the signals at the ends of the faulty line allows tripping of the circuit

breakers. This method is an interesting and novel application of a well-known system of signalling, and may prove to have its advantages in that it includes sequential functioning of relays for faults fed from both ends, thus speeding up the operation on faults of this type; but the means of transmitting the signals would appear to confine its application to pilot-wire working. In one form, the pilot wire is embedded in the core of the earthed guard-wire to effect economy.

A reduction in the operating times of these protective

systems when applied to networks would be a desirable advance towards the ideal of instantaneous protection; but it should not be made by taking a risk in cutting down the time-margin required to secure correct sequence of locking and tripping.

The method of employing superimposed high-frequency current over the power line as the pilot for an interlock system, which is now established in British practice, is shown in simplified diagram form in Fig. 56. The use of a uniform definite time-margin provides the necessary

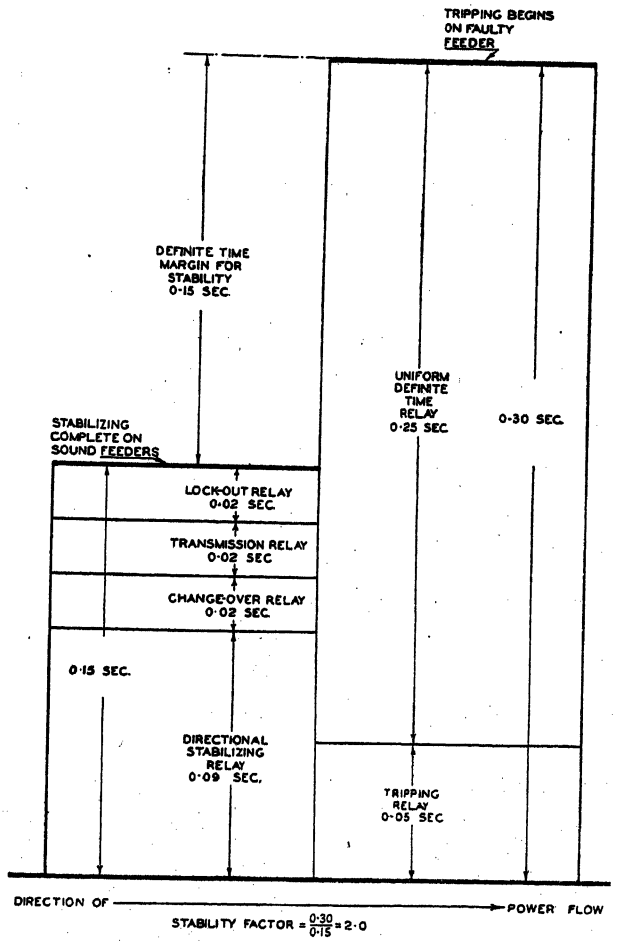

FIG. 57.—Stability diagram of superimposed interlock protective system.

stability by locking out the sound feeder prior to tripping the faulty feeder (Fig. 57). Since operation takes place without the passage of a signal over the faulty section, a breakage of a line does not interfere with the normal operation of the protective system.

The directional class, in general, suffers like the balance class in requiring a pilot, and like the modern time class in requiring voltage elements for direction-detection; but on the whole, in economy, it lies between the two classes, because the voltage element may be disregarded relatively to the pilot, and the pilot itself is, at the most, inexpensive when used in one or other of the phantom forms described. Interlock systems of this class go a long way towards reaching the ideal; and, given a directional element to function on current only, the operating merits of the Merz-Price system would be obtained without the cost of pilot wires.

(iv) Safeguarding Telephone Systems.

A new item not included in the recently-reviewed problem of interference between power and communication circuits* arises out of the introduction into protective systems, and also into the remote-control systems referred to later, of telephone pairs and channels, which thus become electrically associated with the power lines through voltage transformers, current transformers, and earthing network. A failure of insulation on the transformers, which is a rare occurrence, directly raises the potential of the secondary circuits, but in addition, when an earth fault develops in this or any other part of the power circuits, momentary potential differences are set up because of the resistance of the earth-return path, and this also raises the potential at some part of the telephone-cable sheath above that of the enclosed

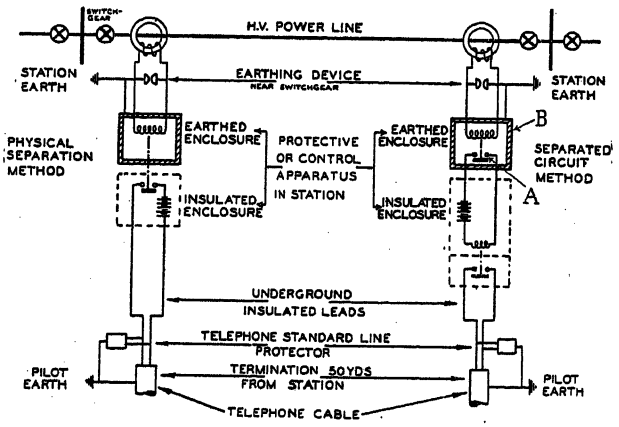

FIG. 58.

For explanation of A and B, see Appendix IV (page 329).

conductors, the amount being dependent upon the proximity of the sheath to the main earth-circuit of the power system. Research on these possibilities, carried out by means of a test plant with fault currents simulating service conditions, has proved that definite precautions are necessary for ensuring safety and non-interference with telephone service (see Appendix IV). These are indicated diagrammatically in Fig. 58, and involve the use of separate earthing-devices for the secondary circuit and, as further safeguards, either "physical separation" or a "separated circuit" in the association between the secondary circuit and the telephone cable, and a separation of the telephone cable earth from the main earth-plates of the power network.

(4) REMOTE AND AUTOMATIC CONTROL.

(i) General.

Now that large areas are dependent for their most efficient supply on a properly controlled division of load between generating units, which are whole power stations instead of single generators, some means is essential of focusing at a central point in an easily

* W. G. RADLEY: *Journal I.E.E.*, 1931, vol. 69, p. 1117.

visible way all the information required to enable the controlling staff to issue general directions to the several units concerned, and actually also to initiate such switching and other major operations as are required from time to time by changing conditions of consumption.

The remote control of switchgear, although it was primarily adopted for convenience in control on account of the compact assembly of the operating switches and instruments, acts as a safety feature also. The safety feature may be extended to promote maintenance of supply by the further development of remote control and the addition of automatic control, in virtue of its acting as a substitute for human thought through operative functions definitely predetermined to correspond to preconceived occurrences.

It was stated* in 1924 that "no system appears to have been constructed taking full advantage of all the means available, i.e. using discriminating protection in combination with automatic indication and code signalling, and it is probably a matter for satisfaction that this possibility of improved working is in reserve and available to meet the more onerous conditions towards which electrical developments appear to be moving. . . . We may expect to see systems in the future more extensive in area and dealing with much larger loads than anything now contemplated. Successfully to control such systems will probably require, in the completest combination, all practicable safeguards known to the present-day electrical engineer."

The time foreshadowed is now upon us, but we have yet to put to their full use all the known combinations of control, indication, and protection. There are, however, instances of partial steps towards the fulfilment of this prophetic statement, sufficient in themselves to justify an attempt to predict the state of practice in another decade.

* P. V. Hunter: "Control and Switching of High-Pressure Distribution Systems," abstract of paper read before the Société Française des Electriciens, *Electrical Review*, 1924, vol. 94, pp. 72 and 118.

The progress of the automatic control of substations has led to other remote and automatic control schemes of great importance, such as automatic synchronizing of generating plant and automatic frequency-control with load-sharing; and these, in a centralized form, are now fully practicable. The problems dealt with during the past seven years, like those of protective gear, have been made more pressing by the requirements of the British grid; and again the type of control equipment used is governed by the pilot or the means of communication available.

(ii) Power-station Control Boards.

A typical control board for a large power station, with its operating diagram, is shown in Fig. 59 (Plate 1). The apparatus in the middle of the foreground is for the remote control of the generators, and at the sides for that of the auxiliary equipment.

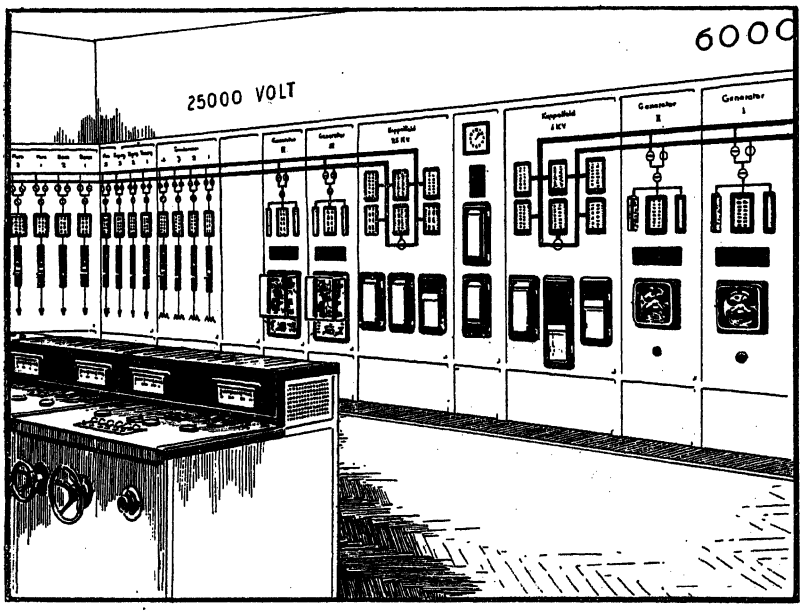

Fig. 60.

Much attention has been given to the neatness of control boards, and particularly to diagrammatic indication and instruments. An example of Continental practice is shown in Fig. 60. The lining-up of a "light-band" on a flat profile-type instrument is effected by having a scale of ground glass illuminated by a small lamp. The light is obscured by a blind, which moves according to the amount of current through the coil. The instruments form part of the diagram, and are uniformly calibrated so that a glance shows an area of light that affords a measure of the total load.

This leads up to a control board as shown in Fig. 61, on which the several circuit breakers, and possibly the isolating features also, are operated by keys situated in the diagram lines and mounted in a sloping circular plane just below the indicating instruments. Relays and recording instruments, which need only occasional inspection, are mounted at the back, with an intervening space forming a well-lighted passage-way and giving access to the wiring, terminal boards, and cable boxes.

In this way the control engineer has only the essential operating features before him, and this simplification allows concentration upon vital issues. A further aid is the use of superimposed system-diagrams embodying the new feature known as premeditated switching (Fig. 62). This enables the control engineer, by the operation of keys, to rehearse on the diagram the switching operations he intends to carry out, and as he does this the differences between the contemplated changes and the actual conditions are recorded on the diagram. Having satisfied himself that the new switching scheme is correct, he then puts it into practical operation, and in so doing brings about agreement on the diagram between the intended and the actual switching conditions.

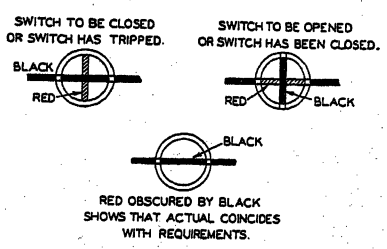

FIG. 62.

A modern control board of this type may include also a diagram of the steam connections, and these connections can be indicated and controlled in the same kind of way as the electrical connections. In one power station,* controls for the boiler fans, dampers, and stoker motors, are arranged on a board together with the steam-valve controls, thereby providing centralized operation of the whole of the extra-high-pressure steam plant. For this installation there is complete desk-control in the e.h.p. turbine room of the 1 100-lb. boiler plant, which is all electrically operated; and although no diagram of the steam connections has actually been incorporated in the control board, such a diagram could readily be added if thought desirable.

* Bradford Corporation.

(iii) Network Control Rooms.

The lay-out of control rooms has afforded scope for much ingenuity in the design of detail parts and of their architectural structure. For example, the old painted diagrams, on which tallies and labels were hung, are replaced by diagrams engraved on metal panels (Fig. 63, Plate 1). Signal lights are operated from a desk keyboard on receipt of information by telephone, and remotely-operated instruments indicate the load distribution continuously. Figs. 64 and 65 show details of the Bennett-system lights and diagrams included in this network control.*

The short-circuit calculator is the latest addition to control-room equipment, and an example is shown in Fig. 66 (Plate 1). It consists of a group diagram representing completely the interlinking of all power stations and distributing points. Each unit of the generating plant, reactances, and network, is represented in miniature by a resistance proportional to the impedance of the actual circuit it represents. The diagram is therefore adjustable to represent any quantity

* London Power Co., Ltd., Ergon House.

of running plant and any condition of premeditated or actual switching. The switching connections are represented by dual-conductor plugs, each circuit being of the dual type in order to enable both earth-fault currents and phase-fault currents to be determined. A complete picture of all connections is seen at a glance, and the short-circuit current that would occur in any vicinity can be read straight off on a portable instrument, which can be plugged in to the position of any of the switches.

The problem of controlling distribution networks extending over large areas, such as those of the British grid regional schemes, has introduced considerations that have resulted in the adoption of selective control over pilots, and a corresponding elimination of hand-operated indicating and recording apparatus in favour of automatically-operated devices.

A difficulty in using pilots in tandem arises out of the congestion of signals, and they are therefore arranged

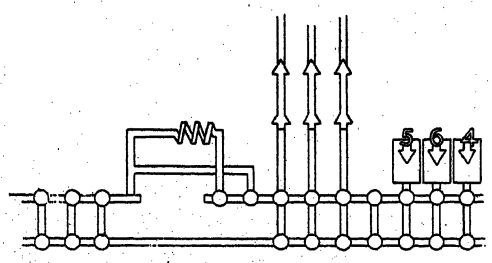

FIG. 65.

radially to ensure immediate indication and flexibility of control. In this system, pilots radiate from the regional control rooms to each of the controlled stations in the area. In the past, the tandem system of pilots has been found suitable for the control of direct-current traction systems, owing to the saving of initial expenditure on pilots; but for the requirements of control of the more vital grid supply the more direct-acting radial system is preferable. To economize in the cost of pilots, Post-Office channels of communication may be used between the control room and the controlled station. Direct current is preferred whenever it is available, but alternating current at audio frequencies may be used as an alternative. A scheme has been developed for places where pilot wires exist already for a balance system of protection, in which the same pilots can be used by the addition of relays to cut in the pilot wire for protective service only when required.

The new requirements have led to the development of equipment that may be divided into two broad classes. The one class uses telephone-relay-type equipment, which has been adapted to meet the modern requirements of plant control; and schemes embodying such apparatus are known as "supervisory control." Trains of impulses

F.—General alarm and telephone (zero position).

are transmitted for the indicating and metering signals, these impulses being received by suitably-adapted telephone-selectors, which in turn operate appropriate relays to control lamp indicators and meters.

The other class of control apparatus centres upon a control dial as shown in Fig. 67, with mechanism more on the lines of switchgear equipment, and the schemes incorporating it are known as "centrovisory control." The principle underlying their development is the replacement of numerous small relays and their electrical circuits by mechanical devices, together with a few robust relays.

The transmission of meter readings is effected by means of a direct-current or alternating-current signal from the controlled station, the duration of the signal corresponding to the time taken for a pointer driven by a timing device to traverse a distance from a fixed zero-point to the position of the pointer on the measuring instrument.

(*See Plate 2 for key.*)

FIGS. 73 and 74.—Oscillograms of (1) Test No. 572B, and (2) 601.
(See Plate 2 for key.)

At the control room a pointer is driven by a similar timing device for a similar period, and indicates and records the reading of the remote meter. In this way meter readings and transformer-tapping positions recorded in the control room tally with those in the controlled stations.

In a regional control room operating on these lines the services provided by the 132 000-volt and 66 000-volt centrovisory control board are as follows:—

(1) Premeditated switching superimposed by hand on a system diagram.

(2) Automatic indication and comparison with (1) of the position of each circuit breaker.

(3) Alarm signal when a change of condition occurs, followed by automatic indication (2).

(4) Indication of the position of all transformer voltage-tappings.

(5) Alarm signal when any transformer tap-position is changed.

(6) Indication of kW input or output through the transformers and feeders.

(7) Indication as in (6) of the reactive kVA.

(8) Indication of voltage at selected positions on the system.

(9) Indication in kW of the total generator load at various stations.

(10) Transmission of stereotyped instruction-signals from the control room to various controlled stations.

(11) Telephone facilities from the control room to all controlled stations and extensions.

(12) Automatic lock-out on failure of pilot, or by key at will.

The control room is elliptical in shape, and approximately half of its periphery is occupied by the centrovisory control board. The remainder contains a system diagram, which forms a complete picture of the 132 000-volt, 66 000-volt, and 33 000-volt interconnected networks. The control engineer sits in the centre of the room at a desk that carries a condensed key-diagram of the whole system, and from this position he can maintain a correct record of all the connections on the large system-diagram.

Equipment with similar control dials is now being used for the remote control of outdoor transforming stations so distant from an available control room that the additional initial cost of the control is more than compensated by the saving in the multi-core cables that would be required for ordinary remote control. The control then includes, as an additional feature, the remote operation of circuit breakers and transformer taps, and thus advances a stage further in the direction of complete centrovisory control. One of the control boards is illustrated in Fig. 68, which shows that the several indications are given on two adjacent dials.

The foregoing indicates the progress made in the field of remote and automatic control, and the time is not far distant when regional control schemes will incorporate not only the direct operation of equipment by the control engineer, but also the further use of automatic control, which has already been tried out, for maintaining constant frequency, giving the possibility of a time-service and securing efficient interchange of load on the network. To this there may be added another function, over and above premeditated switching, namely, the giving of an indication, prior to actual switching, of what will be the effect of the switching. Thus the operator is relieved from mental strain, because of the rehearsal of each proposed performance beforehand.

The way in which the apparatus now coming into actual service extends, so to speak, both range of human vision and length of human arms is one of the important factors making for the success of any national or other widespread scheme.

The author takes this opportunity of acknowledging co-operation from his co-director, Mr. Frank Coates, and his staff, over many years in the design of the Reyrolle products, and from his colleagues, Mr. L. E. Mold and Mr. B. H. Leeson, in furthering the progress of the principles involved. He would also thank Mr. B. H. Leeson and Mr. T. Carter for the large amount of assistance he has received from them in the preparation of this paper as a whole, and other members of his staff, including Mr. W. A. A. Burgess, Mr. A. Allan, Mr. J. A. Harle, Mr. R. H. Brierly, Mr. D. E. Lambert, Mr. H. Leben, Mr. H. Rutherford, and Mr. A. Peel, for help with technical details and drawings.

APPENDIX I.

STANDARD CONDITIONS FOR SHORT-CIRCUIT TESTS OF CIRCUIT BREAKERS.

The predominant factors determining the severity or stress to which a circuit breaker is subjected, when undergoing short-circuit tests to establish its making-and-breaking-capacity performance, are as follows:—

(*a*) The rated voltage of the test circuit.
(*b*) The recovery voltage of the test circuit.
(*c*) The restriking voltage of the test circuit.
(*d*) The "making" current in the test circuit.
(*e*) The "breaking" current in the test circuit.
(*f*) The frequency in the test circuit.
(*g*) The power factor of the test circuit.
(*h*) The earthing of the test circuit.
(*i*) The type of short-circuit applied.
(*j*) The testing equipment used.
(*k*) The operating duty performed.

To ensure that a circuit breaker shall perform its rated "making" capacity and "breaking" capacity satisfactorily in service, it is necessary that the conditions under which the rating is assigned by short-circuit performance tests shall conform as closely as possible to the conditions of severity existing in service. The ideal practice would be for the test conditions to be adjusted to imitate exactly the conditions under which each individual circuit breaker is to be used. These conditions differ widely, however, and in addition to being difficult to calculate within any close limits of accuracy, they vary from time to time owing to the varying amount of plant and load connected to the network, and, further, they change as the plant and network extend. The practice actually adopted, therefore, is to standardize conditions of severity for performance tests in conformity with the average conditions encountered in service.

If a circuit breaker rated on the basis of a test performance obtained in this way is used under more severe conditions in service, its behaviour must be expected to differ also. Such differences between standard conditions and service conditions should be considered when selecting a standard circuit-breaker rating, and if the divergence is considerable, or likely to increase as the network extends, it may be necessary to select the next larger standard rating. Conversely, if the service conditions are easier than the test conditions, it may be permissible to select the next smaller rating.

In addition to standardizing conditions of severity for testing, it is of equal importance to standardize the method of interpreting the oscillograms obtained from short-circuit tests in terms of actual performance figures. Although B.S.S. No. 116–1929 goes a long way towards establishing the desired standard conditions and methods of interpreting oscillograms, it does not cover the requirements completely, and Clause 72(iii), which allows a test performance to be measured in terms of "kVA broken," requires modification in order to line up with the remainder of the Specification, which rates a circuit breaker on the value of the currents it will make and break at the rated voltage.

In the author's opinion, recovery voltage should be treated as a condition of severity in the standard test circuit, in the same way as the standard power factor.

The proposals set out on pages 319 and 320 are intended to assist in establishing an international method of proving the ratings of circuit breakers by standardized short-circuit performance tests; they are based upon average conditions of severity met with in service, as well as upon the experience gained with the aid of a British test plant,* and the behaviour of circuit breakers in service, judged over a period of 25 years.

The proposals standardize testing conditions and methods to be used for interpreting oscillograms, and specify what is virtually a standard test-circuit. Such of them as are applicable may also be used for tests of other devices, including cut-outs, switch-fuses, reactors, and transformers.

In practical application it has been found that the effects of deviations from the proposed standard conditions of severity usually average out satisfactorily, and two examples will illustrate this. The first is that a small circuit breaker rated at 100 000 kVA, and situated at the end of a long feeder with a large amount of generating plant feeding into it, is subjected to a recovery voltage of nearly 100 per cent, whereas the proposed standard recovery voltage is only 80 per cent; but this more onerous condition is compensated by the easement introduced by the improvement in the power-factor condition as compared with the standard of 0·1 lagging. As a second example, a large circuit breaker of, say, 1 000 000-kVA rating, situated in a generating station, will be subjected to as low a power factor as the standard 0·1 lagging; but the recovery voltage is likely to be less than the proposed standard 80 per cent. This means that the service conditions for this circuit breaker are likely to be easier than the test conditions; but this difference on the safe side is desirable in view of the importance of this circuit breaker on the network. In a minority of cases, the conditions, as already indicated, may be such that a larger standard circuit-breaker rating must be selected, or a smaller rating may be selected.

To sum up: The proposals for standardized performance tests are based upon what the author believes to be a fair representation of average conditions of severity met with in service, namely, those under which a circuit breaker would be required to operate on a short-circuit near to generating plant.

With a 10 000-kVA generator having 10 per cent reactance, a circuit breaker would have to break approxi-

PROPOSALS FOR STANDARDIZED PERFORMANCE TESTS.

Item	Specification	Interpretation
(i) Circuit breaker under test	(1) A representative product erected under its service conditions (2) Below 66 000 volts, test 3-phase and 2-phase circuit breakers as complete units on a 3-phase or 2-phase test circuit respectively (3) At and above 66 000 volts, circuit breakers may be tested as single-phase units	The conditions specified imitate general practice in respect of circuit-breaker construction and permit the reproduction of the recovery voltages experienced in service at these rated voltages
(ii) Rated voltage	The standard voltage at which the circuit breaker is rated (B.S.S. No. 116–1929, Clause 47, Table I)	(*a*) The actual voltage of the test circuit may exceed the rated voltage for convenience or in order to obtain the specified recovery voltage (*b*) The voltage used to calculate performance shall be the rated voltage
(iii) Recovery voltage	80 per cent of the rated voltage, at the instant of final current-break	The recovery voltage shall be determined from the oscillograph record by taking the R.M.S. value of its normal-frequency alternating-current component extrapolated back to the point at which current is broken in the last phase to break. The specified value of 80 per cent is a minimum
(iv) Restriking voltage	Not specified numerically	The restriking voltage exists as a transient at the instant of arc extinction, and can only be measured by a cathode-ray oscillograph. These test-proposals do not include numerical values of the restriking voltage, but they implicitly control its order of magnitude and other characteristics by the necessity for including in the test circuit definite values of inductance, capacitance, and resistance, to produce the specified standard conditions
(v) Making current	Peak value of the current in the first major half-cycle after the arcing-contacts make circuit [B.S.S. No. 116–1929, Clause 72(i)]	See B.S.S. No. 116–1929, Fig. 2, in which the peak making-current includes the direct-current component
(vi) Breaking current	R.M.S. value of the current at the instant of separation of the arcing contacts [B.S.S. No. 116–1929, Clause 72(ii)]	See B.S.S. No. 116–1929, Figs. 1 and 2, in which the R.M.S. breaking-current includes the direct-current component
(vii) Frequency	50 cycles per second [B.S.S. No. 116–1929, Clause 44(2)]	
(viii) Power factor	0·1 lagging [B.S.S. No. 116–1929, Clause 44(3)(i)], measured at the instant of separation of the arcing contacts	(*a*) The power factor of each phase of the test circuit shall be the cosine of an angle ϕ determined from the oscillograph records of that phase after superimposing a continuation of the open-circuit voltage-wave on the short-circuit current-wave far enough to include the point at which contact separation occurs. The measurement shall be made as follows: (1) For symmetrical current-waves, ϕ shall be the angular distance between the initial zero of the half-cycle of the current wave in which contact-separation occurs and the superimposed-voltage-wave zero immediately preceding that current-wave zero

[*continued on page 320.*]

PROPOSALS FOR STANDARDIZED PERFORMANCE TESTS—*Continued.*

Item	Specification	Interpretation
(viii) Power factor (*cont.*)	0·1 lagging [B.S.S. No. 116–1929, Clause 44(3)(i)], measured at the instant of separation of the arcing-contacts	(2) For asymmetrical current-waves, ϕ shall be the angular distance between the initial zero of the alternating-current component of the half-cycle of the current wave in which contact-separation occurs and the superimposed-voltage-wave zero immediately preceding that current-wave zero (Note.—For convenience of measurement, the zero of the alternating-current component of the current wave may be projected vertically to the zero line of the superimposed voltage-wave.) (*b*) The power factor of a polyphase test-circuit shall be the cosine of the average of the angular distances ϕ of all the phases (*c*) For calculating the power factor before tests are made, the formula $\phi = \text{arc tan } (X/R)$ may be used, where X and R are the short-circuit values respectively of the reactance and the resistance of the test circuit
(ix) Earthing	(1) Below 66 000 volts, insulate the neutral point on the supply side of the test circuit (2) At and above 66 000 volts, solidly earth the neutral point on the supply side of the test circuit	The conditions specified imitate British practice, and (1) covers also earthing through a comparatively high resistance
(x) Short-circuit	Connect solidly to earth each pole on one side of the complete circuit breaker or of the single-phase unit under test	(*a*) The test circuit shall be so adjusted as to produce the specified standard conditions of severity, and the short-circuit current obtained from the testing equipment shall be regulated to the required value, by means of a combination of resistance and reactance in series, not in parallel, with each other, and/or by varying the field excitation of generating plant (*b*) Resistors, reactors, or condensers, except those authorized for measuring purposes, shall not be used in parallel with the circuit breaker
(xi) Testing equipment	(1) Below 3 300 volts, connect the circuit breaker to transforming plant (2) From 3 300 volts to 22 000 volts, connect the circuit breaker direct to generating plant (3) Above 22 000 volts, connect the circuit breaker to transforming plant	(*a*) The conditions specified imitate those usually applying in service at these voltages (*b*) The records of current, voltage, and power factor, shall be made by means of either electromagnetic or electrostatic oscillograph elements (*c*) The apparatus for measuring current shall consist of either shunts or current transformers inserted in the test-circuit, and the apparatus used for measuring voltage shall consist of voltage transformers, series resistors, or capacitative voltage-dividers (*d*) The connections between the circuit breaker under test and the source of the short-circuit power shall be of the shortest possible length
(xii) Operating duty	(1) Making capacity: M–2 : M–2 (B.S.S. No. 116–1929, Clauses 39 and 42) (2) Breaking capacity: B–2–MB–2 (B.S.S. No. 116–1929, Clauses 41 and 43)	"M" signifies *make circuit* "B" signifies *break circuit* "2" signifies *an interval of 2 minutes* "–" signifies *continuity* within a test cycle ":" signifies *a division* between test cycles
(xiii) Test certificate	A complete and precise record of the performance test, including the condition of the circuit breaker before the test, its behaviour during the test, and its condition after the test	The test certificate shall specifically state any departures from the standard conditions and methods of interpretation, and shall indicate whether such departures increase or diminish the severity as compared with the standard

mately 100 000 kVA on a short-circuit with normal conditions of tripping. On rare occasions, however, it might open on the first half-cycle of the short-circuit transient, and would then have to deal with a possible maximum of the order of 133 000 kVA.* A correct interpretation of the performance tests under standard conditions will indicate what standard rating a circuit breaker must have to ensure its suitability for this service.

APPENDIX II.

Some Short-Circuit Tests of Circuit Breakers.

The breaking-capacity ratings assigned to British circuit breakers are based on standard breaking-capacity currents at given rated voltages in accordance with B.S.S. No. 116–1929. A size to which such a rating is assigned has also, for convenience, a standard kVA rating, obtained by multiplying the standard current-breaking-capacity rating by the rated voltage and by the appropriate phase factor. For instance, a 3-phase circuit breaker of a size† and strength suitable for a current-breaking capacity of 5 200 amperes at 11 000 volts, or 8 800 amperes at 6 600 volts, is also known as a 100 000-kVA circuit breaker (Table IV, B.S.S. No. 116–1929).

Short-circuit tests in Great Britain and abroad show that British circuit breakers perform consistently at and above the rated breaking-capacity currents associated with the standard kVA allocated to them; and a few examples of a large number of 3-phase tests carried out with the aid of a British test plant are summarized in tabular form on pages 322–327. Typical oscillograms, representative of many repeat tests, are shown in Figs. 69 to 74 (Plates 2, 3, and 4), and relate to Tests Nos. 103A, 103B, 244A, 244B, 572,B and 601.

The tests were carried out under the conditions of the standard circuit outlined in Appendix I, and the records were made with oscillograph apparatus of the standard electromagnetic type.

In the majority of the tests the recovery voltage was higher than the author's proposed standard condition of severity of 80 per cent; and in respect of operating duty some tests were more severe than the standard, and some less, as indicated in the operating-duty column. The values of the restriking voltage were not tabulated. The normal frequency of the test supply was 40 cycles per second. The performance of the circuit breakers was in all cases such as to show their entire suitability for their standard ratings.

* It has been claimed on the Continent that in the case of complete asymmetry of current in an inductive circuit the restriking transient voltage is of zero value at the same time as the current. In such a hypothetical case the break is easy. On these premises it is proposed that the direct-current component should be disregarded in calculating the performance kVA. On the other hand, it must not be overlooked that amongst the factors apt to damage circuit breakers in action are the mechanical stress produced by electromagnetic forces and the rate of generation of the gas bubble, which tend to distort the constructional mechanism; and these, together with burning of the arcing contacts, depend upon the magnitude of the resultant of the alternating-current and direct-current components, no matter what method of calculation is arbitrarily agreed upon. Hence the British practice, like the American, has been, and still is, to include the direct-current component. This is important in respect of the maximum of 133 000 kVA referred to here, because the excess over 100 000 kVA is due to the direct-current component; and if it is true that this may be disregarded (which has yet to be proved conclusively by comparative tests on the basis of the stress produced in the enclosure and on the mechanism), the circuit breaker selected need not have a larger rating to deal with the contingency.

APPENDIX III.

Reactance versus Impedance Measurements for Distance Relays.

When applying protection by means of time/distance relays of the time class to overhead transmission lines, it is of paramount importance to decide what quantity the relays should measure in order to provide time-discrimination proportional to the distance of the fault from the relay. Although, in general, correct discrimination may be obtained for heavy earth or phase faults on overhead lines, and for cables, by the use of relays operating on an impedance measurement, nevertheless, on networks of the type of the 132 000-volt British grid, where it is as important to clear small earth-faults as the heavier ones, any time/distance relay protection must be designed fundamentally to meet this requirement. There are three quantities associated with an earth-fault loop, namely, its resistance, its impedance, and its reactance, any one of which might on a first consideration be thought to be proportional to the length of the loop, and therefore suitable as a basis for the required measurement. Further consideration and investigation, however, show that the resistance of an earth-fault loop may vary in many ways, owing to the introduction into the circuit of external resistance, such as the contact resistance of earth plates, the variable resistance of the earth, the contact resistance between the conductor and earth in a broken line, and the resistance of the arcing fault itself, of which more is said below. It has also been shown by tests* carried out by the British Electrical Research Association that the reactance component of the earth-fault loop is reasonably constant.

It will be proved in what follows that the arc resistance is variable, and by no means always negligible in amount; and since it is included in the total resistance of the earth-fault loop, the impedance of the loop contains a variable quantity that may make its value uncertain. The reactance of the loop, however, is not dependent upon the resistance; and therefore distance relays of the reactance type are not affected, but the operation and discrimination of impedance-type relays are directly affected. The seriousness of the effect of arcing faults on the operation of impedance-type relays depends upon the relation between the values of the resistance of the earth-return path and of the arcing fault and the reactance of the earth-fault loop. Since the latter quantity is usually small (approximately 1 ohm per mile of earth-fault loop on the 132 000-volt British grid), even a small resistance in the arcing fault has a considerable effect upon the apparent impedance of the earth-fault loop.

To determine the amount by which the resistance of an arc may affect the correct discrimination of distance relays, tests of power arcs in air, such as occur on overhead transmission lines, were carried out with the aid of a British test-plant. These tests, which are described below, indicate that the resistance of such arcs is a variable quantity, depending upon the length of the arc, the wind velocity, the time during which the arc persists, and the way by which the arc is drawn out. Of these factors, the duration of the arc is of particular

TESTS (*continued*) OF 100 000-kVA THREE-PHASE CIRCUIT BREAKERS WITH STANDARD RATINGS

(*a*) 11 000 volts, 5 200 amperes.

(*b*) 6 600 volts, 8 800 amperes.

(*c*) 3 300 volts, 17 600 amperes.

A series of tests was carried out on another circuit breaker of the same type, to prove its suitability for a 15 000-volt system. During this series, of which the following examples are typical, the test voltage was increased to 16 000 volts for the purpose of maintaining the specified 80 per cent recovery voltage. The neutral was earthed through 12·7 ohms.

Test number	Part of test	Operating duty	Test voltage per phase	Peak amperes per phase in first half-cycle	Breaking current (R.M.S. amperes) per phase	Recovery voltage per phase	Arcing period, half-cycles per phase	Power factor (lagging) of test circuit	Percentage ratio of breaking current to rated breaking current	Remarks
188	A	B	9 240	16 400	6 420	7 600	3·0	0·1	115	Easy. Hiss of escaping gas and slight oil discharge from vents. Contacts, which had been used on previous tests, only slightly more burnt, and retained for next test, No. 189
		2		10 400	5 290	7 780	3·0			
				17 200	6 280	7 600	2·5

				56 000	22 400	2 210	1·25			

TESTS OF A 100 000-kVA THREE-PHASE CIRCUIT BREAKER UNDER FREAK CONDITIONS.

(Tests Nos. 225 to 228.)

A series of four tests was carried out on the circuit breaker used in tests Nos. 165 to 167 recorded above, but with the tank strength reduced by the omission of one tank-stud, and with the total length of break limited to $\frac{3}{4}$ in. (two breaks of $\frac{3}{8}$ in. each). The object of the tests was to discover the effect on the behaviour of the circuit breaker of a hold-up of the plunger-bar travel, owing, for example, to a mechanical defect. The neutral point was insulated during this series. Tests were made with 3 500 amperes at 11 000 volts (No. 225), 6 500 amperes at 6 350 volts (No. 226), and 9 500 amperes at 9 000 volts (No. 227). During these three tests, the maximum arc-duration was 4 half-cycles, and the circuit breaker operated quietly, emitting a slight amount of oil and smoke from the vents. The contacts were not changed, and no adjustments were made to the circuit breaker before the next test, No. 228, which is recorded in detail below.

Test number	Part of test	Operating duty	Test voltage per phase	Peak amperes per phase in first half-cycle	Breaking current (R.M.S. amperes) per phase	Recovery voltage per phase	Arcing period, half-cycles per phase	Power factor (lagging) of test circuit	Percentage ratio of breaking current to rated breaking current	Remarks
228	—	B	6 350	31 200 18 400 32 800	12 300 10 900 13 470	5 530 5 750 5 730	Intermittent arcing for 12 half-cycles	0·1	230	Circuit breaker cleared short-circuit, but high pressure due to arcing period caused weakened tank-flange to bulge $\frac{5}{8}$ in. A tank-stud sheared off. Heavy discharge of oil through flange, and much smoke but no flame

TESTS OF 250 000-kVA CIRCUIT BREAKERS WITH STANDARD RATING 11 000 VOLTS, 13 000 AMPERES.

(a) Tests of a Hand-operated Circuit Breaker with neutral insulated.

255	A	B	6 350	37 760	16 450	5 150	1·0	0·1	133	Easy on A, heavier on B. Slight emission of oil through rope-guides. Arcing contacts burnt, but not renewed for next test, No. 256
				55 850	18 350	4 950	1·5			
		2		47 150	17 600	5 120	1·5

				37 260	18 400	5 620	1·0			

TESTS OF A 1 000 000-kVA CIRCUIT BREAKER WITH STANDARD RATING 6 600 VOLTS, 88 000 AMPERES: NEUTRAL INSULATED.

The following tests were carried out to prove the suitability of this circuit breaker for a 6 000/6 300-volt system.

419	—	MB	3 450	257 100	145 500	4 100	1·5	0·1	140	Switch cleared very sharply. Slight emission of oil from tank flanges and vents. Main contacts clean, but arcing contacts rather heavily burnt
				170 000	101 500	Records	Records			
				215 000	127 000	spoilt	spoilt			
421	—	B	3 450	192 000	72 000	2 700	2·5	0·1	98	With new arcing contacts. Easy operation. Slight emission of oil from vents. Arcing contacts only slightly burnt
				242 000	100 000	2 800	2·0			
				181 000	85 000	2 700	2·5			
549	—	B	3 450	185 800	92 500	3 060	2·0	0·1	113	Arcing contacts in same condition as after previous tests. Operation very quiet. Slight emission of oil from vents. Arcing contacts now badly burnt, and renewed
				151 650	90 300	2 930	2·5			
				214 000	119 500	2 980	2·0			
572	B	B	3 640	163 500	91 250	2 910	2·5	0·1	110	With moderately-burnt contacts. Operation exceptionally quiet. Only slightly more burning. Little oil through vents
				225 000	116 000	2 910	2·0			
				166 000	84 000	3 060	2·0			

The following test was made primarily to prove the straight-through carrying-capacity of the circuit breaker.

601	—	Straight through, followed by break	3 580	229 000	60 500	2 100	4·2	0·1	—	Contacts as used on previous tests. Operation very quiet. Contacts only slightly burnt
				220 400	66 400	2 070	3·5			
				144 500	59 200	2 010	4·5			

importance, in view of the fact that the protective system itself is of the time class. Fig. 75 shows the diagram of connections, and is self-explanatory. The arc was started by means of thin copper wire bridging the two porcelain insulators spaced 6 ft. apart, and the voltage across it was measured by means of a voltage

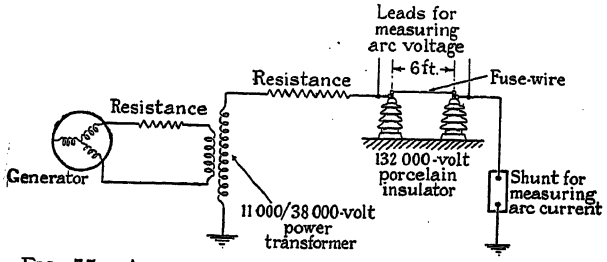

FIG. 75.—Arrangement of plant for tests of power-arcs.

transformer. Both current and voltage were recorded by an oscillograph.

The tests were carried out on a calm day, and there was therefore no undue spreading of the arc by wind, which would tend to increase its resistance. The results are shown in four curves in Fig. 76, which give the arc resistance with various currents after time-intervals of 0·22, 0·45, 0·67, and 0·90 second from the start of the arc. Broadly speaking, the arc resistance decreases as the arc-fault current increases, and increases with increasing length and with increasing time. As was to be expected, the behaviour of the arc was erratic, and it is difficult to forecast the probable variation of the resistance of an arcing fault in actual practice. Since the resistance values shown in Fig. 76 were determined on a calm day, they represent the minimum values likely to be experienced in service, and will suffice to illustrate how the desired discrimination is not necessarily given under all conditions by impedance-type relays.

One of the results of the 132 000-volt British grid will be that generating plant found to be unnecessary will be shut down during periods of off-peak load, and therefore a fundamental requirement of any time/distance type of protection must be to discriminate correctly under such off-peak-load conditions when an earth fault occurs at some distance from a generating station. A study of these conditions indicates that fault currents of the order of 500 amperes are likely to be experienced. On the basis of the curve in Fig. 76 for 0·67 sec., which is taken as being less than the operating time required by the relay at the far end of the feeder, this means that the arc resistance is of the order of 10 ohms. If, as is possible, the fault occurs on a 15-mile 132 000-volt line, which has of itself a total earth-fault-loop reactance of about 15 ohms, the effect is to give an impedance-type relay a falsely related time-delay. The arc resistance continues to increase, and after 0·90 sec. reaches a value of 16 ohms. The process is thus cumulative; and it must be remembered that the values given have to be increased by adding the total earth-plate resistance, which may be as much as 4 ohms. Thus, should the assumed fault occur, say, 12 miles along the 15-mile line, the impedance of the earth-fault loop, excluding the arc resistance, will be about 14 ohms (about 12 ohms reactance and about 3 ohms line resistance, plus about 4 ohms earth-plate resistance); but impedance relays, instead of adjusting their time-delay to this value, will falsely adjust it to an impedance of about 26 ohms (about 12 ohms reactance and about 3 ohms line resistance, plus about 16 ohms arc resistance, plus about 4 ohms earth-plate resistance). This is equivalent to the indication of a fault nearly 100 per cent too far away; and the shorter the line the greater will be the falsifying influence of the arc resistance.

Since the arc resistance diminishes with increasing fault-currents, it is under conditions causing very heavy fault-currents to flow that impedance-type relays give

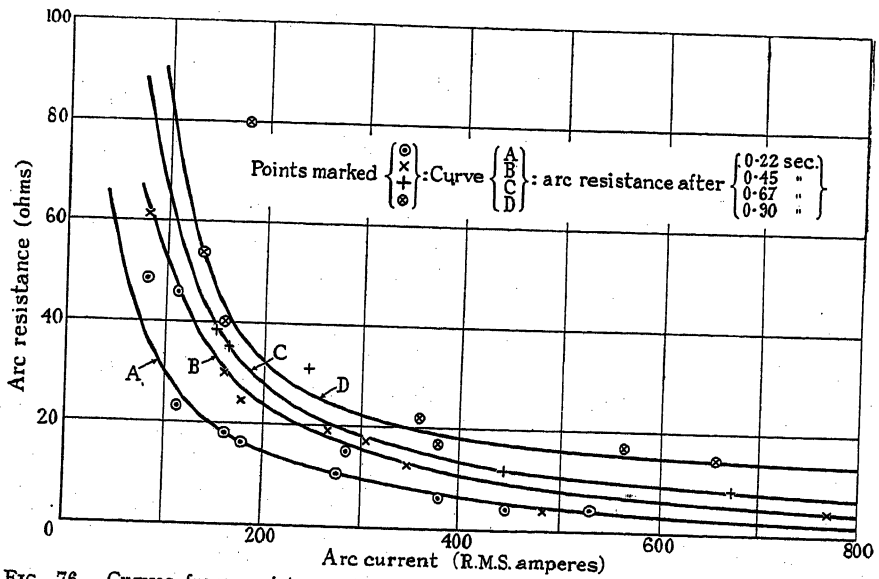

FIG. 76.—Curves from resistance tests of power arcs at 38 000 volts, i.e. 66 000-volt, 3-phase conditions.

their most correct discrimination. On the other hand, reactance-type relays discriminate correctly, irrespective of the magnitude of the fault current, or of the value of the resistance introduced into the fault loop by earth-path or arc resistance.

APPENDIX IV.

The Safeguarding of Post-Office Pilots Associated with Power Networks.

(*i*) *Conditions to be Met.*—Post-Office pairs or channels of communication may be associated with high-voltage power-lines as pilot wires either for automatic power-line protective systems, or for remote control and indication of meter readings. Investigation shows that it is necessary to guard against the following two causes of possible danger to Post-Office pilot wires and the apparatus connected to them (see Fig. 58 on page 313):—

(1) Failure of the high-voltage insulation between the power line and the secondary wiring associated with the Post-Office pilots; for example, the current transformer.

(2) Momentary rise in potential to earth of the secondary wiring and apparatus connected to the pilot wires as a result of an earth fault on the high-voltage power system.

The first of these is very unlikely to occur in practice, but if it does it imposes very severe stress on the protective gear, control equipment, or other apparatus connected to the Post-Office pilot wires. The second state, however, exists every time an earth-fault occurs on the high-voltage power system; but, unlike the first, it imposes comparatively little severity on the apparatus connected to the Post-Office pilot wires. The rises in potential to earth that can occur are of the order of a few thousand volts, depending upon the value of the power fault-current and the impedance offered to it by the earth-return path. The various conditions under which such potential-rises can occur are not dealt with in detail here.

(*ii*) *Provision for Safety.*—The precautions for safety must in every case take into account the two causes of possible danger just described; but it may be convenient to consider them in relation to the two common conditions in practice of association between the equipment connected to a power network and that connected to Post-Office pilot wires: (*a*) the association may be all within a building or site constituting a generating or transforming station; or (*b*) the association may be within a building, such as an isolated control room, in which it only occurs because a connection to the power network enters for the usual purposes of electricity supply.

Fig. 58 shows diagrammatically the precautions proved to be adequate for ensuring the safety of protective or control apparatus utilizing Post-Office equipment associated under condition (*a*) with current transformers housed in the switchgear controlling a high-voltage line.

The primary safeguard was found in the use of an earthing device incorporated in the high-voltage switchgear and connected to the secondary wiring and the station earth-plate. The object of this is two-fold: First, it ensures that the power-line protective gear automatically isolates the high-voltage power line should the insulation of the current transformer fail, and, secondly, it reduces the voltage imposed on the secondary wiring, which might otherwise be the full voltage of the power line, to merely the voltage-drop across the spark-gap.

A second requisite safeguard was found to lie in the termination and separate earthing of the sheath of the Post-Office pilot wires at least 50 yards away from the earth plate associated with the high-voltage switchgear controlling the power line. The object of this is to prevent the lead sheath of the pilot wires from being subjected to undue voltage-rise when an earth-fault current is passing through the station earth-plate. In addition, the pilot wires themselves are protected quite independently by means of standard Post-Office over-voltage and heat-coil devices connected to the pilot earth.

Additional security has been obtained by adopting either the "physical-separation" method or the "separated-circuit" method of arranging the protective, control, or other apparatus, associated with the secondary wiring of the high-voltage power-line on the one side, and with the Post-Office pilots on the other. "Physical separation" is shown on the left-hand side of Fig. 58 and a "separated circuit" on the right-hand side. Either method provides additional security, and the choice between them is governed by consideration of which is the easier of the two to apply to the particular type of apparatus employed.

Under condition (*b*), the precautions necessary to prevent control-apparatus, situated, for example, in an isolated control room, from being subjected to earth voltage-rises caused by faults on the power-network have been found to be that the lighting or power-supply cables should have their lead sheaths and armourings separately earthed at least 50 yards from the control room, the supply being taken into the building through insulated cables, and that the sheath of the pilot wires should be terminated and earthed, and the pilot wires protected, in the same way as under condition (*a*).

(*iii*) *Pressure-Tests.*—It has been agreed by the parties concerned that the secondary wiring associated with the power line, and the secondary wiring associated with the Post-Office pilot wires, must be physically separated, and must be capable of withstanding the following tests:—

	Momentarily	For 2 minutes
For power lines above 33 000 volts	15 000 volts	5 000 volts
For power lines of 33 000 volts and under	3 750 volts	1 250 volts

Insulated enclosures must withstand 3 750 volts to earth momentarily, and 1 250 volts for 2 minutes; and all apparatus must withstand 2 000 volts for 1 minute between live metal parts and their enclosure.

(*iv*) *Safety Afforded.*—Fig. 58 shows that, before the Post-Office protective device is called upon to function and to protect the Post-Office pilots in the ordinary way,

three stages of insulation failure must take place, namely:—

(1) A breakdown of the insulation of the instrument transformer.
(2) A failure of apparatus within the earthed enclosure.
(3) A failure of apparatus within the insulated enclosure.

Safety against breakdown due to rises in voltage to earth is afforded by using apparatus designed to withstand the pressure tests specified above.

(*v*) *Power Tests.*—A number of tests to establish the efficacy of the safety precautions were carried out with the aid of a British test-plant, the apparatus and connections being so arranged as to represent actual service conditions. The apparatus complied with the pressure tests specified above, and earthing devices designed especially for the purpose were used.

A series of tests was made to determine whether a momentary voltage of any appreciable magnitude existed between the contacts marked A and the earthed case marked B in the "separated circuit" shown in Fig. 58. A neon lamp and a photographic plate were used as a means of detecting the existence of any such voltage. The insulation of the current transformer was bared in one place, so that when 19 000 volts to earth was applied to the line (corresponding to the voltage of a 33 000-volt network) this voltage was applied practically instantaneously to the secondary wiring of the current transformer. With currents of the order of 1 750 amperes (corresponding to a 3-phase power of 100 000 kVA at 33 000 volts) no voltage was indicated on the photographic plate, and so it was proved that the relay was not subject to any over-voltage stress. The spark-gaps easily carried the fault current, thus isolating the high-voltage power line.

In general, the tests carried out indicated that, subject to the taking of adequate precautions, Post-Office pairs or channels of communication can be used with complete safety in association with high-voltage power lines.

Discussion before The Institution, 25th February, 1932.

Mr. W. A. Coates: I should like to refer to a method of isolation which is not mentioned in the paper. It was, I think, patented by the A.E.G. company in 1912, and it differs from the author's arrangement shown in Fig. 15 in that whereas the latter has separately-operated isolating switches, this German design (see Fig. A) merely has plug contacts in an oil vessel. The practical development of this arrangement is to-day being applied in one of London's big power stations. In this case the main busbar is in U formation and runs right round the building, the auxiliary busbar being placed in the centre. Above are oil chambers carrying the isolating device and the circuit breaker with which it is linked. This system is designed for 66 000 volts, but, unlike the arrangements which we have seen hitherto, the busbars are not oil-filled for purposes of insulation; they are practically condenser bushings. The only oil used is employed in the isolating chamber, in all the junction boxes, and in the switch itself; everywhere else the conductors are wrapped with solid dielectric, applied as on a condenser bushing. The 66 000-volt circuit breaker employed weighs about 20 tons, and an oil vessel covers the junction between the plug-contact insulator and the switch proper. The control board is an excellent example of the clear system indication suggested in the paper; the busbars and the various pieces of apparatus are all indicated in clear glass, behind which there are three different coloured lights which are used to indicate that the circuit is alive, or dead, or that the apparatus is ready to be switched in. A preparatory signal is thus available for the operator. I should like to make a few remarks about Appendix I and B.S.S. No. 116. British Standard Specifications are intended for practical use, and it is frequently necessary to abandon the strictly scientific in the interests of simplicity and ready comprehension. The circuit-breaker specification, B.S.S. No. 116, is a case in point. Whereas the supply engineer can easily calculate what his short-circuit current will be, the calculation of the probable recovery voltage on his system is a complex business depending upon an enormous number of variables. Consequently it is logical and practical for him to wish to purchase a circuit breaker on the basis of 100 per cent recovery voltage. This is, I think, a sound reason for rating circuit breakers on the basis of system voltage. When it comes to the interpretation of actual test oscillograms, the difficulty lies in obtaining 100 per cent recovery voltage in the test plant. It is often impossible to do anything of the

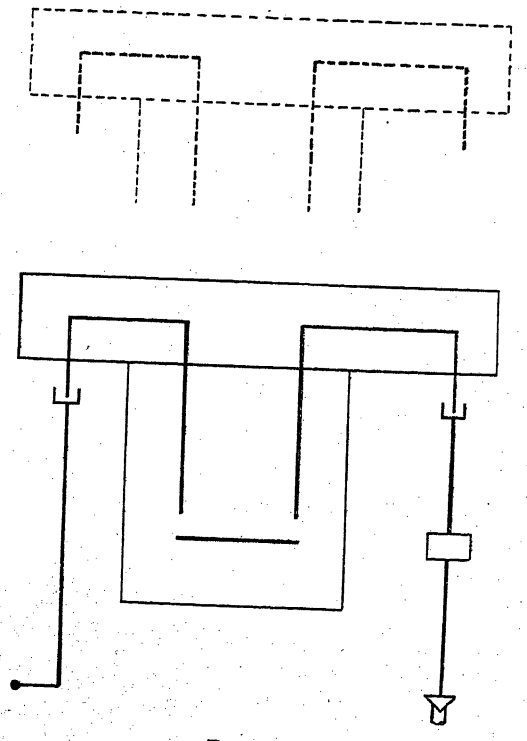

Fig. A.

sort, and allowance must then be made for variations from the desired figure. Unfortunately, so far nobody is in a position to state precisely what allowance must be made for a given departure from a recovery voltage of 100 per cent. We know that in general a high recovery voltage will impose a greater stress on a circuit breaker than a low recovery voltage. Within the last year or two we have realized that a high rate of rise of recovery voltage is probably the more important thing, but the only available apparatus for measuring rates of rise—the cathode-ray oscillograph—is not a test-room device. It can only be used by highly-trained laboratory assistants and even they have yet to develop a common technique, for two men never get exactly the same results from the same instrument. The author showed in one of his slides that during tests the recovery voltage may vary with such factors as the position of the earth connection on the system, and whether field forcing has been used to get heavy currents. I suggest that as a practical way of making B.S.S. No. 116 serve our present purposes, all that is necessary is to define recovery voltage. For this definition I propose that we should take the mean of the R.M.S. value of the first two half-cycles following arc extinction in all three phases, or, alternatively, the line voltage, whichever is the lower. This practical definition will serve until we are able to present a more completely scientific basis for oscillogram interpretation. I should like to comment on the author's suggestions for the future. First of all, with regard to the table on page 319, surely it is more reasonable to state that any circuit breaker, irrespective of voltage, provided it has a single tank per phase and a separated top casting, can be tested single-phase, and equally that any circuit breaker which shares the air space at the top between the three phases must have all its three poles connected when under test. I do not think a voltage limitation is the right way of covering the point. I disagree with the author's suggestion that we should call for a definite recovery voltage. He suggests a figure of 80 per cent, but states that any other value would suit. I think it is far better and far more logical to work back in such a manner that all the figures that are required for computing the results of tests can be read direct from the oscillograph. As we cannot always obtain 100 per cent recovery voltage, it is up to us to find out for the British Standards Institution the basis on which oscillograms can be interpreted, so that it will be possible for all circuit breakers to be compared. I do not think, however, that it will be done by having a standard voltage-recovery figure.

(*Communicated*): When a testing plant is employed it is impossible to predict accurately what the recovery voltage will be, and trial and error must be resorted to if it is desired to get a particular value. Moreover, if the British Standard Specification called for a definite figure, it would automatically preclude the use of field tests except under very unusual conditions. The inclusion in a standard specification of the restriking voltage, of which the rate of rise rather than the amplitude is the important factor, must await the completion of a considerable amount of research and the development of the cathode-ray oscillograph as a test-room instrument. It is surprising to learn from page 320 that the British practice is to insulate the neutral point below 66 kV, and more so to see that it is usual to generate direct from 3 300 to 22 000 volts. I doubt whether this could be called " standard " practice, even on the North-East Coast. Practical considerations of machine and transformer design alone probably control the question of earthing or insulating the neutral of the source of supply. So far as star windings are practicable the neutral should, of course, be earthed if one is attempting to reproduce ordinary working conditions. In addition to the author's proposals for standard tests, it is essential to set up standards for pressure and travel recorders. A lot of new ground has to be broken before a complete revision of B.S.S. No. 116 will be possible, and it is to be hoped that the author's rather bold forecast will not have the effect of holding up the minor but essential changes to the 1929 edition of that specification which are contemplated at present.

Mr. S. Ferguson: With regard to Fig. 38, I believe this record was made with a Collins micro-indicator, and I should like to know what power was being ruptured when it was taken and what was the rupturing rating of the breaker. Would the author be in favour of allowing purchasers to examine the curves of performance of the circuit breakers offered by manufacturers, in order to enable them to make their selection more intelligently? With reference to the tests recorded on page 322, I should like to ask the author what was his experience with the 100 000-kVA breaker, records of which are given, when it was rupturing powers within its rating. All the tests shown were made above its rating, and any defects in performance can obviously be excused on that basis, but I note that at 133 per cent of the normal rating the tank became badly damaged and the top plate slightly distorted. What is the maximum kVA rupturing capacity the author would advocate for direct-operated circuit breakers? I notice that the rather important items of arc length, pressure developed, and rate of rise of recovery voltage on the testing plant, are omitted from the test records. Are these omissions intentional? My next point refers to Fig. 38: although the author states that the tank is designed for 150 lb. per sq. in., no factor of safety is given. The impulse pressure was 950 lb. per sq. in., but there is no proof, of course, that this figure was safe. I should like to correct the impression, which is nevertheless prevalent, about the danger to busbars involved by the vertical type of switchgear. In order to settle the question we have actually carried out rupturing tests on a complete vertical equipment up to nearly 1 000 000 kVA, and, although a very large number of " shots " were made, in no case was there any stress on the busbars. We know that when rupturing tests are being carried out the circuit breaker has a tendency to jump, but in the vertical type of gear stops are provided to take the direct thrust of such upward movement. As regards the horizontal type, in a rupturing test where a complete unit was tested to destruction the cantilever stress due to the tilting of the circuit breaker actually threw the busbars out of position. I disagree that a definite static pressure can be laid down for each tank, corresponding to a certain rupturing capacity, without reference to the design of circuit breaker. It is a question not only of rupturing

capacity but also of the design. Among the thousands of rupturing tests which we have carried out on the modern round-tank circuit-breaker, in no case has a pressure of 350 lb. per sq. in. been exceeded. The pressures which we have measured are very much lower than the figures shown in Fig. 38. I cannot understand the statement (page 302): "Closing on short-circuit is perhaps so rare that in the past it has not been required of circuit breakers in standard specifications." Although an engineer does not always specify it, if he says he wants a certain rupturing capacity he infers, I think, that it must be based on the cycle laid down by the British Standards Institution, which involves the closing of the circuit breaker on the short-circuit. On page 302 the author states: "The problems of the circuit breaker may not be entirely solved by the use of intricate arcing contacts." I, however, believe that they will be so solved. There has been more development in this direction in the last year than there had been in the previous 20 years. We have obtained definite proof that, employing the same outside dimensions of an ordinary plain circuit-breaker, we can double

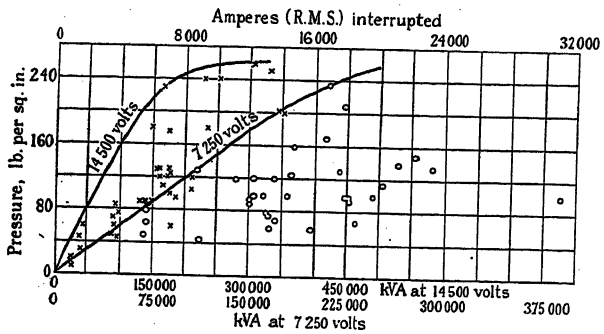

FIG. B.

the rupturing capacity by the provision of arc-control features. I agree with Mr. Coates that the rate of rise of recovery voltage should be specified in the standard performance tests, because that factor may double the stress on the circuit breaker. In America there were considerable misgivings about the differences between circuit-breaker operation on the factory testing plant and in the field. It was not understood why a circuit breaker should always rupture a much greater amount of power in the field than on the test plant, the ratio being of the order of $2\frac{1}{2}$ or 2 to 1. The reason for this difference has been definitely found to be the rate of rise of recovery voltage; as we now know, the operation of the circuit breaker involves a race between the rate of rise of recovery voltage and the rate of rise of electric strength of the space between the electrodes. On a supply system with numerous cables connected to the busbar, the rate of rise of recovery voltage is slow, whereas on the test plant it is rapid. A factor which alters the rating in the ratio 2 : 1 cannot be ignored, and supply engineers have the satisfaction of knowing that any circuit breaker which has proved its rupturing ability on a test plant will have a fair factor of safety on the system. I do not favour rupturing tests with the neutral earthed, as an earthed neutral greatly relieves the stresses. We are testing circuit breakers to destruction in order to find the weakest point, remedying it, again testing to destruction, and so on. Evidence of the enormous forces that are liberated inside an oil circuit-breaker was provided in one of our tests when a channel beam of 3 in. × $1\frac{5}{8}$ in. cross-section was bent up to a deflection of 3 in., and the oil was shot up like a piston from the arc bubble. A weight of about 1·7 tons applied at the centre of the beam is necessary in order to make a bend like the one actually produced in this test. Hilliard, referring to a circuit breaker of this size, suggested that when it is rupturing power at its full rating it develops as much energy as would be liberated by the explosion of 1 lb. of sporting explosive. It would be useful if the Electrical Research Association would investigate this question with a view to the possibility of testing circuit-breaker structures with a definite amount of gunpowder. Fig. B indicates the pressures developed when rupturing definite powers on a typical round-tank circuit-breaker at 14 500 volts and 7 250 volts. The maximum pressure recorded was 260 lb. per sq. in., and the instrument used was sufficiently sensitive to indicate the impulse pressure. I should like to stress the absolute necessity of routine testing of tanks and structures.

Mr. A. R. Blandford: Fig. 21 shows some switchgear which, according to the author, is opening the way to metal-clad gear of much higher rupturing capacity. I do not follow this, because circuit breakers have been constructed with ratings up to $2\frac{1}{2}$ million kVA at 33 kV, and they could just as easily be made to operate at voltages up to 66 kV. The circuit breakers shown in Fig. 21 are of the underhung type, and I think $2\frac{1}{2}$ million kVA is about the highest capacity to which one would care to go with an underhung tank. It may be that I have misunderstood the paper, however, and that the author is really referring to a type (e.g. that shown in Fig. 26) which depends for its success upon mechanical interlocks fixed to the circuit breaker. Such interlocks are, however, very prone to derangement, in view of the heavy mechanical forces set up when rupturing. It would be difficult to rupture charging currents successfully by means of the device shown in Fig. 21, and it might be called upon to do this. I should imagine the design has been produced mainly with the idea of saving space, an idea which can be over-emphasized where outdoor switchgear is concerned. For indoor switchgear, on the other hand, it is important because of the cost of buildings. The advantages of our present outdoor switchgear are: it is accessible, allows of extensions being readily made, and reduces to a minimum the time of shut-down should it develop a fault. Totally-enclosed switchgear is less accessible, and involves shut-downs of much longer duration in the event of the circuit breaker giving trouble. With regard to the question of phase separation, I should like to ask whether the author thinks it desirable even on the smallest types of circuit breakers—rated at 75 000 to 100 000 kVA—to obtain complete phase separation in the tank rather than have common-tank circuit breakers. By a "common-tank circuit breaker" I mean one where the air space and perhaps some of the oil are common to all the phases. I am pleased to see (page 293) that the author includes

the " expansion " switch in the air-blast category. On page 301 it is stated that when selecting a circuit breaker one should allow a safety margin on the rupturing capacity. Is the author prepared, even assuming we come to some definite decision about the interpretation of rupturing capacity, to state what he considers that margin should be? I agree with him that greater precision is required with regard both to the testing of oil circuit-breakers and to the interpretation of the tests. Unfortunately he lapses into the old haphazard way of glossing over the vital few micro-seconds after the zero in which the arc is extinguished. As regards the term " recovery voltage," I prefer to call it " restored phase voltage," and I would point out that it is of normal frequency. What I consider to be the recovery voltage is the high-frequency rapidly-rising overshooting voltage that occurs across the contacts of the circuit breaker immediately after the zero in which the arc is extinguished, and this is controlled by the characteristics of the circuit. To a very large extent the controlling factor is self-capacitance, as was mentioned by Mr. Ferguson. The frequency of the recovery voltage is very important. I do not understand Mr. Ferguson's ratio of 2 : 1 in this connection, because oscillograms which I have studied show that the circuit breaker is not affected by the normal-frequency voltage whilst it is rupturing. The recovery voltage is the only one which affects the circuit breaker at this time. It is easy to understand that as the circuit-breaker contacts are opening, current ceases to flow in the arc at each current zero. The particular current zero at which the arc is extinguished depends upon whether the voltage at the current zero rises sufficiently fast to break down the electric strength of the arc path; if it rises rapidly enough the arc is kept floating. The action of rupturing, therefore, resolves itself into a race between the rate of rise of recovery voltage and the rate of recovery of the electric strength of the arc path. The author suggests in Appendix I that we should have a standard circuit but take no notice of this recovery voltage; in other words, he wishes to rate the circuit breaker on the normal-frequency voltage. I do not understand why, if we have a standard circuit, standard capacitance, standard characteristics of generator, standard reactance, standard resistance, and an almost constant frequency, the rate of rise of recovery voltage should not be regarded as one of the standard test conditions. The oscillograms shown in the paper give no indication of the self-capacitance or the characteristics of the author's standard circuit, nor does he offer any information regarding the high-frequency voltage to which I have referred. I think we shall have to adopt a standard circuit, as the author suggests, but a record will have to be made both of this standard circuit and of the recovery voltage. I agree with Mr. Coates that the latter will have to be recorded by means of the cathode-ray oscillograph. All we need to be sure about is that when the test circuit has been accurately standardized, a circuit breaker which passes the test will stand up to the worst conditions of recovery voltage which it will meet with in practice.

Mr. W. R. Cox: Referring to Fig. 58, which illustrates methods of safeguarding telephone systems, it seems to me to be of great importance that the spark-gaps referred to for what we may call " initial " protection (e.g. protection against breakdown of a current transformer) should be placed as near as possible to the current transformer. If it is any considerable distance away, the damage which is done by such a breakdown will spread to other control circuits, and is almost certain to get through, by other channels, to the Post Office equipment. I mention this point because in many cases it is somewhat difficult to add these spark-gaps after the design has been settled. Referring to system control, it seems to be present-day practice to concentrate indications at a central point, whence by means of telegraphs or telephones the control engineer directs the carrying-out of various operations in remote power stations or substations. For this purpose a supervisory system is installed, which is often so designed that a slight addition will convert it from an indicating system into a true control system. This change will effect a great saving of time and will probably lead to fewer operating mistakes. Developments of this kind ought to be put in hand in the near future, as the capital outlay will be comparatively small and the advantages gained considerable. On page 316 the author refers to two types of remote-control gear, one the " supervisory control " gear which is based upon the telephone-relay type of apparatus, and the other the " centrovisory control " gear which has been developed along separate lines. The former has many advantages over the latter. In the first place, it is more flexible, secondly it is very much quicker in operation, and thirdly the type of control board developed for the centrovisory system seems to me to be rather clumsy owing to the fact that the indicating lamps and indications generally are in circular form. Finally, I wish to refer to the application of supervisory switchgear to circuits of very much smaller power. If a large power system is to be useful, a very large number of secondary circuits of lower voltage and lower power must be employed. These all need a certain amount of control, and in this connection a simple and inexpensive form of supervisory gear is very useful. At least one such system has been developed using two pilot wires which can be looped in tandem into at least 30 stations, and can control 10 separate operations in each station. These operations can be telephony, switch opening and closing, metering, and initiation of tap changes for voltage variation or load distribution, or the control of induction regulators (which serve very much the same purpose as tap-changing gear). The time is now ripe for these small schemes to be considered seriously, bearing in mind that we hope to increase the use of the " grid " by the extension of the lower-voltage transmission systems, thus making electric power available to a larger number of consumers.

[This discussion was adjourned until the 3rd March (see page 334).]

ADJOURNED DISCUSSION BEFORE THE INSTITUTION, 3RD MARCH, 1932.

Mr. E. B. Wedmore: In the paper* on this subject which I read before the Institution 14 years ago I suggested that wherever supply depended on any one busbar, that busbar should be duplicated. Although my suggestion was at that time regarded by some as extravagant, I notice that in the designs now set before us there is ample provision of duplicate busbars. However, I am still uneasy about the proximity of the main and alternative busbars in many of these designs. At one time I was entirely opposed to the use of such concentrated types of switchgear in important power stations, not because the resultant economy was not good in itself, but on account of the great engineering difficulties of developing such a design in a sufficiently reliable form. The experience of the last 14 years, however, has shown that such apparatus can be made to function satisfactorily in large power stations. In several of the designs shown, and particularly those where the main circuit-breaker is duplicated, there would be little difficulty in inserting a substantial wall between the busbars and thus obtaining much more complete isolation at a very small additional cost and with little additional space. Where the voltage is high the duplication is better justified owing to the reduction of the number of insulators necessary, these being a very costly part of the complete structure. In 1918 we were considering the use of reactances to limit the amount of power with which the switchgear had to deal, and it was concluded that manufacturers were able to supply switchgear to meet any conditions at that time obtaining in service. Mr. Ferguson and others are doubtful whether all the circuit breakers now on the market are capable of standing up to their ratings, and I agree that in their performance there is an element of uncertainty which we should try to remove. I am concerned also at the high cost of circuit breakers as part of a complete system. The necessary six insulators for the incoming and outgoing terminals of a large circuit breaker account for a good deal of the capital outlay, but there is still a considerable margin for economy in the cost of the remainder of the structure. Manufacturers are now aiming at producing more reliable types, which shall be more uniform in operation and yet prove less costly. We ought not to have to provide large structures for withstanding high explosive forces; it should be practicable to confine such forces in a small structure inside the circuit breaker and so arrange the parts as to secure complete control of the arc, the arc products, and the conditions under which the circuit is prevented from re-establishing itself. There is another factor, however, in regard to which there is room for improvement in practice. Notwithstanding the reactance in the different parts of the grid system, there never was a time when so many supply engineers were uneasy as to the rupturing capacity of their existing switchgear and of the equipment which they will have to install when the grid comes into full operation. There will be a great market for circuit breakers having 2 or 3 times the present rupturing capacity without any increase in the present dimensions. Most manufacturers are faced with the difficult task of proving and developing the new types of circuit breakers that the market requires. Many tests under working conditions are necessary, and these tests can only be made where heavy plant of adequate capacity is continuously available. The Electrical Research Association has been advocating the provision of such plant in this country for general use since 1924. We realized at that date that the situation with which we are now faced was bound to arise. British engineers have to produce their own new designs of circuit breakers to compete with the new types now being prepared for the market in all parts of the world. This matter is of equal importance to the supply industry, because the buyer desires to have an assurance from some independent authority as to the performance of the circuit breakers which he desires to purchase. As regards the type of test to be employed, it will not be sufficient merely to have agreement between the buyer and seller as to the nature of the test. We must be satisfied that the test is sound in itself. Turning to the oscillograms shown in Figs. 69 to 74 (Plates 2, 3, and 4), there is one feature as to the interpretation of which there is no general agreement. I refer to the phenomenon of the recovery voltage which appears in the several phases during 2 or 3 half-cycles after the circuit is broken. This depends mainly on the properties of the test circuit. Dr. Slepian is responsible for the broad conception that we can equate the recovery of the voltage with the recovery of the electric strength of the gap in the circuit breaker. The Electrical Research Association has also been engaged on a study of this phenomenon and has discovered some factors which do not seem to have been dealt with in the papers published hitherto. The quantitative effect of changing the character of the testing circuit varies according to the type of circuit breaker under test. The author raises the question of the effect of the arc on the properties of the circuit where the arc occurs and which may contain protective gear. This problem has been referred to the Electrical Research Association, but we have so far done only a little theoretical work on it. We feel that the presentation of the matter and its application would be simplified if the author's results were expressed in terms of the voltage-drop per unit length of the arc.

Mr. T. W. Ross: As regards Appendix III, I should like to assure the author that his fears as to the reliability of impedance relays are without justification, since relays of this type have proved very effective and reliable both in this country and abroad. I would, however, put forward a plea for greater simplicity in protective gear than is sometimes displayed to-day. Protective devices are called upon to function very infrequently, and if they are complicated or if they depend for their action upon a combination of devices which are in turn dependent upon each other, it is bound to be more difficult to maintain them in efficient operating condition. The reactance relay is more com-

* "The Control of Large Amounts of Power," *Journal I.E.E.*, 1918, vol. 56, p. 289.

plicated than the impedance type, and I feel that one should give very careful consideration to the question of simplicity before embarking upon any of these theoretically more perfect schemes. Turning to the pilot-wire type of protective gear, there is a statement on page 310 that the author's split-pilot system is provided with a tuning arrangement to prevent incorrect operation on the abnormal frequencies. Although it has been supposed that some cases of incorrect operation of the older Merz-Price type of protection were due to abnormal frequencies at times of short-circuit on some other part of the system, I would suggest that probably the cause was not so much an abnormal frequency as the fact that the short-circuit current in its earlier stages is of an asymmetric nature and gives rise to unidirectional impulses. It is practically impossible to balance these out in current transformers, and any protective gear which utilizes an electromagnetic relay may be subject to operation from d.c. impulses. In the Translay gear, for which I am responsible, the relay is of the induction type and is therefore immune from operation on direct currents. It is probably for this reason that the Translay relay has been so successful under very onerous conditions, and perhaps the tuning condenser which the author has introduced also bypasses these d.c. impulses. In any case, the acid test of immunity from incorrect operation must be the test of service. The type of protective system shown in Fig. 56, in which a high-frequency carrier current is injected into the circuit cables, is being tried on a single section of the British "grid." The author places a rejector at each end of the phase to transmit this high-frequency current, and it occurs to me that it will be necessary to put rejectors in all three phases if this carrier current is to be applied to more than one section of the network. The electrostatic capacitance coupling between the phase in use and the other phases will probably transmit the high-frequency current through to the other sections, and cause operation of the locking devices when they are not required to operate. It would be of interest to know whether the author has considered the possibility of this, and whether he considers such a scheme capable, without the addition of such rejectors, of being applied to several sections of the same network. Carrier-current protection suffers from the disadvantage that a comparatively complicated apparatus incorporating a hot-cathode valve has to be employed. The fact that the hot-cathode valve has only a limited life also necessitates relying on the human element to replace it, and although signals may be given when a valve is burned-out it is not always convenient to have attendants on the spot to notice the signals and replace the valves. On page 299 the author suggests the use of a condenser coupling instead of a potential transformer for measuring the potential, and states that the condenser coupling is more reliable than the transformer. I do not agree, because I feel sure that a good modern potential transformer with its windings so designed as to equalize capacitance stresses will be in every way as reliable as a condenser coupling. In the first part of this discussion Mr. Cox raised the question of supervisory control systems, and mentioned that the new method for which the author has coined the name of "Centrovisory" control is less flexible than a system using the standard telephone apparatus. In my opinion the automatic telephone apparatus is now extremely reliable, and to substitute for it something which is less flexible is a very doubtful advantage. Supervisory control can only give of its best if it is introduced in the form of a mimic diagram, and centrovisory control does not lend itself so easily to such a diagram as does the automatic telephone apparatus. The latter has the advantage that it is already being manufactured by mass-production methods.

Mr. J. R. Wilkinson: The first point I should like to take up is the comparison in the paper between the horizontal and vertical types of isolation in switchgear. Figs. 24A and 24B do not afford a true comparison. In the vertical type there are two independent circuit breakers, whereas the horizontal gear has only one circuit breaker with oil-immersed selector switches, and this does not give the same scope or range of operation. The vertical arrangement has an advantage in that the number of insulators is reduced. Mr. Wedmore remarked that he was rather concerned about the extreme proximity of the two sets of busbars, and in this connection again the vertical gear is the better because it does not involve placing the busbars one above the other, as in the normal horizontal construction. My next point refers to metal-clad switchgear having internal isolation in the circuit breaker (Fig. 16). The author indicates that this may have some advantages as compared with the orthodox type of vertical isolation, but it seems to me there are two very considerable disadvantages. In the first place, every time the circuit breaker is plugged on to the busbars six joints have to be made in the top plate. These joints must be gas- and oil-tight under a pressure of several hundred pounds per square inch when the circuit breaker is functioning under short-circuit conditions, and it is very difficult to make a joint of that description simply by winding the bushing up against the top plate. The second serious disadvantage is in case of damage to the circuit breaker under short-circuit conditions. The first slide which I propose to exhibit shows the effect of explosive forces produced under short-circuit conditions on a circuit breaker which had been tested to destruction. In this case the stout channel-iron beam just under the top plate has been bent upwards by the force of the oil, and to do this requires a force of about 2 tons. If the isolating mechanism is inside the circuit-breaker tank, a deflection of the members caused by the explosive forces may prevent the station engineer from isolating the circuit breaker from the busbars. My second slide, taken from a cinematograph film, shows an old-type rectangular-tank circuit-breaker at the moment of bursting under short-circuit stresses. It emphasizes the absolute necessity, both for the sake of the safety of the operator and for that of the continuity of supply on adjacent circuits, of the outer carcase of the circuit breaker being one of the strongest points in its construction. Considerations of this kind have led to the development of the circular tank with a domed top plate and dish bottom: if this construction is adopted and the other features are carefully designed, the carcase of the circuit breaker is found to be one of its strongest portions.

All the damage is then confined to the inside of the circuit breaker, instead of spreading to adjacent circuits or injuring the operators.

Mr. B. H. Leeson: Some years ago I carried out a series of explosion tests in a large dug-out to ascertain the ability of circuit breakers to withstand the pressures set up within their enclosures during the process of breaking short-circuits. It was thought at that time that the pressures developed would consist of an initial impulse pressure of high value associated with a sustained pressure of much lower value, and for this reason each explosive charge consisted of a blend of high-explosive and ordinary gunpowder. The number of charges exploded within an enclosure was increased on each successive test until destruction occurred. The pressures were recorded by devices similar to those used to record explosive pressures in gunnery research, and impulse pressures as high as 5 000 lb. per sq. in. were utilized. The metal enclosures were tested first for their ability to withstand a steady hydraulic pressure, and subsequent explosive tests indicated that the enclosures could be quite safely subjected to momentary pressures of 15 to 20 times the value of the steady hydraulic pressure. Having compared these tests with the time/pressure curve of Fig. 38, I consider the value of 10 given by the author as the ratio between the steady and impulse pressures to be well on the safe side. The subsequent satisfactory behaviour of the circuit breakers, when tested on a short-circuit test plant, was due in no small measure to the knowledge gained from the earlier explosive tests. A modern short-circuit test plant should be capable of testing standard circuit breakers ranging from 1 500 000 to 5 000 kVA at the standard rated voltages given in B.S.S. No. 116—1929, and I should like to consider whether the author's proposals as set out in Appendix I for testing and service conditions usually associated with the duty of standard circuit breakers. The duty imposed upon a circuit breaker under test depends (*a*) upon the normal frequency, and (*b*) the oscillatory characteristics of the test circuit (see Fig. C). With reference to (*a*), the specified rated voltage, making current, breaking current, power factor, and recovery voltage at normal frequency, can be obtained by suitable adjustments of the generator field, reactors, and resistors, so as to impose the desired normal-frequency duty upon the circuit breaker. With reference to (*b*), the duty imposed upon the circuit breaker by the severity of the rate of rise of restriking voltage is dependent upon the natural oscillatory frequencies of the test circuit and the normal-frequency recovery-voltage. When testing a large circuit breaker for use in service in close proximity to generating plant, the connections between the circuit breaker and the source of the short-circuit power at the test plant should be of the shortest possible length, so as to ensure a high rate of rise of restriking voltage. When testing a small circuit breaker, a larger amount of reactance must of necessity be included in the test circuit to reduce the normal-frequency short-circuit current to the desired amount, with the result that the natural oscillatory frequency, and with it the rate of rise of restriking voltage, is automatically reduced, although the self-capacitances of the test circuit remain virtually constant. The order of variation in the rate of rise of the restriking voltage (in volts per microsecond) is shown by Fig. D, in which the four ordinates are arbitrary and are intended to represent circuit breakers of four different ratings used under correspondingly different service conditions. The black bands on the ordinates indicate the order of magnitude of the rate of rise of restriking voltage, which is shown thus in order to include possible differences in values arrived at from calculations and measurements made by different observers on different test plants and cathode-ray equipments. Ordinate 1 represents a large circuit breaker, Ordinate 4 represents a small circuit breaker, and the other two ordinates represent intermediate severity in restriking voltage for other circuit-breaker ratings. The diagram is not intended to represent approved numerical values of restriking voltage, but is included to illustrate the point that what is

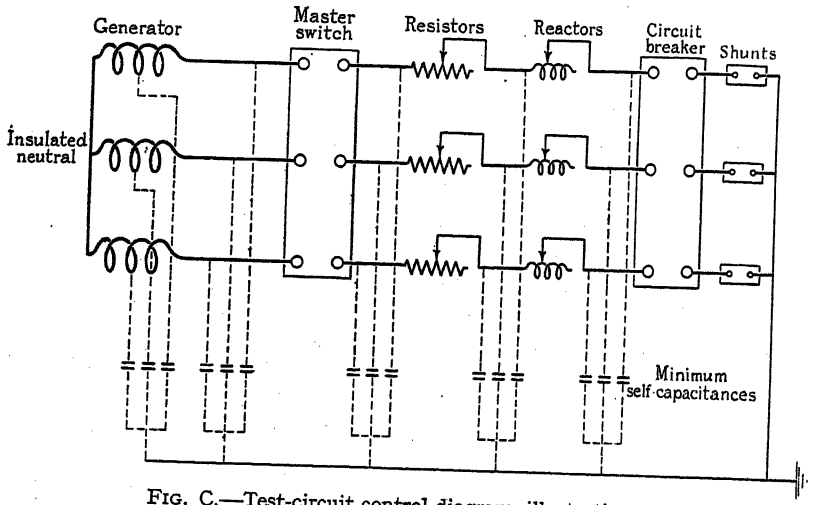

FIG. C.—Test-circuit control-diagram, illustrating:—
(*a*) The adjustability of the severity arising out of normal-frequency characteristics.
(*b*) The inherent dependence on (*a*) of the severity arising out of oscillatory-frequency characteristics.

required is the standardization of a range of rates of rise of restriking voltage for various values of short-circuit currents, and not the standardization of a universal rate of rise of restriking voltage, which, if low enough to be suitable for a small circuit breaker, would be absurdly easy for larger circuit breakers, and conversely, if high enough to be suitable for a large circuit breaker, would be physically impossible to obtain in tests of smaller circuit breakers. In my opinion the author's "Proposals for Standardized Performance Tests" do legislate for the required range of rates of rise of restriking voltage (see Fig. D), because his conditions implicitly control the order of magnitude of the restriking voltage under different service conditions by reason of the necessity for including in the test circuit (Fig. C) definite values of inductance and resistance to comply with the specified standard conditions corresponding to the size or rating and use of a circuit breaker in service,

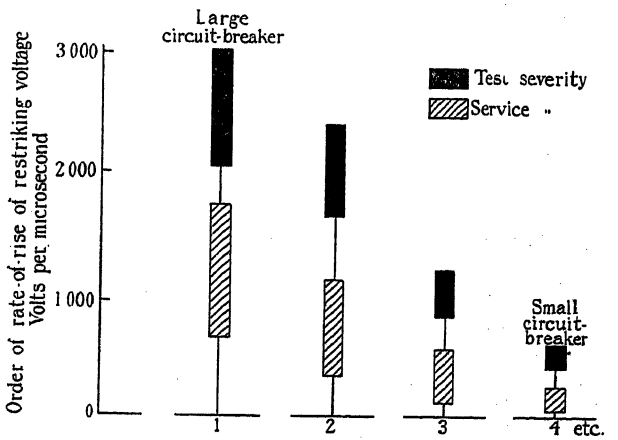

FIG. D.—Restriking voltage severity-diagram, illustrating:—

(*a*) Ranges of test severity and service severity, which are inherently dependent upon values of short-circuit current.
(*b*) The reduction in severity of service conditions as compared with test conditions.

and by reason of the small self-capacitances of the test circuit remaining virtually constant in value and appropriate for the large circuit breaker. Another fact which Fig. D is intended to illustrate and which is legislated for in the author's proposals (Appendix I) is that the severity of the standard test circuit is automatically greater than that of the conditions of service it is intended to represent. For example, a large 3-phase circuit breaker of a voltage rating below 66 000 volts would be tested with the generator neutral of the test circuit insulated, which would give a normal-frequency recovery voltage across the poles of the circuit breaker on the first phase to break 50 per cent greater than if the neutral point of the generator were solidly earthed, and would result in a restriking voltage of the order shown by the black band on Ordinate 1. In service, however, there are two primary easements. The first arises from the usual practice of earthing the generating plant through a comparatively low resistance, which gives a much lower recovery voltage on the first phase to break; and the second lies in the greater electrostatic capacitance of the length of cable or overhead line between the circuit breaker and the source of power and that of the network as a whole, as compared with the small self-capacitance of the test circuit. The rate of rise of restriking voltage for the conditions of service is therefore lower than that of the corresponding test conditions, and its order of magnitude is shown by the band with section lines on Ordinate 1. Similar easements apply to the small circuit-breaker rating of Ordinate 4, but they are more pronounced because of the greatly improved power factor and the further reduction in the rate of rise of restriking voltage produced by the capacitance, inductance, and resistance, of the comparatively long cables or overhead lines connecting the small circuit breaker to the source of larger power supply. In service, the small circuit breaker is likely to be subjected to a normal-frequency recovery voltage in excess of the minimum of 80 per cent specified by the author; but here again a similar increase would automatically result on the test circuit because of the small amount of power taken from the generating plant in proportion to what it is capable of developing for testing the large circuit-breaker ratings. Research is required to determine the numerical values of the rate of rise of restriking voltages that exist at different points on typical supply networks under varying conditions, with the object of standardizing a minimum range of numerical values of restriking voltage under which to carry out standard performance tests. Although some research is in progress, it is likely to be many years before this object is attained. This important study also includes investigations of the degree to which the behaviour of different types of circuit-breaker constructions is affected by different rates of rise of restriking voltage. In my opinion it is premature at this stage of progress to include numerical values for restriking voltage in any proposals for standardized performance-tests. I would therefore make a plea for the early adoption of the author's proposals, which specify conditions of severity for the test circuit well in excess of the corresponding conditions of severity in service, and in this practical way form the much-needed standard by which circuit breakers may be judged.

Mr. J. P. Cranmer: I am surprised to find that the paper makes no reference to the multi-break contact oil circuit-breaker, and I should like to know whether mention of it is omitted because its performance has not come up to expectations. Passing to the question of busbar capacity, I am glad to see that the author gives some current-density figures (page 301), because one has considerable difficulty in impressing on some people the necessity of running at these low densities when the current rating of the busbar exceeds 2 000 or 3 000 amperes. Referring to Fig. 76, I presume the author has in mind the arc on a 132-kV line, and I do not quite see why an arcing distance of 6 ft. is taken there. I should have thought a more practical distance would have been the length over a string of insulators (about 42 in.); this would make a big difference to the arc resistance. Moreover, the fact that the curve is based on low current values makes it a little misleading, because on 132-kV protective gear the minimum operating current would in any case be of the order of 200 amperes. If only higher values than this were employed in plotting the curve, the sharp bend at 200 amperes would be

eliminated. Reducing the arc resistance in the ratio of 6 ft. to 42 in. shows that although the arc resistance does affect the impedance type of protective gear, its influence is not so important as theoretical considerations would lead us to expect. This point, combined with the more robust construction of the impedance relay, should be considered in a comparison of the two types of protective gear. On page 299 the author advocates the use of capacitance transformers rather than the ordinary potential transformers. In a large number of the shut-downs caused by incorrect operation of protective gear the trouble is due not to the high-tension apparatus but to its associated low-tension equipment. Far greater care is usually given to the high-tension apparatus than to the insulation or design of the secondary connections and apparatus, and this is where the capacitance bushing is at a disadvantage as compared with the ordinary potential transformer. Our present design of potential transformer is as reliable as the capacitance transformer; the former has the advantage that it involves no condensers and smoothing arrangements to complicate the secondary circuit and cause trouble under service conditions. Furthermore, the potential transformer has the greater output and accuracy.

Mr. S. C. Bartholomew: I wish to refer to a matter which is dealt with on page 313 and also in Appendix IV, namely the steps to be taken where Post Office lines are used for the subsidiary service associated with power-circuit operations. The author indicates that the metallic sheathing of the telephone cables should not come within 50 yards of the power station, and should be separately earthed there, these precautions being necessary owing to the potential gradient which is set up on the occurrence of faults on the power system. I should like to know how this figure of 50 yards was arrived at, and I should welcome details of the tests which have apparently been carried out by the author and those associated with him. I notice that the word "station" is used: a "station" may be a very extensive building, and perhaps "station earth-connection" is intended. A factor of some importance may be the presence of gas and water pipes and the metallic sheathings of power cables. Is it not likely that in certain circumstances these pipes and cable sheaths may form an indirect and undesirable connection with the station earth-plates, and so extend the danger area? We have had trouble with Post Office cables and circuits that might be attributed to this rise of potential gradient on the occurrence of faults at power stations. In some cases, particularly in districts where a great deal of trouble from lightning occurs, the protective devices on the telephone circuits have operated, and cables leading into a power station have actually been burned through in the ground, the lead sheathing being melted. There has, however, always been some difficulty in ascertaining whether the trouble was due to a fault on the power circuit or could be attributed directly to lightning. It is possible that the lightning produced a fault on the power circuit, and that this in turn caused damage to the telephone plant. A consideration of all the relevant facts, however, suggests that the cause of the trouble has been the rise of potential in the soil in the neighbourhood of the power station.

Mr. J. F. Shipley: I should like to refer to the operation of a telephone system installed directly beneath the 33-kV power lines of an extensive transmission network in the tropics, where lightning occurs every afternoon from 1 p.m. to 6 p.m. for 6 months in the year. The telephone system is of great importance owing to the necessity of avoiding the effect of sudden floods and stoppages on the mining plants connected to the network. It is protected by drainage coils, transformers, lightning arrestors, vacuum gaps, and fuses, and with it we have been able to maintain permanent and clear communication during, and in spite of, the lightning. Even if—as has already happened—a 33-kV power line falls on to the telephone line while men are speaking, no harm results beyond the blowing of a fuse. We have trained the native linesmen to be prepared to replace the fuse at once in the event of an interruption. A careful record is kept of all faults, but contrary to expectation these have been exceedingly few in number. Were the system unprotected an earth fault on the network would, owing to the high specific resistance of the earth, give rise to high voltages on the telephone line which might injure the apparatus and cause shock to the operators. We have experienced some insecurity owing to our relay batteries being of the alkaline type. The electrolyte has to be renewed annually, and this has made us consider very seriously whether we shall install such batteries in future. Even our white engineers, although they are told to put special electrolyte into these cells, fill them up with acid!

Mr. W. A. Crocker: I am disappointed that no figures are given in the paper which would help the power engineer or purchaser of switchgear to decide how to allow for the effects of power factor and recovery voltage. Assuming a power factor of 0·5 and a calculated short-circuit kVA of 300 000 on a 100 000-kVA system, is the author able to state the breaking capacity of the switchgear required? Can the factor of 2 to $2\frac{1}{2}$ referred to by Mr. Ferguson for test results compared with field results be applied in such a case? I think it is time that breaking-capacity tests were undertaken by an independent authority, as a great many "mushroom" firms are now marketing switchgear and the purchaser cannot decide from the technical data whether it is properly designed. I agree with the author as to the advisability of earthing cables through the switch, but I would point out that operating staffs need help in this procedure. So long as it takes several minutes to apply the earthing device, and until it can be done with safety, operating engineers will neglect this precaution. Manufacturers have not paid sufficient attention to this matter; in many cases it is dangerous to apply the earthing device, as in order to do so it is necessary to uncover the isolating-contact orifices and presume the contacts to be dead. In one instance which occurred within the last 2 years it was considered satisfactory by the manufacturer to remove the circuit breaker from its rack by means of a truck in order to apply the earthing device. I should like to stress the need for simplicity in switchgear, because delays often arise when several manufacturers' switchgear is used on one system and three or four interlocks of different types are incorporated in each.

Mr. J. W. Rissik: From the author's statements on pages 292 and 293 I gather that he regards the expansion switch as a particular type of air-blast circuit-breaker. I do not think this view is correct: the expansion switch is different from the air-blast circuit-breaker in that it is the only switch in which the gas generated by the arc is subsequently expanded adiabatically. In the ordinary air-blast circuit-breaker a blast of air is merely trained on to the arc in order to scatter it. In the expansion circuit-breaker the arc is struck under water, and when the two contacts separate the steam which is formed cannot escape from the expansion chamber; but as soon as the contacts draw apart still further the pressure is suddenly released and the steam expands adiabatically, with the result that a very rapid temperature-drop takes place in the superheated steam, which immediately condenses. It can be shown that when an arc is ruptured in a saturated vapour the gases are rapidly de-ionized, so that there is no tendency for the arc to restrike. The free adiabatic expansion causes such a rapid temperature-drop that de-ionization occurs before the recovery voltage has time to reach a value high enough to restrike the arc.

Mr. E. O. Taylor: The principle underlying all the circuit breakers which have been described in the paper and by speakers in the discussion is to build them in such a way that they will withstand any explosion that may occur as the result of the liberation of the arc energy. It seems to me that a better way of approaching the subject is to do as the last speaker suggested, and de-ionize the gas between the contacts, thus preventing the arc from re-igniting after it has gone out at the end of the first half-cycle. The expansion switch and one or two of the circuit breakers mentioned by the author are based on this idea. I should like to ask whether it is possible to use the grid-control rectifier as a switch. This device makes it possible to prevent the arc from re-igniting after the end of a half-cycle, and with a little modification it might be made suitable for use as a switch. In this connection, the grid-control rectifier and various other pieces of apparatus are being developed with a view to utilizing high-tension direct current for transmission. Have the manufacturers considered the question of switching high-voltage direct currents, or would all switching have to be done on the low-voltage side?

Mr. P. F. Grove: I should like to point out that there is a difference between rectangular-tank and round-tank circuit-breakers, in that it has hitherto been understood, at any rate in the earlier square-tank designs, that there ought to be definite separation of phases where three phases are in one tank, and for that purpose steel barriers have been interposed between the phases. In the case of the round-tank circuit-breaker definite welded-in partitions between the phases are unsuitable, owing, I believe, to the unequal distribution of oil volume and bad distribution of stresses. Is the design of the round-tank circuit-breaker such that the pressures in it are equalized and barriers therefore become unnecessary? On putting switchgear into service it is often found that moisture in the oil has found its way to the bottom of chambers, other than the oil switch tanks, and formed a small pool of water which has seriously decreased the clearances of certain insulators. Manufacturers should therefore take special precautions to allow for moisture being drawn off from the bottom of such chambers. It might be advocated that works tests should be carried out with oil of low electric strength. Generally speaking, works tests are carried out with oil of the highest electric strength, and it might serve a useful purpose for the designers to make a test using oil of 20-kV electric strength. The use of fibrous materials inside circuit breakers may result in fibres mixing with the oil, and if moisture is present the resultant oil will tend to break down far more easily than if mixed only with colloidal carbon, which has up to the present been regarded as one of the most common causes of the breakdown of oil, owing to the difficulty of its extraction. It is further of interest to note that there is considerable danger in using semi-fluid compound fillings owing to the difficulty of ensuring sufficient freedom from moisture and fibres.

Mr. W. E. Highfield: The breakdown of switches may be divided into two classes, those in which there is a total destruction and those in which the damage can be repaired in a reasonable time. In my opinion minor mechanical faults occur far too frequently. Switchgear has become so large and the mechanical forces involved so considerable that the mechanical parts are similar in design to those associated with the old low-speed engine. Twenty or thirty years ago we had a fine body of firms able to produce designs that would work continously without breakdown; the Lancashire mill engine and the marine engine were of this type. The operating gear of a Corliss engine involves mechanical devices very similar to the operating mechanism of an oil switch, with the exception that whereas the engine gear worked continuously the switch mechanism must be able to work at any moment between long rests. I think that greater attention should be paid to making the mechanism between the first point of mechanical movement and the mechanism in the tank, completely immune from failure.

(*Communicated*): The paper makes clear the high efficiency to which the design of the oil circuit-breaker has been brought. It is interesting to recall the days of the air-break switch, barely thirty years ago, when shift engineers were usually equipped with a short piece of leather belting to " swat " out the arc. Although the types of circuit breakers mentioned in the paper differ in various ways, they have one mechanical feature in common, namely, that the switch is thrown out by a spring which is compressed by a full-power solenoid. This fact is rather surprising in view of the many mechanical methods that exist for producing quick movement of parts, e.g. hydraulic and compressed-air systems. I should have thought that hydraulic movement would certainly have been explored, since the medium of oil is already present. There are few mechanical devices more sure in action than the hydraulic ram, which is simple to control, robust, and capable of withstanding severe weather conditions. Compressed air is widely used in railway work for the operation of points and contactors of all sorts, and it has been proved to be thoroughly robust and reliable. A good argument against the use of hydraulic or air systems is that there

are already sufficient services on a substation. On the other hand, the fact that large and costly switches controlling important supplies are far too often put out of service by minor mechanical defects makes an improved design imperative. Having made a suggestion that might seem to imply more complication, I must now plead for simplicity and low cost. As the field of electric supply extends, the supply authority has to go further afield to obtain additional load and has to spend more and more capital to reach it. There is a definite limit to the economies that can be gained by increased efficiency of generation and transmission, and it is a moot point whether we do not now invest too much capital in equipment for obtaining improved efficiency. If cheaper electricity is to be supplied one of the widest fields for gain is in the reduction of capital cost. The largest single item in the cost of a unit of electricity is that of distribution, but considerable economies could also be effected by a reduction in the cost of making a connection to the high-tension lines. A relief in this direction would be of immense assistance to the national "grid" system. It could only be achieved by a reduction in the cost of switchgear. I should imagine that rather more than half the net cost of a large oil switch goes to pay for the material, the rest being assigned to labour and "on cost" charges. By far the largest single item of cost is the pair of bushing insulators in each phase tank, and at the moment this is the only item that offers possibilities to the scientist and engineer in the way of reduced cost. The economy to be achieved in this direction is, however, not large. Any considerable reduction in the cost of a high-tension connection must therefore be sought in a different method of application of switchgear, and there is a possibility in this direction if advantage can be taken of the reactance of the transformers in the total circuit between the high-tension line and the consumer. I raise this point in order to make clear the desirability of reducing the switchgear breaking-capacity after the high-tension connection. For example, if the switch at the high-tension connection is rated at $1\frac{1}{2}$ million kVA, the switch on the secondary side of the transformer may be of $\frac{3}{4}$ million kVA capacity. We want some safe method of connecting to this circuit a system with switchgear of only 50 000 kVA capacity. This suggestion for keeping down capital costs has perhaps not received all the attention it deserves. Instead we have tended to raise the standard of low-capacity switchgear. Confusion will ensue if this path is pursued, because more and more small systems desire to be linked up with larger systems, and they must be so linked up if the national system is to have full scope.

Mr. G. E. Moore (*communicated*): The paper is regrettably lacking in information with regard to the instruments which are incorporated in modern metal-clad switchgear. It has yet to be generally appreciated, first that the integrity and intelligent use of instruments can have a marked beneficial effect upon the internal economic working of a supply undertaking, and secondly that the metering in consumers' premises safeguards the revenue of the undertaker. A low-tender metering equipment of poor design may through lost revenue ultimately be the most costly. From the cursory way in which the author deals with the subject of transformer accessibility (page 290) it is obvious that he does not regard the maintenance and life of the instrument transformers as of particular moment. It has yet to be shown, however, that transformers remain unaffected no matter how they are mounted. Moreover, doubts occasionally arise as the result of disputed accounts and through ageing of the equipment; in such cases, for the purpose of complete practical assurance, the performance should be checked. In addition, ratio checks every 10 years are advantageous. Sometimes it is possible to isolate a set of current transformers and test them by means of a neighbouring low-voltage source. Again, temporary current transformers may be inserted elsewhere in the circuit. In other cases the potential transformer may be tested with a portable potential transformer by direct access to its primary fuses or power-transformer terminals; or the chambers may be withdrawn and taken to testing headquarters. Cubicle and truck-type switchgear is not old-fashioned, at least as regards accessibility. Makers do not appear to appreciate the necessity for thorough tests of metering equipment both before it leaves the works and on erection. Much expense and delay would be avoided if all primary and secondary fuses were made accessible. Wherever possible, the use of plug connections should be avoided.

Mr. H. Trencham (*communicated*): In examining the numerous suggested switchgear arrangements to which the author refers, I am struck by the number of attempted innovations for which the only justification appears to be a desire to do something differently. In oil-filled switchgear it is certainly a step forward to have rendered current transformers more readily accessible. A thoroughly satisfactory arrangement for potential transformers, however, is not so easily found. A feature which would be appreciated, especially in the export market, would be an easier method of arranging for extensions or modifications. It is possible to attach too much importance to the weight of the circuit-breaker unit when considering the question of isolating the latter by moving it from contact with the busbars. The switchgear engineer is a little slow in taking advantage, for his own purposes, of the wonderful flexibility of the power which he controls. The actual power consumption necessary for carrying out isolating operations electrically would be small, and it is surely no disgrace to make use of electric motors for this purpose. Simplicity is the guiding factor in the matter of isolation. Many engineers attach great importance to the actual visibility of the isolating process, and in this respect movement of the circuit-breaker unit—whether horizontal or vertical—is simple. An isolating and earthing switch was provided in the first 132-kV oil-filled enclosed switchgear system, but it was also specified that the isolator unit should be made suitable for complete withdrawal on plug-and-socket contacts. I do not advocate such duplication, and it was probably employed solely as a precautionary measure on what was really a piece of bold pioneering work. The author's treatment of oil circuit-breaker operation is very brief and does not do full justice to the advances which have recently taken place. I have lately noticed a tendency to criticize the British switchgear engineer for not

offering such devices as gas-blast and expansion circuit breakers. In a recent article* I have attempted to sum up the pros and cons of recent developments in a.c. circuit-breaking, and to prove that the improved oil circuit-breaker is still the best answer to our own particular circuit-breaking problems. In this connection I should have welcomed greater stress on the importance of " arc control " in short-circuit interruption, instead of the mere separation of arcing contacts. In reference to recovery voltage, care is necessary to avoid confusion between its amount and its rate of growth, the latter being often a more troublesome factor than the former. It is in this respect that an isolated test plant may be found to stress a circuit breaker more severely than do system conditions. I should like to correct an assertion regarding explosion pots which is made at the bottom of page 291.† The use of an explosion chamber of insulating material applies to certain conditions only, and the steel pot is still retained for many applications. I support the suggestion (page 301) that breaking capacity and voltage should be correlated, and I would advocate going further than the author suggests where high breaking capacity is dealt with. A reason for this is provided on page 303, in that owing to the enormous currents involved at low voltages the stresses set up in forcing a circuit breaker to close on a fault reach impracticable figures, and ordinary closing mechanisms are generally unsuitable. To trip free as soon as contact is made also demands much more robust arcing contacts than are usually provided, in view of the time involved. The most rational solution is the use of as high a voltage as possible for heavy power control. Under the heading " Saving Switchgear " (page 303), the author touches upon distribution economy as exemplified in the American solid distribution network. The case mentioned is that of dense load areas, but the principles employed therein have also been applied a stage higher up—to what are called " secondary " networks—with results calculated to effect remarkable savings. Followed to its logical conclusion, the scheme would do away with distribution substations and their attendant switchgear as we know them to-day, and substitute a standard 5-circuit-breaker switching unit of constant size and breaking capacity for all systems. The effect of such a measure of standardization is difficult to imagine. I believe there are great possibilities for development in the field of remote and automatic control. Some time ago I had to deal with the problem of the totalisator, and the experience gained during its development strongly impressed me with the benefits which might accrue from a closer connection between switchgear and communication engineers, because it is only a short step between communication problems and those of remote control.

Mr. W. Wilson (*communicated*): There are two points to which I should like to refer, namely busbars and protection. The former is given considerable attention on page 295 and in Fig. 28, which shows a special arrangement designed to reduce the heating experienced with closely-spaced a.c. busbars. While there is no doubt that the type illustrated will give much better results than the usual laminated pattern, I am not satisfied that it is the best form. The difficulties attending the design of a.c. busbars are due to the unequal distribution of current in the various parts of the conductor owing to skin or edge effect and proximity effect, and the special difficulty with metal-clad gear is the great increase of proximity effect owing to the necessarily reduced spacing between the conductors of the various phases. So serious have these joint effects become that it is impossible with the ordinary design of busbars to pass a greater current than about 3 000 amperes at spacings of about 1 ft. without an excessive rise of temperature, however many additional laminations are introduced in the usual parallel-strip arrangement.

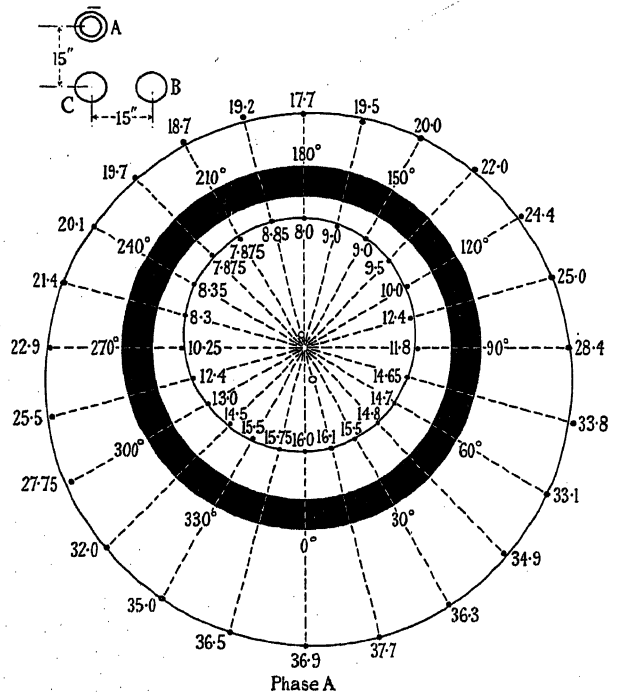

FIG. E.—Relative distribution of 50-cycle alternating current in the uppermost busbar (phase A) of the 3-phase arrangement indicated in the small figure. The current densities on the outer and inner surfaces of the tubular bar employed are shown by the curves.

Although the cross-section of copper is thus increased, the a.c. effects cause the current to crowd to the outlying portions of each phase conductor and also to those nearest the other phase conductors, the remaining portions of the busbar carrying only a small amount of current, and that at a very bad power factor. These effects are illustrated in Figs. E and F, giving the results of tests in which currents of 4 000 and 3 000 amperes respectively at 50 cycles per sec. have been passed through 3-phase conductors. Fig. E shows the distribution of current in the upper one of three copper tubes each having an external diameter of 6½ in. and a thickness of ½ in., arranged as shown in the small sketch. The current density has been measured round both the outside and the inside of the upper busbar at intervals of 15°, and its relative magnitude is represented by ordinates at each point. It is of interest that the heights of the ordinates,

* " Alternating-Current Circuit-Breakers," *Engineering*, 1932, vol. 133, p. 224.
† Since corrected for the *Journal*.

marked by small dots, lie almost exactly on circles. The skin effect is shown by the much greater magnitude of the current at each point outside the conductor than inside; direct measurement shows that the current on the outside surface averages 2·33 times the current on the inside. Proximity effect is indicated by the much greater height of the ordinates towards the other two phase conductors, these being 2·27 times as long as those farthest from them inside the busbar as well as outside. The diagram illustrates graphically the surprising unevenness of current distribution even with such moderate spacings as those shown. The best methods of minimizing the effect are first to give the conductor as symmetrical a shape as possible, and secondly to construct it all in one piece, so that the portions which are producing less heat will receive some by conduction from the hotter portion and so assist in the process of heat

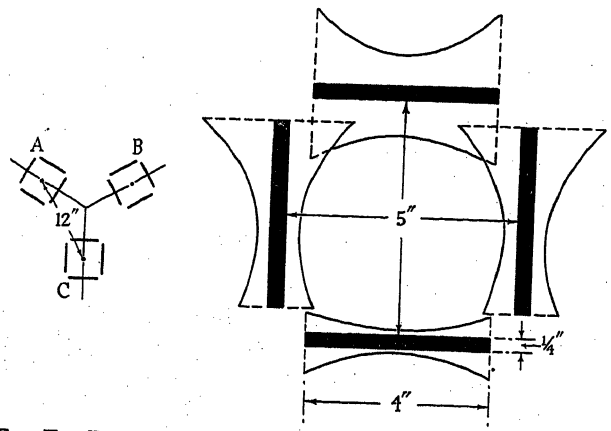

FIG. F.—Relative distribution of 50-cycle alternating current in a 3-phase arrangement of box-type busbars passing 3 000 amperes. The current densities on the outer and inner surfaces of the lowest busbar (phase C) are shown by the curves.

dissipation. Of the various busbar designs, the tubular form is obviously the most symmetrical, while the laminated portion is probably the least satisfactory from the present point of view. The shape shown in Fig. 28, which is almost identical with that illustrated in Fig. F, approximates to the tubular, and at first sight might appear to possess its advantages. The current-distribution curves indicate, however, that this is by no means the case. It will be seen that the distribution does not vary uniformly round the periphery of the "box," as in the case of the tube, but behaves almost as though the busbars were not arranged in a ring, in that the current crowds towards the edges. In this case the current distribution plotted is that of the lowest of the three conductors, and the marked manner in which the current crowds into the top strip of the set and to the upper edges of the vertical strips is well shown. While there is no doubt that this arrangement is much superior to the usual parallel-plate type, since there are no members sandwiched between others and thus rendered almost entirely useless, it suffers from two defects as compared with a tube. The first is that the outside strip, namely the lowest in phase C, is doing very little work at all and might—in this instance, at any rate—be omitted without affecting the efficiency of the conductor very much. Secondly, the conductor is in four separate pieces and thus the heat from the strip at the higher temperature cannot be conducted to the others, which would then serve as additional cooling surfaces. This is the more unfortunate in that the inside strip is the hottest, while the comparatively idle one is that nearest the external atmosphere. As regards protection, British practice has within recent years trended too much in the direction of copying methods produced abroad, and in particular has departed too far from the original principle of instantaneous protection, in favour of foreign methods securing discrimination by means of a time-lag. The full disadvantages of this change have not yet been experienced in this country, since up to the present we have had no large interconnected systems with comparatively long transmission lines between them. These conditions are coming, however, and since the stability of such a system to through faults depends upon the ability of the protective gear to isolate the fault before the two ends of the line have had time to get out of synchronism to the critical extent, it will probably be found that we shall be compelled to return to instantaneous methods before satisfactory working is possible. In this connection I should like to refer to the case of an important transmission line in America* which was originally equipped with the usual type of protection employing a species of time-lag discrimination. During 1928, the first year of working, there were four faults, each of which caused the generators to fall out of step and disconnect the whole station of 250 000-kW capacity. The relays were therefore changed for "high-speed" models, while the inherent time-lag of the circuit breakers was also much reduced by the substitution of an improved pattern. During 1931, the year following these changes, one fault occurred which caused instability, in addition to three others which were cleared satisfactorily; but in order to obviate further trouble balanced parallel-feeder protection was added. This is merely one example of changes that have had to be made within the last 3 years in foreign practice through the use of quite a small time-lag, and it confirms the author's opinion regarding the necessity of rapid action for protective relays. Where pilot-wire protection is possible for feeders, e.g. underground cables, it should always be used, since it combines sensitivity, discrimination, and instantaneous tripping. The difficulty that has arisen within the last few years is that it is impracticable to support pilot wires upon widely spaced towers, and their use is thus attended by great expense. Where it is decided that this expense is not justified, a type of protection should be chosen which depends upon time-lag to the least possible extent, and in this connection the "signal-current" methods described on pages 310 to 313 seem to offer an interesting solution. The carrier-current method appears to be a sound one, and its future seems to be hopeful. The Kapp-Carrothers scheme is of a similar type and should also meet the conditions. The pilot cable employed with this scheme can be used for telephony at the same time as for protective gear without any form of switching, the two functions not

* R. A. HENTZ and J. W. JONES: "Stability Experiences with Conowingo Hydro Plant," *Electrical Engineering*, 1932, vol. 51, p. 95.

interfering with each other in the slightest. The author does not do the McColl system full justice in his reference on page 310. Besides securing stability on the occurrence of through faults by bias opposition on the tripping relay, it is so arranged that the pilot capacitance-current and the other vagabond and harmful currents all pass through the restraining coil of the relay and hence stabilize the scheme, instead of tending to make it trip. Thus, without the tuning arrangement or other added complications of the schemes mentioned later in the paper, this one is quite unaffected by the usual capacitance currents in pilot or feeder, or by high-frequency surges. The author makes but a passing reference to parallel-feeder protection, although he mentions the split-conductor type, which differs in principle from the former only in that both conductors are isolated when one of them breaks down. I should like to ask his opinion as to whether it would not be cheaper in the long run to employ double-circuit lines as a standard and protect them by the parallel-feeder method, on account of the high speed and efficiency of this form of protection.

[The author's reply to this discussion will be found on page 351.]

NORTH-EASTERN CENTRE, AT NEWCASTLE, 22ND FEBRUARY, 1932.

Mr. F. C. Winfield: I should like to comment on one or two of the forms of metal-clad switchgear dealt with in Section 2. I consider that Type 1*e* (Fig. 6) and Type 2*e* (Fig. 11) are definitely bad designs. If the term "duplicate busbar" has any real meaning in practice it is surely wrong to lead both busbars directly into a common explosion chamber, which is precisely what these designs do. Types 1*c* and 2*c* suffer from a similar objection in that both busbars may be fouled by a breakdown of the oil insulation in the selector isolator tank, due to moisture or other causes. This is particularly so if these selectors are used for changing-over under load conditions. Type 3*c*, in which two independent selectors are housed in separate tanks, is much superior. The arrangement shown in Fig. 23 seems to be quite sound for the smaller sizes, but at the same time I have always felt that the "replaceable current-transformer" bogy is rather overstressed. In practice replacement occurs quite infrequently in proportion to the total number of equipments installed, and the chief objection is the high charge made by switchgear contractors. A compound-filled current-transformer chamber is better than an oil-filled chamber, and it is a pity to lose the former through overstressing a detail. If switchgear contractors would make special arrangements to deal with replacements of current transformers on a low-cost service basis I think the preference for oil-filled chambers would rapidly disappear. An addition of less than $\frac{1}{4}$ per cent to the cost of all panels would, I think, pay for most of the service necessary in this direction. I am not sure that I agree with the statement (page 299): "It is common practice to put large transformers outside, and the case for similar treatment of well-protected switchgear is equally strong." When the "grid" arrangements were first being considered in this country metal-clad switchgear and cables were for all practical purposes not available, and even now, assuming we could accept them as proven articles, I think that the decision to use mainly outdoor switchgear and lines would be adhered to in view of the very great difference in initial cost. At the same time, to maintain reliable service from outdoor apparatus very careful maintenance will be essential, including conditioning of oil, cleaning of bushings and post insulators, greasing and adjustment of mechanisms, and painting of steelwork, all under difficult service conditions frequently made more difficult by the weather. When reliable information is available in a few years' time as to the cost of maintenance of outdoor 132-kV switchgear, we may find that the disparity in total cost between metal-clad and outdoor switchgear is very much less than would appear at present after taking into account the possible improvement in service. The author's comparison between outdoor circuit-breakers and outdoor transformers is not, I think, quite a fair one. Outdoor transformers are filled with oil and are fitted with conservators and (usually) breathers. The oil and the internal insulation are therefore kept in good condition and require very little maintenance. With circuit breakers, however, a large space exists at the top for condensation of moisture, and this space cannot be eliminated. Bakelized-paper insulation must be used, and this is very susceptible to deterioration due to the presence of moisture. Frequent oil-conditioning, therefore, is essential with outdoor circuit-breakers for high voltages. Apart from this, a circuit breaker is ultimately of much greater importance than a transformer because failure of a circuit breaker may affect the supply in general, whereas failure of the transformer can usually only affect a single supply. For 66-kV and lower-voltage switchgear in the larger sizes I am of the opinion that indoor enclosure ought always to be employed, as it implies a relatively small additional cost, will very considerably reduce maintenance, and, in addition, enables provision to be made (by heating of the switch house) for the prevention of condensation. It also permits of more effective provision for fire-fighting. I have no records of any serious troubles with bakelite insulation where the switchgear is properly housed and kept warm. In this connection I have in mind four similar installations of large metal-clad switchgear all enclosed in buildings, three of which were warmed. A failure of insulation occurred on the unwarmed switchgear, followed by a serious fire. This was almost certainly caused by deterioration of the bakelite due to moisture. Examination of other equipments subsequent to the fire bore out this contention. That particular switch house has since been warmed, and no further troubles have been met with. I agree with the author that it is difficult to find any justification for the difference of permissible temperature-rise in switchgear equipments below the 2 000-ampere rating as compared with equipment above this rating. The fact that B.S.S. 116—1929 gives temperature-rises for oil only, and

makes no reference to insulation, renders this specification misleading. The ratio of 1/125 of the rupturing capacity which the author suggests as a rule for the minimum working voltage of switchgear, seems to me rather better as an indication of the minimum practicable voltage. In new work I would suggest the ratio of 1/75 as a good minimum, the ultimate decision being based on system conditions. If 6-kV switching were adopted for a station having a 300 000-kW output taken by standard 0·25-sq. in. 3-core cables, at least 150 cables and switches would be necessary. Obviously such a number is impracticable. Even if 11 kV were employed nearly 100 such cables would be necessary. The congestion on site and the difficulty of leading away large numbers of cables down adjacent roads is a serious factor in power-station design. The author's remarks about switching capacity are well timed, as it is at present extremely difficult for the buyer to compare designs produced by different manufacturers or to determine the best rating to adopt. The methods of switchgear testing adopted in this and other countries differ so widely and the presentation of results is so varied that it is almost impossible to draw definite comparative conclusions from them, and ultimately the buyer is forced to base his choice on the reputation of a particular manufacturer quite as much as on his own examination of the various designs. The British Standards Institution would be doing very useful work if it would produce some standardized performance tests on the lines the author suggests. He refers on page 308 to the practice of making main generator field-switches operate immediately after the initial movement of the main circuit-breaker. This practice was introduced originally because the older alternators with low armature reaction were incapable of keeping in step when the main field circuit was open, and it was therefore necessary to exclude the possibility of the field switch opening before the main switch. With modern machines this condition no longer holds, and the present practice is to operate the main field-switch and the main oil-switch simultaneously. I do not agree that the short-circuit calculator mentioned on page 315 is the latest addition to control-room equipment, as in America a still later form of calculator has been developed capable of investigating problems of line regulation, current distribution, power factor, and stability in both normal and fault conditions, as well as of making ordinary calculations of short-circuit kVA. I believe that one manufacturer is considering the introduction of such devices into this country. As regards the use of a tandem system of pilots for the control of d.c. traction systems (page 316), I have experience of one suburban system abroad in which this system was employed with rather unfortunate results. It was ultimately abandoned in favour of a radial system.

Mr. L. C. Grant: The application of the metal-clad principle to 66 000-volt switchgear is one of the most important switchgear developments of recent years, and probably the most fundamental change that this e.h.t. switchgear has brought about is the substitution of an oil or semi-fluid dielectric for compound insulation. This change has made possible, amongst other things, the use of an isolating system operating directly on the oil-immersed busbars as shown in Fig. 35, and has resulted in reduced bulk and lower housing costs. In the author's summary of existing switching methods I find no mention of the recently developed oil-insulated cross-jet circuit breaker, which appears to be a development of the explosion-pot circuit breaker. It is probable that the extinguishing action of an explosion pot is most effective at the orifice, and the new cross-jet circuit breaker appears to be an attempt to intensify this effect, although, incidentally the name "cross jet" seems to be a misnomer. Turning to the author's remarks (page 291) about steel contacts, I do not think such contacts are completely reliable as the action of arcing on the contacts produces hard steel globules of glass-like appearance. These globules are not removed by the rubbing action of the switch contacts, and the result is incipient arcing at the closed contacts which quickly develops into contact heating and burning. Is the author definitely of the opinion that the demand upon the circuit breaker is greatest with a low power factor? My experience shows the demand to be the most severe with a power factor of the order of 0·5. Nearer unity the duty is not so heavy, and nearer zero it is on the average lighter, but there appears to be a zone of great variability in which exceptional demands may be made on the circuit breaker.* It is possible that the author's conclusions are based on too few tests to give complete assurance on this point. Short-circuit calculating boards are not entirely above reproach. In the majority of these the results are obtained with direct current on an ohmic board, and it is impossible to eliminate some degree of error. We must be prepared for errors until calculating boards co-ordinating resistance, inductance, and capacitance, come into general use, and until our calculations take into account the change in impedance during the decrement period of a short-circuit.

Mr. D. M. Buist: The paper reveals that switchgear is practically the most costly item in the electrical circuit to-day. Are we not going too far in regard to the strengthening of switchgear? I should be glad of figures comparing the weights per kW of switchgear, transformers, and alternators. The 15 different arrangements of switchgear mentioned on page 288 have been designed to meet conditions many of which are relics of open-type switchgear. The majority of these arrangements would disappear if we had more standardization of conditions, and if less allowance were made for the individual preferences of customers. As regards page 297, I think it is going too far to separate group and section switches by brick cubicles. If this goes on we may expect to see each switch surrounded and separated from its neighbours by 9-in. brick walls, or with moulded reinforced-concrete on top of the metal. This tendency is arising because of the "occurrence of a few fires" (to use the author's own expression). Has he a record of the cause of these fires and of the damage which was done in each case? The additional cost of brickwork, etc., to safeguard against a relatively remote contingency is tantamount to a lack of faith in present-day switchgear. I agree that the practice of placing outdoor-type switchgear

* See *Journal I.E.E.*, 1930, vol. 68, p. 1097.

within a brick building is to be deprecated. According to the paper, in the future switchgear will give a rehearsal of its performance before it allows an operator to switch in. When that day comes there will obviously be no need for operators, because the switchgear will be the " robot " of the electrical circuit. As regards the necessity for earthing resistances (page 307), I expressed myself very strongly on this question at a discussion* in 1925 on a paper by the present author. I cannot understand why engineers are still so exact in their predetermination of the ohmic value of the earthing resistance, which, with the very large power stations now being built, is of small value and therefore very cumbersome. It is placed in a circuit of varying resistance, often having an ohmic value greater than that of the earthing resistance itself, this procedure being based upon the assumption that the only resistance in the circuit between the neutral and the earth plate is what is inserted artificially. The result is that protective-gear calculations are upset, and, to meet varying values of resistance at the earth plate, protective settings would require corresponding adjustments. Has the author ever made any tests to verify this? I have done so, and can assure him that such conditions exist. If a consumer insists upon an earthing resistance, let him bury it in the ground, encased in a metal shield which can constitute the earth plate.

Mr. F. A. Orchard (*communicated*): It would be interesting to know what is considered to be a reliable form of bakelite insulation (see page 290) for semi-tropical conditions. This question is especially important in view of the fact that in the future the market for the larger sizes of switchgear is more likely to be abroad than at home. As most oil-filled apparatus will in the future be for outdoor use, would it not be an advantage if by-pass oil pipes were provided at suitable points which would enable a sufficient quantity of oil to be drawn off for testing purposes at regular intervals without dismantling any of the switchgear? Tests of this kind would be useful for detecting whether moisture had entered the equipment via the mechanical joints. This idea might be further extended to circuit breakers proper, particularly to those types for outdoor use where the examination of the oil is likely to be a fairly lengthy process. If due precautions were taken such draw-off pipes could be arranged for use when a circuit breaker is in commission; this should be an advantage where, under normal conditions, feeders have to remain closed for a considerable length of time. In regard to the proposals for standardized performance tests (page 318), the author rightly bases his interpretation of the severity of service conditions on the circuit breaker's nearness to generating plant; but I suggest that if service conditions are to be entirely simulated it is reasonable to go a stage further and try out the circuit breaker under all its working conditions. It would be interesting to know whether the author proposes that short-circuit tests on outdoor switchgear should be carried out in the open. Does the British test plant to which he refers cater for tests under the conditions met with in actual service, e.g. would an outdoor circuit breaker be subjected to short-circuit in the open under both fair and severe weather conditions? The risk of widespread damage may have led to the decision to enclose almost completely the apparatus under test, as in the test plant already referred to, but such an arrangement rather improves the service conditions which the performance test proposes to imitate. I feel that pressure and short-circuit tests should be carried out simultaneously, and, further, short-circuit tests should be made with normal pressure applied under the worst possible weather conditions likely to be experienced where the circuit breaker has to be finally installed.

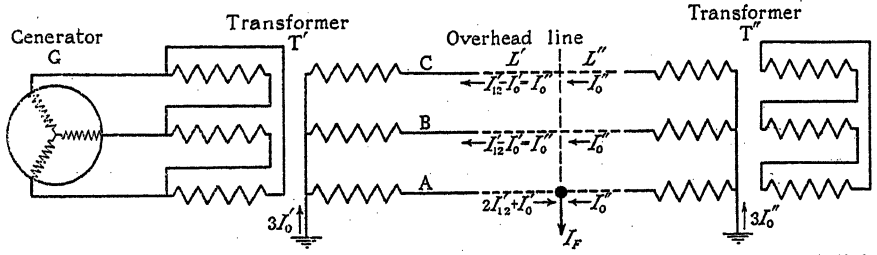

FIG. G.—Distribution of fault currents in 3-phase transmission line connected to solidly earthed star/delta transformers.

Mr. G. G. Smail (*communicated*): I am interested in the dual-circuit short-circuit calculator mentioned by the author and illustrated in the paper. The object of this is to evaluate the probable short-circuit kVA which the switchgear installed on the grid will have to rupture, and to determine the values of short-circuit currents available for relay operation. On overhead-line systems earth faults are more probable than phase faults. An earth fault constitutes an unbalanced load on the system and the ordinary method of calculating 3-phase short-circuits is not applicable. The reactance of the network is different under earth-fault conditions, and the paths by which current is fed to the fault depend on the transformer connections. In the case of the grid, the transformers are all star-connected, earthed on the h.t. side, and delta-connected on the l.t. side. Under these conditions fault current can flow from all the transformer neutrals. Transformers which have no generating plant behind them are energized via the two sound phases. Fig. G shows the simple typical circuit consisting of a line connecting two transformers, one of which has generating plant behind it. Phase A is assumed to be earthed as shown. In the calculation of earth-fault currents one may use the method of symmetrical components due to Mr. C. L. Fortescue and applied particularly to the consideration of earth

* *Journal I.E.E.*, 1925, vol. 63, p. 1028.

faults by Mr. A. P. Mackerras.* The application of this method to the circuit of Fig. G is shown in Fig. H. The fault-current distribution at any point is derived from the determination of the three symmetrical components known as the positive, negative, and zero phase-sequence components. Typical vector systems are shown on the right of Fig. H. I'_{1A}, I'_{1B}, and I'_{1C} are three symmetrical vectors having positive phase sequence, I'_{2A}, I'_{2B}, and I'_{2C} have negative phase sequence, and I'_{0A}, I'_{0B}, and I'_{0C} have zero phase sequence. These circulate between the fault position and the transformer neutrals. The zero phase-sequence reactance of the grid lines has been calculated to be 1·57 ohms per mile. In Fig. G, T′ and L′ refer to the transformer and line on the left-hand side of the fault. T″ and L″ similarly refer to the right-hand side of the fault. In the equivalent network of Fig. H the same symbols refer to their reactances. The suffixes 1, 2, and 0 relate to the positive, negative, and zero phase-sequence components, and A, B, and C to the phases. Referring to Fig. H,

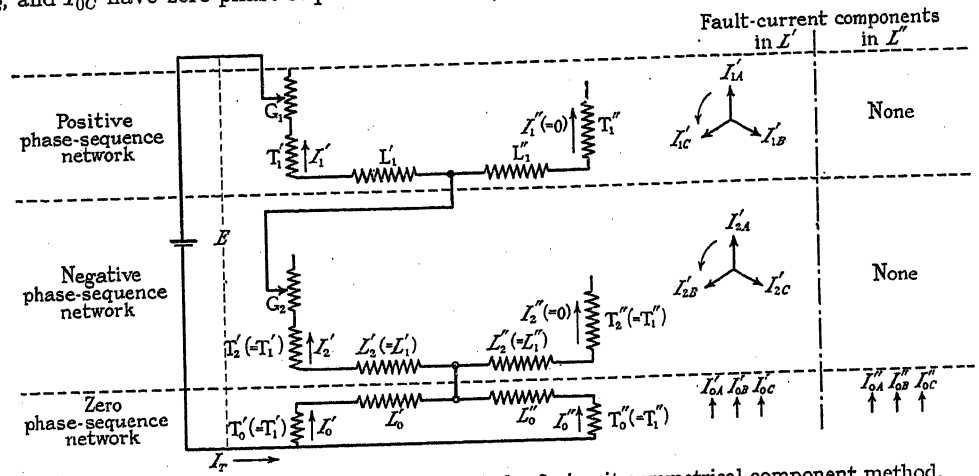

FIG. H.—Calculation of earth fault currents by 3-circuit symmetrical component method.

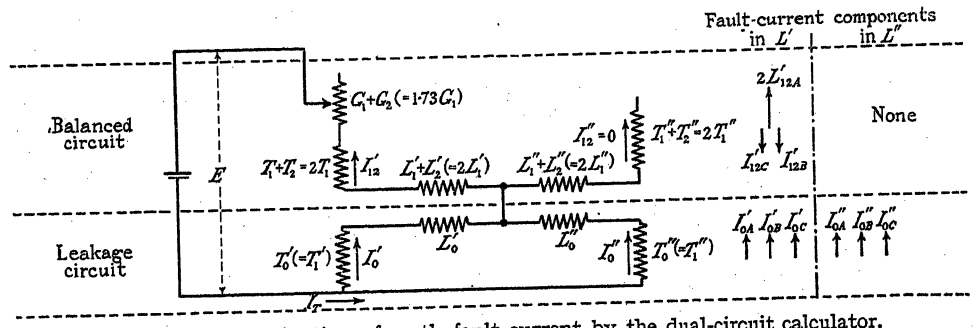

FIG. J.—Determination of earth fault current by the dual-circuit calculator.

components must be determined separately. The total earth-fault current has been shown to be $3E/X_1+X_2+X_0$, where E is the voltage to neutral and X_1, X_2, and X_0 are the total equivalent reactances of the network to the positive, negative, and zero phase-sequence currents. The components are all equal at the fault. Since the positive and negative phase-sequence networks are practically identical, these two components are very approximately equal to each other at all other points. The positive and negative phase-sequence components flow in the same paths which would be traversed by the currents feeding a 3-phase short-circuit at the same point. The reactance offered by the system to each of these components is identical to that offered to balanced 3-phase currents, with the exception of the negative phase-sequence reactance of the generating plant, which is 73 per cent of its normal positive phase-sequence reactance. The zero phase-sequence components are confined to the h.t. lines, and the fault current and its distribution would be found as follows:—

The total earth-fault current I_F	$= 3I_T = 3(I'_0 + I''_0)$
Fault current in Phase A fed from left	$= I'_1 + I'_2 + I'_0$ $= 2I'_1 + I'_0$
Fault current in Phase A fed from right	$= I_1' + I_2'' + I_0' = I_0''$
Current in phases B and C	$= -(0{\cdot}5I'_1 + 0{\cdot}5I'_2)$ $+ I'_0 = I''_0$ $= I'_0 - I'_1$
Current in neutral of transformer T′	$= 3I'_0$
Current in neutral of transformer T″	$= 3I''_0$

In the dual short-circuit calculator the above method has been simplified for the purposes of a calculating table so that only two components are necessary. The

* See also C. G. CARROTHERS: *Electrical Review*, 1929, vol. 105, p. 309.

arrangement for the case given in Fig. G is shown in Fig. J. The positive and negative phase-sequence networks are replaced by a single network in which the reactances of the lines and transformers are twice the normal 3-phase reactance, and the generating reactances are 1·73 times the normal short-circuit reactance. This combined network is called the " balanced component circuit." The second circuit is known as the " leakage component circuit " and is identical with the zero phase-sequence network previously mentioned. The balanced current components consist of the sums of the positive and negative phase-sequence components, and are shown on the right of Fig. J. In using the calculator the instruments are suitably scaled so that the fault-current components are read direct without the use of conversion factors. The total fault current and its distribution in the network are determined from the readings of the balanced and leakage component ammeters I_{12} and I_0 respectively.

The total earth-fault current $I_F = 3I_T = 3(I'_0 + I''_0)$

Fault current in phase A fed from left $= 2I'_{12} + I'_0$

Fault current in phase A fed from right $= 2I''_{12} + I''_0 \ (= I''_0)$

Current in phases B and C $= -I'_{12} + I'_0 = -I''_{12} + I''_0 (= I''_0)$

Current in neutral of transformer T′ $= 3I'_0$

Current in neutral of transformer T″ $= 3I''_0$

The generators are shown as variable rheostats. This enables the various running conditions to be taken into account. It is also possible to use the " balanced " circuit by itself to investigate 3-phase faults. The only necessary alteration to the circuit is to alter the generator rheostats to the value corresponding to the balanced reactance. Absolute accuracy is impossible with any type of calculator, because certain factors are present which it is impossible to take into account in a calculator circuit. An indeterminate variable is the arc and earth-plate resistances. Another variable is the short-circuit decrement which becomes of importance when relays, having a time-lag, are used. This can be most satisfactorily allowed for by referring to typical decrement curves by which the current value at any instant after short-circuit can be obtained. When the network consists entirely of overhead lines the resistance of the lines may be neglected. The maximum error introduced by this would be less than 5 per cent where the ratio of line reactance to line resistance is about 3. Where problems such as transient voltages and high-frequency phenomena require investigation, model circuits containing capacitance, inductance, and resistance must be used. Such a calculator would be large and expensive, and should preferably be built up so that any system could be represented by rearranging the components suitably. Where the object of the calculator is to determine short-circuit currents, a resistance calculator of the d.c. type is sufficiently accurate and is preferable to the a.c. calculator on account of its simplicity.

[The author's reply to this discussion will be found on page 351.]

North-Western Centre, at Manchester, 23rd February, 1932.

Mr. S. Ferguson: I do not agree with the author regarding the reliability of British circuit breakers, as the rupturing tests which we have carried out lead us to believe that a large proportion of the circuit breakers at present in service have nothing like so large a rating as was originally assigned to them. Faults such as " slowing up " and " stopping and reclosing " would actually take place on some of the designs at present on the market, if the appropriate tests were conducted. With regard to the author's standard conditions for rupture tests, while I agree that these are necessary I would point out that they are very fine points in comparison with the general question of knowing that the circuit breakers will actually rupture the powers for which they are designed. What factor of safety would the author suggest for rupturing ability?

Mr. T. T. Evans: In his comparison (page 291) between horizontal and vertical switchgear the author intimates that there is a limiting voltage up to which air insulation can be employed at the isolating points, and I should like to know what he considers that limit should be. In my opinion 33 000 volts is the limit to which air insulation can be employed with safety, because of the dirty and damp nature of our atmosphere and the fact that for higher voltages the space required would be rather large. Complete oil insulation should therefore be provided for voltages above 33 000 volts, even at the points of isolation. In all the cases referred to in the paper, complete oil insulation entails first isolation, then in some cases the draining of oil, and finally the removal of the circuit breaker for inspection and maintenance. This would appear to be a long and costly procedure, particularly at a time when speed is essential. The author omits to mention an important class of switchgear, distinguished by its method of isolation, namely the vertical lift-up type. For voltages where complete oil insulation is necessary, particularly at the isolating point, this class of switchgear offers many advantages. Figs. K and L (pages 348 and 349) show a duplicate busbar 2-switch scheme, Fig. K being in diagrammatic form. The chief advantages of vertical lift-up switchgear are: (*a*) Complete oil immersion of all bare live connections, even with the circuit breaker in the isolated position. (*b*) The oil circuit-breaker in the service position is fixed in a solid and rigid manner. (*c*) The busbars are arranged in a convenient and safe position in relation to the oil circuit-breaker, and if desired a complete floor can be arranged between them. This reduces fire risk to a minimum. (*d*) Complete phase separation by earthed metal is provided.

Mr. W. Kidd: Where space is limited the drop-down type of switchgear is usually more convenient than the horizontal draw-out type, although both types give satisfactory service. A change-over from one set of bus-

bars to the other can be made rapidly on drop-down gear. With regard to Fig. 37, the author suggests that considerations of temperature-rise render necessary a special type of busbar for currents of 3 000 amperes; I should be glad if he would give some further information about these special busbars. He also states that the ratio between voltage and kVA breaking capacity should be 1 : 125, and that for large power stations the economic switching voltage is about 12 000 volts. In my opinion the voltage should be substantially obsolete in a few years' time. Control boards are at present far too big; the ideal board for a power station would be of the supervisory type with an illuminated diagram which would differentiate between live and dead circuits. Miniature indicating instruments would be incorporated in the diagram, and small telephone-type control switches would be employed. The idea of trying to visualize the total load from the positions of the pointers on numerous instruments should be abandoned in favour of the use of summation instruments. The

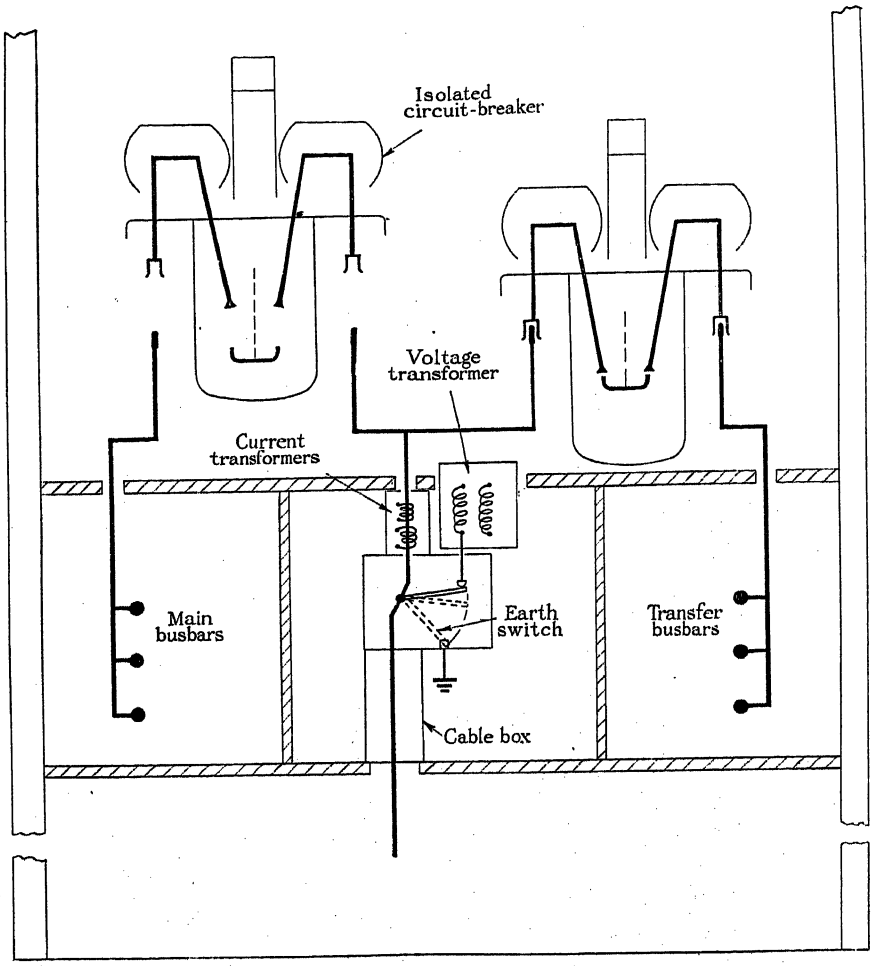

FIG. K.

higher, and as regards future large stations connected directly to the "grid," a good case can be made out for switching at 132 kV. Would the author seriously advocate 12-kV switchgear when the short-circuit kVA was of the order of 1½ million? Single-switch substations, mentioned on page 303, were adopted in Manchester before the War, and at the present time there are about 200 of them in operation. Each substation has two high-voltage feeders and one, two, or three, transformers rated up to 3 000 kVA, but only one circuit breaker; the supply can be maintained even when the circuit breaker is made dead (see Fig. M, page 350). In regard to control boards, even the type foreshadowed by the author will probably be relays should be placed in the switch house, or in a small room immediately adjacent to the switch house, so as to render it unnecessary to bring the present type of multi-core cables from the switchgear to the control board. What should be brought in is the smaller telephone type of multi-core cable, and if this were done a large saving in the cost of cable work and buildings would result. Further, the operator would have his control board within a reasonable range of vision and reach. The operations of switching and control should be kept distinct, and the operator's control board should have an entirely separate diagram. The control engineer should give definite instructions to the operating engineer. I agree with the author that metal-clad switchgear will

probably be adopted more in the future than it has been in the past, but I think that if possible a housing should be provided for it, because if compound-filled switchgear is exposed to the sun, local expansion of the compound occurs. Expansion chambers do not relieve the trouble, which causes leakage and, if the switchgear is small and incorporates thin castings, may give rise to fractures.

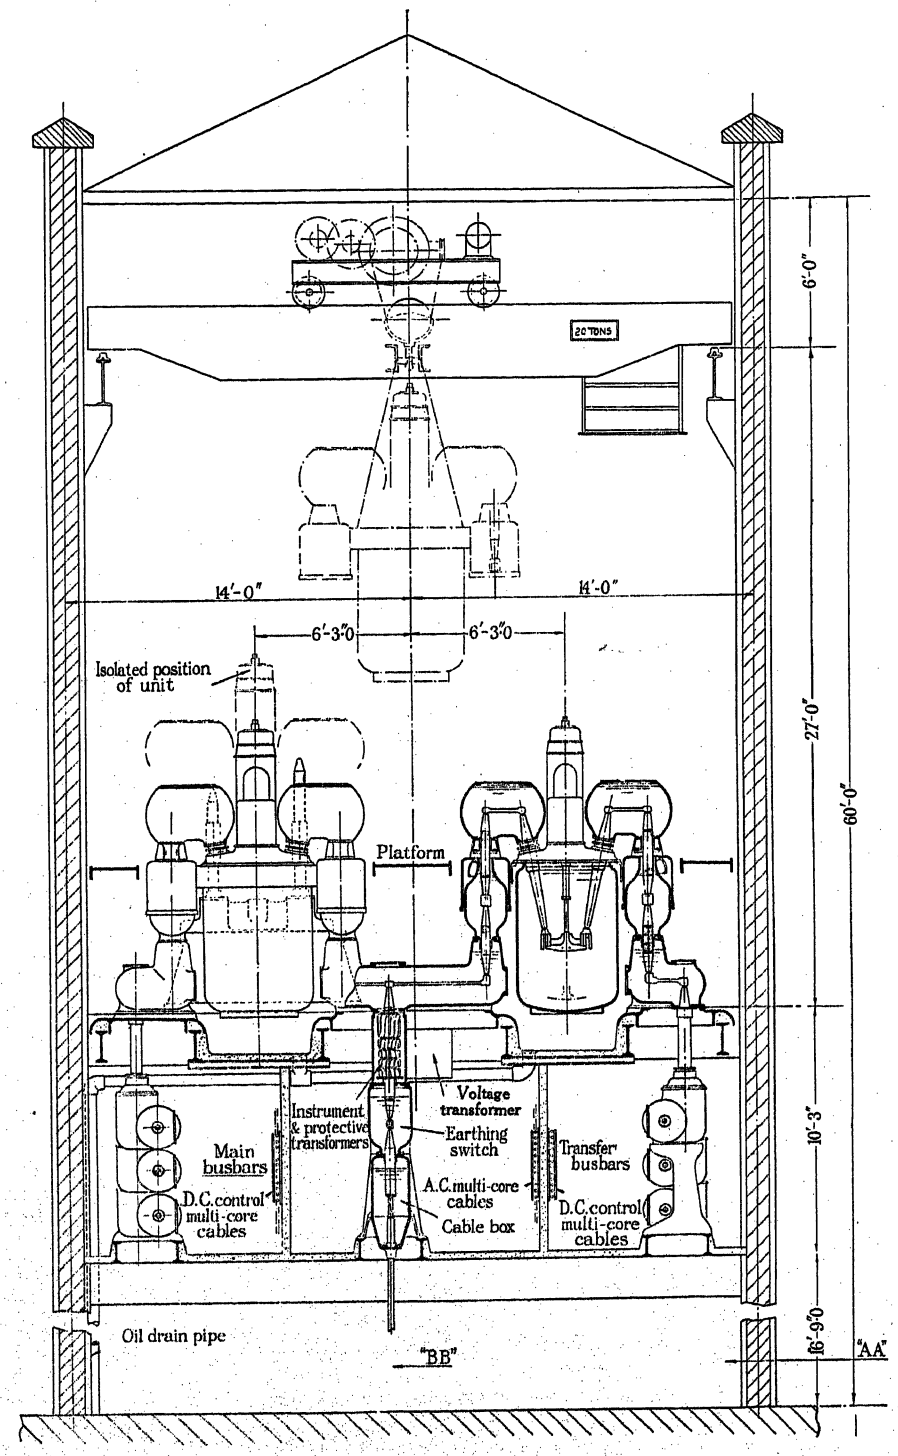

FIG. L.

Mr. H. Pearce: I shall refer particularly to Appendix I, as I feel that the author's standard short-circuit tests for oil circuit-breakers form one of the most important parts

of the paper. While I agree that standardization is a splendid thing when carefully applied, it is essential that it should avoid imposing unnecessary limitations on design or practice. As an instance of a difficulty that the author has himself experienced in this connection, it may be noted that he gives the results of several tests, not one of which complies with his own standard conditions, since the tests were made at 40 cycles per sec. The criterions of severity of the test are still very little understood. The author himself, as Mr. Ferguson mentioned, has left out what is believed by many people to be the most important factor, viz. the rate of rise of recovery voltage. Assuming that the power factor of the short-circuit current is fairly low (of the order of 0·1, as mentioned in B.S.S. No. 116—1929), at the moment of break the voltage is very nearly at its maximum value. The way in which the voltage will rise to the maximum depends entirely on the constants of the circuit on the generating-station side of the circuit breaker. The reactance, which dictates principally the drop in voltage, will, with any capacitance there may be between that reactance and the circuit breaker, form an

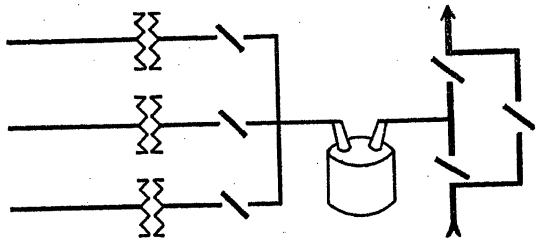

FIG. M.—Manchester single-switch substation.

oscillatory circuit. The frequency of that circuit and the magnitude of the recovery voltage will together largely determine the rate of rise of voltage, though other and smaller oscillations may also be present. The author carefully adjusts the power factor of his test circuit to the specific value 0·1 mentioned in B.S.S. No. 116, a procedure which makes the duty of the circuit breaker easier because it reduces the rate of rise of voltage. I cannot believe that B.S.S. No. 116 is designed to make the duty of the circuit breaker lighter when it is under test. I hope that as short-circuit testing becomes more common and more precise we shall find some way of defining the severity of the test. At present the only device for measuring the rate of rise of recovery voltage is the cathode-ray oscillograph, which is still a rather cumbersome piece of laboratory equipment, unsuitable for regular use on short-circuit tests.

Mr. W. A. Coates: I propose to confine my remarks to those portions of the paper which deal with 132-kV apparatus. While no engineer would question the reduced insulator-maintenance and site costs associated with metal-clad equipments, against these advantages there must be set off a measure of inflexibility, and often of inaccessibility, which might well tip the scales in favour of open-type 132-kV switchgear of equal initial cost. Designs are at present being prepared for extensions to two of the " grid " stations in Scotland. These, which are of the 3-switch type (see Fig. 39), must now be altered to what is termed the " mesh " connection, to bring in an extra feeder. Equipments rather like that shown in Fig. 35 could clearly be assembled to form a 3-switch group, but I cannot imagine such a modification to a 5-switch mesh system being carried out, except by shutting down the whole station for some weeks. With the standard open-type equipment, I expect to carry out the above extensions without once interrupting the supply. Further, practically no changes will be needed to existing structures or foundations, and all the present items of equipment will be used again. It would be difficult to design a metal-clad switchgear system to which the extensions mentioned could be effected without scrapping a lot of existing material, and I should like to know whether the author has a solution for this problem. The footnote to Fig. 34, explaining the functions of the by-pass isolator A, is more plausible than complete. The switches at A are intended to permit access to the feeder circuit-breakers for maintenance purposes. By closing the by-pass, the busbar coupler on the right can be used in linking up to the top set of busbars. Even with a metal-clad design, therefore, a by-pass isolator should be included, to give maintenance and operating facilities equivalent to those of open-type switchgear. The ingenious principle involved in the isolating feature shown in Fig. 35 strongly resembles the patented arrangement of bushings which is being employed on the grid circuit-breakers in this district, as well as in East Anglia and South Wales, with the object of speeding-up erection and maintenance work. Were the bushings shown in Fig. 35 actually designed for 132 kV, and, if so, what is their overall diameter? The extra length of earth band provided will be useful for the accommodation of current transformers, which in this design must all be on one side of the circuit breakers. The busbar side bushings, being allocated one to each busbar, are obviously not usable. The problem of including the circuit breaker in the relay protective zone is rather difficult with this arrangement, and I should be glad to know its correct solution. The condenser-coupler method of potential measurement seems to be the result of a firm determination not to do the obvious. The weakness to which high-voltage potential transformers were at one time subject have been eliminated by modern coil-winding machinery, and the most recent designs, such as are being used on sections of the grid for which my firm is responsible, incorporate features of coil-shaping and shielding which make the winding quite surge-proof. No primary fuses are used, as they are deemed quite unnecessary. A straightforward device of this type, costing no more than a capacitance coupler and needing no adjustment with varying burdens, is surely preferable to the mysterious assembly of tuning devices shown in Fig. 36.

Mr. E. C. McKinnon: The title of the paper implies that the small paragraph devoted to tripping batteries completely covers all the developments during the last 7 years in relation to storage batteries for remote control, although this, of course, is by no means the case. I agree with the author regarding the deficiencies of Leclanché cells, and I fail to understand the attitude of Post Office engineers in adhering to this type of battery for telephone systems when suitable secondary batteries of various makes are readily available. With regard to

the relative advantages of the nickel-iron and lead-acid secondary batteries, I would point out that the nickel-iron type of alkaline battery is the one secondary battery which cannot be trickle-charged. The author is by no means alone in his failure to differentiate between the nickel-iron and nickel-cadmium types of alkaline batteries.* Lead-acid batteries have many points of advantage, particularly the types specially designed for substation work, and their use is rapidly extending.

Mr. T. W. Ross: I will confine my remarks to the section dealing with protective gear of the distance type. The distance relay had been used abroad for some years prior to the commencement of work on the British grid, and when it was found necessary, in protecting the 132-kV lines, to depart from the well-established practice of using pilot wires, this alternative was the first choice. At that time the large majority of distance relays were based on the impedance-measuring principle, and when carefully designed they had proved entirely satisfactory. Impedance relays of a type which had been designed and manufactured in this country for export were chosen for the protection of the first section of the grid. Their 2 years' service in Scotland has demonstrated that this choice was fully justified: the relays have operated and discriminated correctly on the faults which have hitherto occurred, in spite of the statements on page 310 and in Appendix III to the effect that the resistance of the arc might lead to incorrect location of the fault by impedance-measuring relays. Turning to the author's experiment for settling the rival claims of reactance-measuring and impedance-measuring relays as regards fault location, the method of carrying out this experiment must give results favourable to the reactance relay, since the arc obtained is not entirely comparable with that resulting from a fault under practical conditions. The great majority of line faults result in a flash-over on an insulator or string of insulators, which on 132-kV lines means an arcing distance of the order of 40 inches. The electrodes in the experiment were spaced 72 inches apart, and, moreover, the arc was struck in space and not across the face of an insulator. This latter point is of some importance, since the arc resulting from the flash-over of an insulator usually clings to the insulator surface and does not spread as rapidly as an arc in space. The difference in the test conditions may explain the comparatively high values of arc resistance indicated by the experiment. Reference to the available data on the subject shows that the figures given in the paper are from 30 to 60 per cent higher than those resulting from other experiments carried out for the same purpose. It would be of interest to know how the R.M.S. values shown in Appendix III were deduced from the oscillograms, since the current and voltage wave-forms must have been considerably distorted. This distortion would cause the apparent power factor of the arc to be less than unity, with the result that distance relays might be appreciably affected unless special precautions were taken in their design. The distance relays of the impedance type in use on the British grid are designed for quick operation over 70 per cent of the feeder length, and having once operated they do not reset until the impedance has increased to more than twice that of the whole feeder. It is therefore apparent that the arc has not time to lengthen before the relay has taken up its position. This it will do in less than 0·1 sec. A time-delay has, of course, to be introduced for faults on the remaining 30 per cent of the feeder length. The time-delay may be of the order of 0·7 sec. without the addition of any extra impedance due to the arc, and if we assume an arc of reasonable length the time-delay may automatically be increased to a maximum of 1 sec. Is it, therefore, desirable, in order to eliminate the probable extra time-delay for faults on 30 per cent of the feeder length, to substitute all the complications of reactance-measuring equipment for the comparatively simple impedance relay? Simplicity, in my opinion, is of greater importance than any theoretical advantages, and simple relays are more likely to be satisfactory in service than the many complicated relays used in the author's distance-measuring equipment.

Mr. S. R. Mellonie (*communicated*): The relationship suggested on page 301 between the kVA rupturing capacity of the switch and the minimum voltage gives a figure of 320 volts for a rupturing capacity of 40 000 kVA, and the author will agree that the cost per kVA of such a unit would be high. A more satisfactory figure would be twice the voltage. I should welcome the author's opinion regarding the maintenance of metal-clad units. As the only exposed insulation adjacent to live metal is that in the spouts, the question arises whether this can safely be cleaned when the busbars are alive. With a specially-designed circular hollow cleaner made of insulating material, which makes it unnecessary for a man to place his hand any nearer the live metal than the outside earthed cover, the risk appears to be very small. In industrial districts the amount of dust which collects in the spout insulators is considerable, and if this could be removed without making the busbars dead the advantages of metal-clad switchgear would be still greater than at present.

* The reference in the advance copies of the paper to the nickel-iron battery has been altered for the *Journal*.

The Author's Reply to the Discussions at London, Newcastle, and Manchester.

Mr. H. W. Clothier (*in reply*): The discussion is lengthy, but it may be hoped that it has clarified some of the many outstanding problems. It has turned mainly on the rating and test-performance of circuit breakers. It has raised a repeated demand for a specification of the rate of rise of restriking voltage, the reply to which is that the paper covers the point by specifying the constants of a standard test-circuit upon which all ratings shall be based. Criticisms of the proposed standard test-circuit conditions are such as will, I think, lead in the end to a much better understanding on the part of the purchaser of how to determine circuit-breaker ratings for different vicinities on his system.

The erstwhile demand for radical changes in breaking-capacity methods has sobered down to suggestions of boxed improvements in the arcing contacts of oil circuit-

breakers. I agree that increased margins are within reach by these means, but further investigation is necessary, particularly in respect of " making " on short-circuit, before the limits of the improvement can be determined. The proposals of the paper for increasing the range of voltage for which metal-clad construction is advantageous have not been shaken.

Absolute reliance on continuity of supply is of such vital public importance that I have been led to suggest that the operation of protective systems should come more closely under the observation of the Institution.

An extraordinary number of important questions and points of detail have been raised in the discussion, which spread over six evenings, and an endeavour is made below to reply to them collectively under analysing headings, as far as possible in the order of the items in the Table of Contents printed on page 285.

Switchgear Construction.

Innovations.

I do not agree with Mr. Coates in associating his Fig. A with the German design, which, on reference to British Patent No. 23348/1913, is found to be as shown in Fig. N. Rather his outline is a replica

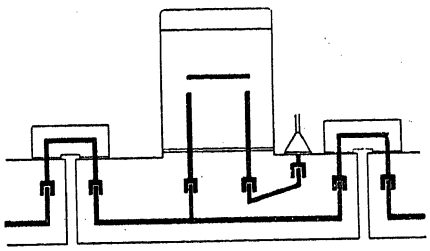

Fig. N.—Oil isolation with ring busbar.

of an illustration that I have already recorded in the *Journal*.* Moreover, he is only right in assuming that his arrangement of condenser-insulated busbars differs from what has hitherto been seen in respect of the questionable advantage of the absence of oil-filling. Figs. 17 and 21 of the paper show busbar tubes so small that the busbars could only be insulated by completely covering them with insulating material, which was also of bakelite paper with condenser-layers of foil.† The only difference is that the small remaining clearances were filled up with oil to avoid any risk of ill-effects from possible air-spaces.

I agree with Mr. Evans as to the limit of 33 000 volts for air-insulation of isolating orifices, and for power-station services on the lines of Fig. 15 oil is preferable at 33 000 volts and under. As Mr. Evans says, the vertical lift-up has been omitted from the list of generic classifications (page 288). This was due to my not having, at the time of writing the paper, the information now shown in Mr. Coates's Fig. A and Mr. Evans's Figs. K and L, and to the abandonment of my own earlier proposals for this class.

Contrary to Mr. Evans's statement, the ordinary inspection and maintenance of circuit breakers of the new forms with complete oil-insulation shown in the paper only necessitate the usual process of removing the tank in the suspended types, or the draining of oil for access through a manhole cover in the type with the tank resting on the ground. This is done, after isolating and earthing, by means of hand levers, which is really not such a long and costly procedure as in the form he advocates, for which the circuit breaker, complete with its tank, must be removed by a crane, as shown in Mr. Coates's Fig. A, before the tank can be removed. All Mr. Evans's itemized advantages (*a*) to (*d*) apply equally to Figs. 21 and 35, except for the possible addition of a floor, which is not switchgear and seems to be losing one of the advantages of metal-clad switchgear, namely self-contained unit construction and factory grouping; and in my preference for busbars above circuit breakers of this particular type I have Mr. Ferguson on my side.

Instrument Transformers and Instruments.

I heartily endorse Mr. Winfield's preference for compound-filled current transformers in small and medium-sized switchgear. No one outside the factory could realize the additional cost and delay that come in the train of accessible current transformers and oil-filling in the truly compound-filled class of switchgear. The extra cost would assuredly be paid over and over again if on the few necessary occasions the compound-filled chambers were brought back to the works, notwithstanding the need for breaking and remaking the cable joint. Mr. Moore suggests that the ratio of meter transformers should be checked every 10 years, to ascertain whether there has been any ageing, with consequent change of accuracy in the readings of instruments. He raises a doubt, but gives no evidence of ageing of either current transformers or voltage transformers. Thousands of the former have been fixed solidly in compound-filled chambers for use during the last 25 years, and voltage transformers have always been removable.

In further reply to Mr. Moore, I think that other papers recently read before the Meter and Instrument Section have recorded details of progress in instruments so adequately that there is no need for repetition here. I agree on the importance of accuracy in integrating-meters, in view of its effect upon revenue. The meter, unlike the transformer, contains moving parts, which may be slowed down by age, and must be periodically checked.

I do not like to hear about direct access to primary fuses or power-transformer terminals. It savours too much of the risk of accidental access to live conductors. Rather than eliminate plug connections, I would concentrate upon perfecting their good-contact-making quality, for the sake of easy withdrawal of apparatus for safe isolation. Mr. Moore says that much expense and delay would be avoided if all primary and secondary fuses were made accessible. This may be thought to be so in considering the operator's time only; but accessibility of high-voltage apparatus must not be attended with personal risks, and for this reason some high-voltage fuses have been deliberately so placed that they cannot be reached until the circuit breakers connecting them to the busbars have been opened and isolated. As to the secondary side, although I agree

* *Journal I.E.E.*, 1925, vol. 63, p. 428, Fig. 5; also British Patent No. 110808/1916; and Figs. 8 and 9 of my British Association paper, 1927.

† British Patent No. 339677: Application date 13th September 1929.

with the need for easy access when considering the comfort and efficiency of the operator, another vital point, mentioned elsewhere in another connection, is that some protection is also necessary as nearly adjacent to the secondary winding as possible. This is because a short-circuit on the secondary generally means a burn-out of the primary, and so the protection is required to cover the whole of the circuit, and not only the part from where a conveniently accessible fuse would be placed.

The truck type, in which the whole of the instruments, the wiring, and the current transformers and voltage transformers, are removable intact, may be thought to be ideal for meter testing; but ought Mr. Moore to couple it with the cubicle type, in which the tester has to work in a confined space, which may be alive inadvertently? Moreover, even with the truck type, if the whole thing is withdrawn, great care must be taken before making full use of the facility, since otherwise it is possible to get high voltage on the bare exposed conductors through the voltage transformer. Again, it is neither safe nor convenient to make a test by passing high voltage through the panel; and so all that is really gained is that the current transformer is made accessible.

Tests, other than for ordinary accuracy of transformers, connections, and meters, such as a "thorough test of metering equipment" before leaving the works and on erection, are usually controlled by the purchaser's specification. Frequent repetition may involve costs that the purchaser is not prepared to face. It depends upon what is meant by "thorough."

Horizontal or Vertical.

From illustrations of broken top-plates shown by Mr. Ferguson on the screen at Manchester and by Mr. Wilkinson at London, one would fear distortion of busbars when placed immediately over these top-plates. Mr. Ferguson assures us, however, that in thousands of tests this has never occurred; but the horizontal type has been proved equally under tests. I think that the evidence is, if anything, in favour of the horizontal type, in which the circuit breakers are more remote from the busbars; but really in both types it is a matter of forethought in design, and there must always be adequate provision for holding down the circuit breaker. The same applies to top-plate insulators, which, if insecurely fixed, may be forced into the busbar chamber structure in the vertical type; but incidents of this kind may be common to either class, and although such an occurrence would be less harmful in the removable horizontal type, because it would be easier to repair on the circuit breaker, in both forms it is only a matter of knowing what stresses are to be met with, and designing accordingly.

Mr. Wilkinson draws attention to a point already dealt with in the paper (page 291), namely that the horizontal arrangement is designed in accordance with the usual British practice of using change-over switches in preference to a duplicate circuit-breaker for changing over from one busbar to the other; but I do not agree with him that it does not give the same scope or range of operation. I have always contended that, for the same cost of production, one circuit breaker is better than two, because there are fewer parts, and these are of a higher quality, and are therefore less costly to maintain. There is not much to be gained by the wide separation of compound-filled busbar chambers; this is an idea associated with open-type switchgear, but not relevant when busbars are properly metal-clad.

I agree with Mr. Kidd that both the horizontal and the vertical type will give satisfactory service, provided they are designed with the same care and with equal study of the varying characteristics of each; but I do not agree that a change-over can be made more rapidly with the vertical type. This also is a matter that can only be judged from the method adopted.

Disposition of Busbars and Phase Separation.

Although I agree with Mr. Winfield on the desirability of avoiding having two sets of busbars and connections thereto in the same chamber, it must be admitted that there are very few ways of doing it. Fig. 15 is satisfactory, but is not immune from the criticism, because when one isolating switch is closed it connects its busbar into the other tank. Duplicate circuit-breakers (Figs. 5 and 10) are not immune, because, when both circuit breakers are in position, and one is closed, the idle busbar connections and the live busbar connections both enter the idle circuit breaker. Fig. 8 does it; but this necessitates complete removal of the circuit breaker when changing over. Fig. 35 is near perfection, because the unused busbar connection is both isolated in two places and also earthed in two places, one of which is visible. At the same time it should be recorded that, although the largest proportion of duplicate busbar switchgears do not comply with the ideal, I do not know of any failure in consequence. No device that has to change over on load can comply, because there must obviously be one last contact that has to be closed in order to join the two busbars together; but it is possible so to interlock that this last contact shall not be made until the busbars are paralleled. Again, at the place where the busbars are paralleled the two must come together in one chamber, and before paralleling the potential difference still obtrudes itself.

Mr. Blandford asks whether it is desirable to obtain complete phase-separation in the smallest types, rather than to use tanks with an air space common to all phases. This seems to me to be merely a question of cost of production. Comparing the two alternatives, I think that the combined quality of three separate enclosures has to be greater, and is therefore more costly, than that of a single enclosure of the same switching capacity. Up to and including 750 000 kVA, I prefer the common tank with earthed metal between phases; but I would not attempt to fit complete barriers, either of metal or of insulating material, between phases in one tank, on account of the tendency to distortion of the barriers by occasional greater stress in one phase than in its neighbour. Beyond 750 000 kVA, other mechanical considerations are a determining factor and lead to a single tank for each phase. Mr. Coates also refers to testing circuit breakers with single versus three tanks, and I agree that common top-plates and air spaces introduce a distinction in respect of test requirements. It may be argued, however, that it is not sufficient to test separately one single-phase unit of a

3-phase circuit breaker, or, if this is done, it is not correct to assume that the proved breaking capacity of one unit can be multiplied by three to give the rating of the 3-phase circuit breaker, since under actual service conditions any one phase may do more work than either of the other two phases. If it is assumed to do 50 per cent more, it may be taken as a guide that the sum of the kVA-performance values of the three units tested individually is of the order of 30 per cent greater than the corresponding value for the three units taken collectively.

For voltages of 66 000 and upwards, it may be very difficult to obtain 3-phase testing on test-plants, owing to the large size of the transformers required; and, seeing that circuit breakers for such voltages are always earthed in service, Appendix I (page 319) allows for the alternative of testing single-phase units.

Switchgear Lay-out.

Mr. Wedmore raises an issue about duplicate busbars, and in reply I should like to refer him to the 1925 paper and discussion,* in which he will see that my criticisms were not directed against duplicate busbars as such, but rather against duplicate circuit breakers when used with duplicate busbars. I contended then, as I do now, that duplicate busbars have certain uses in large generating stations, but that one of these is not for the kind of rapid change-over that warrants the use of duplicate circuit breakers also. It is preferable to isolate the circuit first, and then to make the necessary change-over. Mr. Wedmore speaks of his conversion by the experience of the last 14 years as though it was only in that period that development in a "sufficiently reliable form" had taken place; but the development has been satisfactory over the last 25 years at least. Switchgear units of the largest capacity still in use to-day had already been made more than 14 years ago, and these units were fitted with duplicate busbars and single circuit-breakers, as was all other power-station metal-clad switchgear prior to that time. My experience with this type of switchgear has not justified Mr. Wedmore's suggestion to place a wall between duplicate metal-clad busbars, and I think he is mistaken in saying that the additional cost would be very small. In some cases, indeed, such as those of Figs. 21 and 35, it would lead to an entire re-design of the switchgear, and for what seems to me little or no gain he would have to abandon the factors leading to the very economy that he in common with other speakers demands. I feel that the hankering after duplicate circuit-breakers changing over on load, and separation of duplicate busbars by walls, has been handed down from the time when the control of operating conditions was very different from what it is to-day.

Mr. Highfield finds minor mechanical faults too frequent, and calls for greater attention to the mechanical movement. He suggests compressed-air or hydraulic operation. Mr. Trencham gives the cue for saying that, as electrical engineers, we need no excuse for taking advantage of the "wonderful flexibility" of the power we control; and so we do not disregard our own product for power-supply purposes in operating switch-mechanism. But I think that, even apart from this, the greater cost of producing and maintaining a power supply by pneumatic or hydraulic systems must be a reason for their non-adoption. Mr. Highfield instances railway signalling by compressed air, but should we not advocate, for economy and greater reliability, the use of electricity for this purpose? I have had pneumatically-operated circuit breakers* on trial for several years. The operating cylinders are certainly perfect in their simplicity; but we fear to put them into practice lest there should be condensation and freezing; and, moreover, it would be fatal if the compressed air failed at the critical moment, for which everything must all the time be maintained in perfect readiness, even though it occurs, perhaps, only once in six months.

Mr. Buist is one of the users who criticize the strengthening of switchgear, but he is also one of the culprits in putting increased power behind it. He asks for weights per kW of switchgear, transformers, and alternators. For a typical case, say a large power station stepping up from 11 000 volts to 33 000 volts, with the switchgear in the reasonable place, namely on the 33 000-volt side, these are as follows:—

Transformers	6·8 lb. per kW
Generators, including condensers, air pumps, etc.	39 lb. per kW
Switchgear	12·5 lb. per kW

The switchgear includes the feeder circuits, each of which has to be of nearly the same weight as the generator circuits.

Regarding Mr. Buist's constructional criticism of the separate-room power-station switch-house, I must admit that I would prefer to put the whole gear out in the open as a cheaper precaution against fire arising, for example, from the effects of bombs. The causes of damage in the past have, I believe, been principally insulation failures, which are curable when the possibilities are properly realized; but I foresee that in the future there may be failures in the operation of circuit breakers on short-circuits when under new conditions above the true ratings. If Mr. Buist likes to put it that way, it is a lack of faith in all the switchgear in use to-day, which in the future, on account of extensions and because of the grid, is likely to be over-stressed. I think that an increasing degree of automatic control will free operators for some more soul-inspiring occupation than the present-day monotony of standing-by and watching, and occasionally turning a handle.

Outdoor Switchgear.

Mr. Orchard would carry out circuit-breaking and high-voltage tests simultaneously in the open, so as to reproduce operation under the worst weather conditions. This is sound enough, but would need some staging, since test-bay bomb-proof enclosure, automatic fire-extinction, 2 to 3 times normal voltage, and the reproduction of a scorching hot day or a snowstorm, do not mix well together. I hope the introduction of metal-clad switchgear for outdoor use will in future remove some of the reasons for this proposal. A full study of the programme outlined by Mr. Leeson will show that in due course ordinary field tests may be checked by

* *Journal I.E.E.*, 1925, vol. 63, pp. 428, 447, and 465.

* British Patents Nos. 297012—1927 and 298272—1927.

calculation from the results of tests on the standard circuit. In the meantime, this may not eliminate the desirability of field tests; but they are very difficult to arrange for on a large scale. I have rarely found a supply authority prepared to put at one's disposal a complete system, with sufficient power behind to be of any use; and even if help is forthcoming the tests have to be so much curtailed that they are apt to give very misleading results when compared with the full measured work in properly designed test plant. The comparison is analogous to the difference between the hurried performance of an untrained amateur and that of a full-time professional.

Mr. Winfield makes a good case for housing metal-clad switchgear, and the reduced dimensions make it reasonable to think of doing so even at 132 000 volts; but the risks of deterioration will be no more than those to which open-type circuit breakers for the same voltage are already exposed on the grid. The bakelite to which he refers in comparing its behaviour in a cold and a warmed building was probably of a quality much inferior to that which is procurable nowadays. As to provision for fire-fighting, I think that, if required, this could be made just as effective in the open as within a building. This leads one to a consideration of men who might happen to be near the switchgear at the start of a fire; they would have a much better chance of making their escape from metal-clad switchgear in the open, and certainly the chances would be enhanced by the absence of live conductors. To quote Mr. J. L. Hecht *—and rightly so, because he has had experience of metal-clad 132 000-volt switchgear, although of a non-unit panel type—" Hazards to personnel are almost completely eliminated."

On the issue of " indoors or out of doors " for metal-clad switchgear, Mr. Winfield and Mr. Buist take opposite sides; and since they both advise those who pay the piper I leave them to settle the tune. Mr. Kidd prefers housing on account of expansion of compound in the sun. It is not an easy matter to provide for this expansion and for breathing of air spaces when compound is used; and I agree that the difficulty is reduced with indoor mounting, which is usual for switchgear of ordinary dimensions. For the higher voltages, oil-filling, with conservator tanks and breathers, provides for changes in weather conditions.

132 000-*volt Metal-Clad Switchgear.*

After all that has been learnt about metal-clad switchgear, it is a wonder that Mr. Coates and Mr. Blandford should still anticipate difficulty in making extensions to it. Do they have trouble with metal-clad switchgear for ordinary power-station voltages? If not, they should have no reason to confess to any anticipation of difficulties, either in extensions or in maintenance, when the same principles are applied to higher voltages. Mr. Hecht records† that " the carrying on of constructional work is simplified and expedited," and he goes so far as to claim that metal-clad switchgear has a large salvage value when the growth of the system compels replacement.

* J. L. HECHT: "Development of the Waukegan Station of the Public Service Company of Northern Illinois," American I.E.E. Paper No. 32M9. (An abstract of the paper appears in the March 1932 issue of *Electrical Engineering*.)

† *Ibid.*

Mr. Trencham refers to some 132 000-volt equipment in which oil-immersed isolating switches and earthing contacts were used, with, in addition, air-break withdrawal plugs and sockets. I understand this relates to the American arrangement that I illustrated diagrammatically in Fig. 33, in the absence of full information* when writing the paper. I note that Mr. Trencham does not agree with the duplication of isolation to which he refers, although it is apparently a safeguard approved by the users. I would point out that practically both features are embodied in the new proposal as illustrated in Fig. 35 of the paper. In this design the central isolator is of the plug-and-socket type, and in addition there is an oil-immersed isolating and earthing switch co-operating with it.

Mr. Blandford, referring to Fig. 35, says he would not care to trust his life to mechanical interlocks, and prefers a visible isolation before engaging on any inspection or adjustment of the contacts in a circuit breaker. Mr. Trencham also refers to this point. There is much to be said in favour of visible isolation; but enclosed isolation, with definite and positive earthing, if the earthing is also visible, is just as effective. In the design shown in Fig. 35, a definite and visible isolation may be secured by the entire removal of the circuit breaker, if the additional trouble is thought to be worth while.

Replying to Mr. Blandford, my reference to further development (page 289) relates to prospects of using the metal-clad principles for more than 66 000 volts, when the circuit breakers will be heavier owing to increased clearances. They would not necessarily be overhung. Fig. 14, which is associated with Fig. 21, indicates the alternative. I think the interlocks can be made just as immune from derangement as in any of the better-known forms of metal-clad switchgear, of which it is a characteristic that the compact arrangement of parts renders interlocking more substantial than on the known forms of open-type switchgear. I do not anticipate Mr. Blandford's suggested difficulty of breaking charging-currents on any device used on Fig. 21, since all the contacts are in oil, as shown in Fig. 26. The advantage of space reduction is again that which applies to all metal-clad apparatus, particularly when it is to be enclosed within a building. As compared with the open type, the reduction is permissible because of the convenience it affords in inspection and maintenance while adjacent panels in close proximity are alive, and even out of doors the space consideration is important in congested areas.

Replying to Mr. Winfield, I am satisfied that the designs shown in the paper will bring the initial cost of the production of metal-clad switchgear very close to that of the open types now used on the 132 000-volt grid, and that, when information is available on the cost of maintaining the respective types, the disparity will turn the scale entirely in favour of the metal-clad type.

Some speakers complain that switchgear has become too bulky, and plead for reduction. I think we are apt

* E. C. WILLIAMS: "Electrical Design Features of Waukegan Station," American I.E.E. Paper No. 32—57 (published since my paper was written). (An abstract of the paper appears in the March 1932 issue of *Electrical Engineering*.)

to overlook the fact that the increase is due to the great increase in power and voltage of recent times. At all events I hope that the present proposals will be accepted as evidence of a tendency to reduce dimensions. For example, Fig. O compares the type recommended in the present paper with the vertical-lift-out oil-immersed-contact type of switchgear in accordance with my earliest proposals* for oil isolation. The lower part of the illustration shows the duplicate circuit-breakers. The upper part corresponds to the circuit breaker illustrated in Fig. 35 of the paper, which allows an oil-break change-over for the duplicate busbars and thus requires only one circuit breaker per unit, and also avoids conductors from the two busbars in the same chamber. It does not follow that this design is final; but it does show progress in the economical replacement of bare-conductor switchgear for such voltages as 132 000 volts.

In reply to Mr. Coates's statement in Manchester about the conversion of a 3-switch group mesh sub-station into a 5 or 6 group mesh, I cannot think that he has given full scope to his imagination, because it is eminently simple and safe to open the ring for the short period during which the new connections are being made to the additional panels, which would previously have been erected in safety alongside. He suggests that the footnote to Fig. 34, relating to the bypass, is "more plausible than complete." It is not plausible: it is true, because it represents not only common but

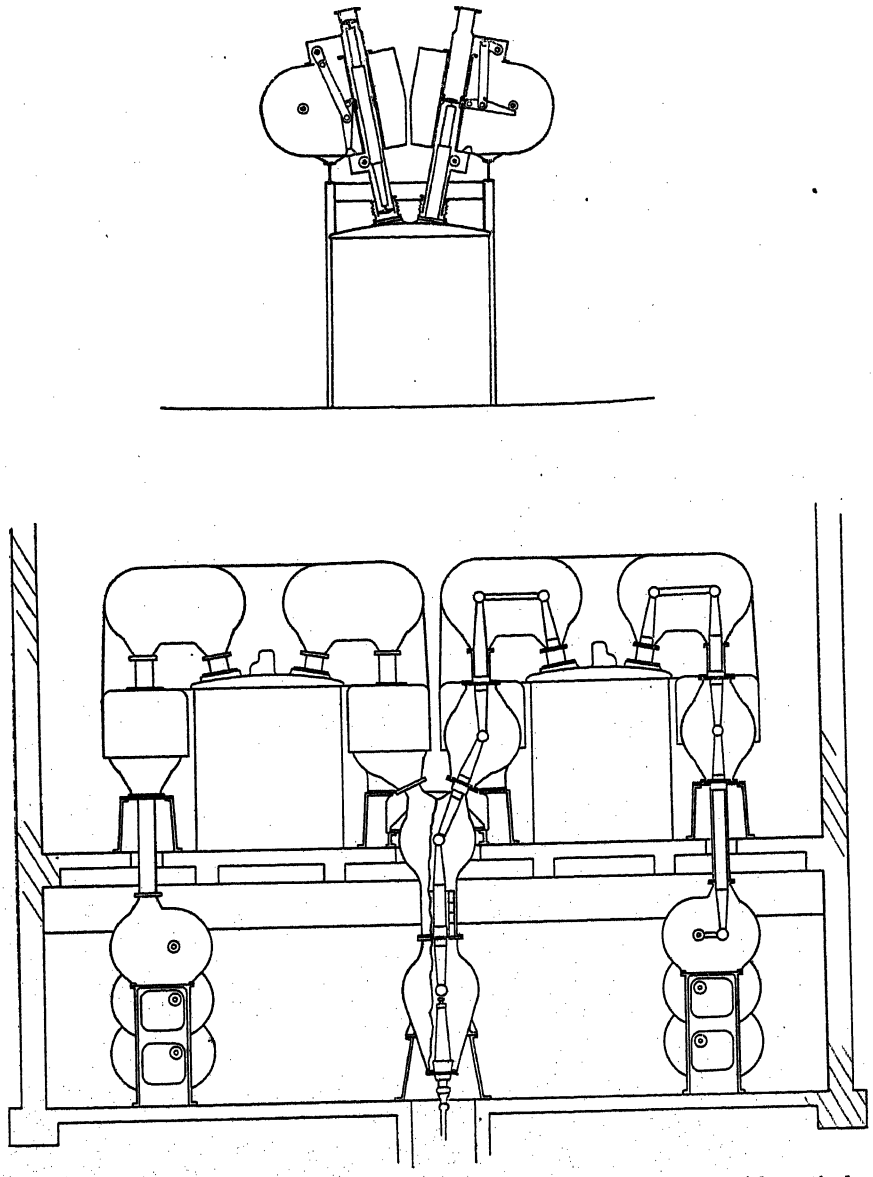

FIG. O.—Comparison of type of switchgear recommended in the paper with vertical-lift-out oil-immersed-contact type.

* British Patent No. 110808—1916; see also Figs. 8 and 9 of my British Association paper, 1927, which forecast the somewhat expensive type of switchgear now adopted by Mr. Coates and Mr. Evans for 66 000 volts.

universal practice with metal-clad switchgear. On straight metal-clad switchgear the need for bypasses has not been found, even in the largest power-station equipments, and so it is also reasonable to suppose that the same maintenance considerations would apply to metal-clad switchgear for 132 000 volts arranged like any other duplicate-busbar change-over job. If the footnote is incomplete at all, it is because it does not elaborate on the amount of attention likely to be required with the open type of construction, and does not emphasize the dangers that arise during cleaning and maintenance. Already there have been fatalities. To clean an open insulator or to do maintenance work on an open-type circuit breaker or isolator involves not only the opening of an isolating switch but also the preliminary provision of a clearance of about 15 ft., which necessitates very difficult screening or the shutting-down of complete sections. All of this, with the accompanying risks, is avoided if all the conductors are completely covered when alive, as they are in the alternative metal-clad construction.

My objection to a bypass in an ordinary duplicate-busbar equipment is that it adds to the initial cost and complicates the operation. Both these items are worth considering in view of the demands from many speakers for economy and simplification. Moreover, the advantages of metal-clad construction should be given full and free scope, and it should not be burdened with parasites that have developed because of the limitations of open-type construction.

I do not quite know what is behind Mr. Coates's reference to the isolating bushing of Fig. 35, to the effect that it strongly resembles the patented type used on some sections of the British grid; but it is only fair that any inference tending to deprecate British initiative should be nailed down once and for all. Mr. Coates, at my request, has kindly given me a reference to the patent,* and I find that it is of American origin. It does not anticipate the British patents on the movement of the central conductor or bushing for isolation. It makes no reference whatever to metal-clad switchgear, nor is it intended for isolating purposes. In fact, it is only a very ordinary bushing with a hollow interior through which a flexible conductor passes so that the top part of the bushing insulator can be removed if the porcelain surface or bakelized interior has to be replaced. This can be done, when it is applied to switchgear, without removal of the current-transformer chamber or of the switch contacts. There are objections to the arrangement, even as a component of an open-type switchgear device, but since I am discussing metal-clad switchgear, to which the invention does not refer, it is only necessary for me clearly to remove any wrong impression on the question of origin, which might otherwise arise from Mr. Coates's remark. An arrangement with a plug instead of the patented flexible conductor is the natural means of attaching a metal-clad cable to power-transformer terminals to enable the cable-sealing to be done outside and the conductor to be plugged in without disturbing the terminal connections of the transformer winding. The bushings shown in Fig. 35 were designed for 132 000 volts, and their diameter is consistent with standard practice for open-type switchgear. The place for current transformers is relatively a small point. On ordinary metal-clad switchgear they are not usually placed on the busbar side of the circuit breaker, but if this is absolutely necessary in order to include the circuit breakers in the protected zone in duplicate-busbar equipment of the type shown in Fig. 35, the current transformers could also be readily duplicated and placed over each connection between the circuit-breaker main contact and the busbar.

My conclusion is that Mr. Coates either had not really given thought to the possibilities up to the time of this discussion, or has been misled by approaching the design along unsuitable lines.

* British Patent No. 290651.

Purity of Oil.

I agree with Mr. Grove on the need for avoiding the use of semi-fluid compounds, on account of their attraction for moisture, and I also agree with what he says about loose, floating, fibrous materials in oil. I think it is necessary to carry out high-voltage type tests with oil of high electric strength (45 to 50 kV), because oil with a low or variable electric strength would interfere with the obtaining of the requisite fundamental data on the design and performance of the insulation, particularly in respect to puncture test. On the other hand, routine works pressure-tests to check quality of manufacture are not made at 20 kV, as Mr. Grove suggests, because the pressure tests of B.S.S. No. 148 are based on a 30-kV value. Mr. Grove and Mr. Orchard refer to risks of moisture in oil. Mr. Winfield also draws attention to condensation of moisture in circuit-breaker tanks, and the possibility that it may mix with the oil. I see no objection to Mr. Orchard's proposal to tap off oil from suitable places for examination, and for clearing away moisture. Given taps not likely to leak, it would be a good plan to fit them even on circuit breakers, when the oil could be circulated through filters and dryers while the panels were in service, without interfering with the supply. At one time I suggested that the warm oil from transformers should be circulated through the switchgear, so serving the dual purpose of keeping the switchgear warm and cooling the transformers; but I think that the idea has not yet received full consideration in suitable quarters.

Voltage Measurement.

The coming of the condenser coupler appears to have expedited improvements in voltage transformers. Both Mr. Ross and Mr. Coates refer to transformers with special windings to equalize capacitance stresses, but since the conductors must be continuous I cannot overlook the possibility of a burn-out on the primary turns. The saving grace of the condenser coupler is that it avoids the use of fuse protection, and the removal of the protecting fuse in the transformer circuit suggests imitation of the practice adopted for condenser couplers. The condenser coupler is a condenser insulator pure and simple, requiring no high-voltage protection, but in my opinion it is unwise to omit such protection on the high-voltage side of a voltage transformer. I believe it to be common knowledge that in America recently a serious

fire was started on a 132 000-volt voltage transformer, which was without this protection. There is nothing to prevent a conflagration if a high-resistance arcing fault is allowed to persist inside a transformer tank. The voltage transformer is the weakest part of the whole system, because it is a place where fragile high-voltage and low-voltage conductors must be brought into close proximity. The insulation must run the same voltage-stress risk as that of a large power transformer, in which, however, there is more room and the conductors are more substantial. It would appear to me to be unfortunate if the introduction of the condenser coupler for light instrument measurements were to bring about any impairing of the safety of the system by the removal of the voltage-transformer fuse merely as a result of price competition. Mr. Cranmer refers to the secondary connections. It is here that the condenser coupler scores, because if the secondary circuit becomes short-circuited no harmful effects would occur on the high-voltage line or on the high-voltage side of the coupler, whereas a similar fault on a voltage transformer may cause a burn-out of the high-voltage winding, whether or not it is provided with fuses. I agree that the output of a condenser coupler may not be as great as that of a voltage transformer; but, so long as it is sufficient for instrument and protective-gear purposes, this does not constitute an objection to the condenser coupler. Mr. Coates's implication that the condenser coupler requires adjustment with varying burdens is unfounded; the secondary apparatus inherently provides automatic regulation with the same accuracy as the voltage transformer.

Busbars.

I agree with Mr. Wilson that the tubular form of busbar is theoretically ideal as a conductor from the points of view he has illustrated in Figs. E and F. I have considered using tubular conductors, but the square or " box " formation of conductor was adopted because of its practical advantages and its close approach to the theoretical ideal. In metal-clad switchgear, one of the important factors is the ease and efficiency with which busbar sections can be jointed to each other and connections can be taken off to branch circuits. From this point of view the " box " formation is definitely better and more convenient than the tubular. In practice, the four conductors forming the " box " are bonded together along their length by metal spacers, and so conduction of heat does take place between the conductors, and the actual distribution of heat approaches the ideal obtained with the circular form more closely than Fig. F indicates.

Fig. 28 and Mr. Wilson's discussion, taken together, reply to Mr. Kidd's request for further information about busbars and temperature-rise.

Correlation of Breaking Capacity and Voltage.

I am glad to have Mr. Trencham's support of my proposal to place a limit upon power-station switchgear current by stepping up to high-voltage busbars when the larger breaking capacities are required. Other speakers have expressed their approval, and I am convinced that it would be a great benefit to switchgear design to eliminate awkward large currents. Mr. Winfield goes farther than the paper, and would alter the factor to 1/75 against my 1/125. I suggest a compromise in the nearest practical ratings as follows:—

Maximum breaking capacity for main circuit breakers	Maximum voltage (3-phase)
kVA	volts
1 500 000	22 000
1 000 000	11 000
500 000	6 600
250 000	3 300
50 000	660

These values would impose a reasonable limit on the ability of the circuit breaker to close on short-circuit, as required by Mr. Trencham, and would reduce the section of copper for circuits and feeders, as required by Mr. Winfield; and they would also tend to reduce the heating of the framework and busbars of metal-clad switchgear, as discussed by Mr. Wilson and other speakers.

Mr. Kidd wants to take voltages higher, and I would agree with him. In reply to his question, a voltage of 12 000 volts for 1 500 000 kVA is on the border-line of convenience. It has been employed by my Company, and so has 6 600 volts for 1 000 000 kVA (as shown by the tests in Appendix II); but I would prefer the 11 000-volt limit given above for 1 000 000 kVA. I am now practically in agreement with Mr. Mellonie.

Switching Capacity.

(*a*) *Rate of Rise of Restriking Voltage.*—A marked feature of the discussion is the frequent reiteration of the theory, propounded and explored by Dr. Slepian, of the effect on the critical happenings at the arcing contacts of a circuit breaker of the rate of rise of restriking voltage during each zero-current pause of the arcing period. This evidence of the wide reading of Dr. Slepian's works is a well-merited compliment to him. In keeping with his theory, I have proposed that circuit-breaker ratings shall be based upon a common standard of severity. The measure of severity at any given line voltage is the amount and duration of the current, both because of the mechanical stresses it brings to bear upon the conductors, and because of the static stresses occasioned by the thermal effects of the arc. Current is therefore the foremost factor in the ascertainment of ratings. It is controlled by the efficacy of the breaking devices and by the incidence of the voltage. The former is a matter of forethought, experience, and trial; but, as Mr. Pearce confirms, the latter depends upon the constants of the test circuit, which determine the rate of rise of the restriking voltage. Hence, in the proposed standard test-circuit (Appendix I), the lengths of conductors are to be kept as short as possible in order to reduce the self-capacitance of the whole test-circuit to a minimum, whereas the greater lengths of the conductors on a system increase the capacitance, and thereby introduce an easement in the stress of circuit breaking. Mr. Leeson has

dealt with this fully in his discussion, which confirms what Mr. Ferguson and Mr. Trencham have both observed, namely that tests in the field are less severe than those on a test plant. This affords an element of security to the user. The fact that circuit breakers operating on a system have a large amount of capacitance in parallel with the breaks may account for their satisfactory behaviour in positions where the vicinity short-circuits are apparently greater than the true ratings of the circuit breakers as proved on an individual test plant.

Mr. Blandford accuses me wrongly of glossing over the vital few micro-seconds after the zero at which the arc is extinguished. In addition to Mr. Blandford, Mr. Coates, Mr. Ferguson, Mr. Trencham, and Mr. Pearce, all make inferences about the rate of rise of restriking voltage; but they will see that "rate of growth" is referred to on page 301, and my expressed desire is to establish a standard test-circuit that will control the happenings at this critical moment. For this reason, the restriking-voltage interpretation (page 319) is most specific.

Mr. Leeson's clear and constructive contribution will do much to establish the constants for the standard test-circuit, and when we have reached an agreement in Great Britain the next step will be to make a move to secure international uniformity.

(*b*) *The Standard Test-Circuit.*—Mr. Coates wishes to compute test-results from readings direct from the oscillograph, but in common with others he declares the rate of rise of the restriking voltage to be the important factor, rather than its amplitude. He realizes, however, the unfortunate difficulty that exists in measuring this factor, at any rate for the present. Hence there seems really nothing left for him but to agree with me in taking its equivalent from the test-circuit constants. This requires a determination on a standard basis, and when this is agreed upon the performance results will be computed simply from the oscillograph current-record.

Mr. Coates suggests that standard pressure and travel recorders are also essential. This may be so, if the intention is to compare different makes on the basis of the data so furnished; but, interesting as that might be, it is hardly essential, since the factors do not affect the test-circuit standard of severity. Travel and pressure records would only have to be standardized if it were necessary to standardize the details of the design and operating characteristics of all circuit breakers; but that is not the present intention. We shall make quite sufficient advance if we standardize the meaning of rating as compared with test and service performance. When the purchaser is assured in this way, he will not need to compare tank-pressure tests, speeds of breaks, and a host of other items, as he probably does now in a rough and ready endeavour to work out for himself, and in his own way, what the standard test-circuit should do for him on scientific lines in the future.

Mr. Coates is surprised "to see that it is usual to generate direct from 3 300 to 22 000 volts." I almost hesitate to take him seriously, for he must know that there is direct generation at 3 300 volts, and at the upper end of the range the proposals, if anything, do not go far enough, because, as he must also know, there is already direct generation at 33 000 volts at Brimsdown. I submit that, considered widely enough, Proposal (xi) (*a*) is true; and there is the further point, which is really the main issue, namely that the test circuit for the ascertainment of standard ratings, within the range of voltages specified in Proposal (xi) as a whole, must be of one standard of severity; and the proposals do actually recommend a practically convenient basis of division into groups.

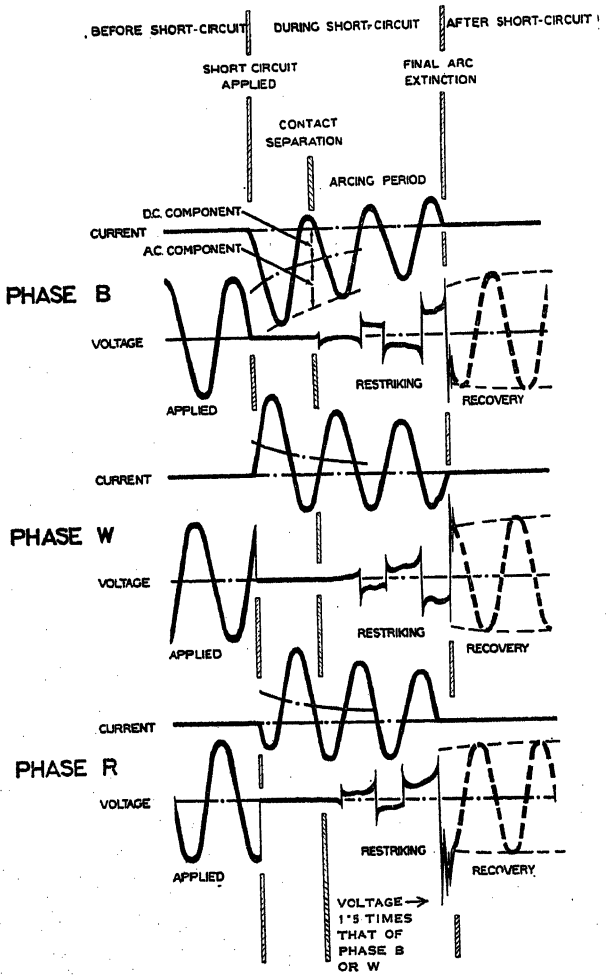

FIG. P.—Diagram of typical 3-phase asymmetrical short-circuit, illustrating (*a*) Factors for calculating performance; (*b*) Voltages for determining severity.

NOTE.—Neutral insulated; recovery voltage 80 per cent; power factor 0·1 lagging; arc extinguished first on red phase. Final restriking-voltage transient shown exaggerated in duration.

(*c*) *Definition of Terms for Voltage Phenomena.*—Although I appreciate the point of Mr. Blandford's definitions, the voltage when the current ceases is no longer restriking but recovering, and the recovery then becomes an intermediary stage to restoration. But, on the other hand, the voltage is not fully restored until it settles down, or up, as the case may be, to the applied voltage. Hence, considering everything, I trust that he will help to avoid confusion by using the following terms, which are illustrated in Fig. P, to define the different voltages

that exist in a circuit before, during, and after a short-circuit on a circuit breaker in that circuit.

(1) *Applied voltage* is the R.M.S. value of the normal-frequency voltage that exists at the initiation of the short-circuit.

(2) *Restriking voltage* is the series of high-frequency voltage transients that exist at the zero-current pauses during the arcing period, together with the final and more pronounced high-frequency transient that begins at the instant of arc-extinction. Its magnitude is measured on a peak-value basis, and its severity also depends upon its rate of rise.

(*d*) *Appendix I and B.S.S. No.* 116—1929.—Mr. Coates and Mr. Pearce are in agreement with the paper in referring to the need for cathode-ray oscillograph investigation into the restriking voltage phenomena, and for a clarification of the means of interpreting an oscillograph record in terms of a kVA performance. Mr. Coates is aware of the vagaries of the voltage phenomena, and yet he suggests that all that is necessary to make B.S.S. No. 116—1929 serve our present purpose is to define recovery voltage. He proceeds, however, to make the solution more remote by proposing the indefinite method of taking the mean of the first two

TABLE A.

Relative Short-circuit kVA Performance Values obtained by Different Methods of Calculation from the Factors illustrated in Fig. P.

Method	The sum of the products in each phase of			Neutral	3-phase kVA broken	
	Current components		Voltage		80 % V	100 % V
					per cent	per cent
1	British and American	A.C. and D.C.	Rated line/$\sqrt{3}$	Insulated or earthed	100	100
2	British and American	A.C. and D.C.	Recovery: at arc extinction on *each* phase	Insulated	93	117
				Earthed	80	100
3	British and American	A.C. and D.C.	Recovery: at arc extinction on *last* phase to break	Insulated or earthed	80	100
4	British and American	A.C. and D.C.	Separation	Insulated or earthed	95	100
5	Continental	A.C.	Rated line/$\sqrt{3}$	Insulated or earthed	75	75
6	Continental	A.C.	Recovery: at arc extinction on *each* phase	Insulated	70	88
				Earthed	60	75
7	Continental	A.C.	Recovery: at arc extinction on *last* phase to break	Insulated or earthed	60	75
8	Continental	A.C.	Separation	Insulated or earthed	71	75

(3) *Recovery voltage* is the R.M.S. value of the normal-frequency* voltage that exists during the interval between the end of the final restriking voltage-transient and the restoration of the applied voltage.

These terms appear to be generally acceptable to other speakers in accordance with the suggested definitions, and are also used in the proposed sense both in the paper and in this reply to the discussion. In support of the term "restriking voltage," I would emphasize the fact that the voltage-transient that occurs at each current-zero, and the voltage-transient that occurs at arc extinction, as shown in Fig. P, are in reality the same phenomena. The only difference is that the transient that occurs at arc extinction is more pronounced than those that occur during the arcing period, because the re-establishment of the arc eliminates the greater part of the transient. In other words, the restriking-voltage transient is successful in its unwanted efforts during the arcing period, but unsuccessful at the particular current-zero pause at which arc extinction occurs.

* Obviously, the frequency here called "normal" may differ slightly from the frequency of the applied voltage because of remanent effects of the short-circuit.

half-cycles following arc extinction, or, alternatively, the line voltage, whichever is the greater.

On the other hand, Appendix I of the paper recommends that the whole voltage characteristic shall be treated as a condition of severity, just as power factor is already treated. The criterion of performance is the value of the current made, carried, and interrupted, and so the method of measurement by current is the only definite one. Current values, however, are not easy either to memorize at different rated line voltages or to associate with plant sizes, and it has therefore been the practice, and is still necessary, to rate circuit breakers, and to state performance, in kVA. Values of kVA at the best are only arbitrary, and, as shown in Table A, are widely divergent according to the many different ways of ascertaining the voltage multiplier. Appendix I recommends the use of rated line voltage, and when this is coupled with actual current measurements on a test-circuit of standard characteristics there will no longer be any doubt about the meaning of a declared kVA rating. It will be possible to compare all circuit breakers on a common basis, without the

delay that Mr. Coates anticipates will be necessary if the rate of rise can only be specified after research and measurement on an instrument not yet developed in a form suitable for practical service. Mr. Pearce infers that I may adjust the power factor of the short-circuit test-circuit to the value of 0·1 specified in B.S.S. No. 116—1929, and may so obtain an easier test, because the adjustment reduces the rate of rise of restriking voltage. Presumably he thinks that it always introduces additional capacitance; but, whatever the values may be, the practical experience remains that an easier test is obtained at a higher power factor. Moreover, the test-circuit, however it is adjusted to give the British standard power factor, must always be more severe than the working conditions of a normal power station, on account of the difference in the lay-out of the conductors. I accept as good humour Mr. Pearce's gibe about the frequency of the existing test-plant, which, as he infers, does not practice what the Appendix preaches; but it may nevertheless make a virtue of necessity, because of the claim that a test at 40 cycles is more severe than one at 50 cycles.

(*e*) *Ratings and Vicinity.*—The questions asked by Mr. Crocker, as well as by Mr. Haws at Middlesbrough, are very typical of what most users want to know at the present time. What rating of circuit breaker is suitable for particular positions on the system? Mr. Winfield also refers to the different methods of rating, and particularly to variations between Great Britain and other countries in this respect. As Mr. Leeson has explained, it may take years of research, but eventually it will be possible, if the standard test-circuit is established, to tabulate for the guidance of users the margins on standard ratings afforded by specific conditions of service. The amount of short-circuit calculated from the size of a generating plant and the impedance of a network to any particular circuit breaker on the system is the vicinity short-circuit, and when this is considered in relation to a standard circuit-breaker rating, as determined on a standard test-circuit, the easements, such as those due to higher power factor and lower rate of rise of restriking voltage, may be taken advantage of, either as additional margin for safety, or to effect the much-desired economy by way of selecting circuit breakers of a rating lower than the vicinity short-circuit. Purchasers having the knowledge that circuit-breaker ratings were based upon a standard representing the most severe conditions of service would be in a position to exercise with confidence their discretion in regard to the allowances to be made for the reduction in stresses occasioned by the easements afforded by working conditions. But it must always be remembered that these easements do not enter into the problem of closing on short-circuit.

(*f*) *Closing on Short-Circuit.*—Mr. Ferguson says he cannot understand my statement on page 302 about closing circuit breakers on short-circuit. What I wish to infer is that insufficient attention has been given to this subject in the past. Notwithstanding the inclusion of the "make" test in the duty cycle, it is still not infrequent to hear reports of test-demonstrations in which "make" tests are not included. Indeed, for large currents these are not so simple as might at first be supposed. It has to be remembered that the easement secured by the current-decrement in the short-circuit transient when breaking is not afforded when making a short-circuit. The "make" is against stresses due to electromagnetic and thermal disturbances set up by the first few waves at the maximum-current stage of the short-circuit transient. The short arcs occasioned by any slight chattering of the arcing or main contacts, or by any tendency for the plunger bars to pump, set up distortion, burning, and very high static stresses within the circuit-breaker enclosure. On occasion (Appendix II) these stresses have proved to be as difficult to deal with as those set up by breaking short-circuits. Hence I suggest that the reason for the apparent freedom from trouble on making short-circuits is the fortunate infrequency of the occurrence at full rating in practice. This rarity has led users in the past to overlook the necessity of providing for making-capacity as well as breaking-capacity in their specifications, and Mr. Ferguson will remember that it was not included in the British Standard Specification prior to 1929.

(*g*) *Tanks.*—Mr. Grove raises the very practical issue of round and rectangular tanks. I prefer the rectangular shape, because it gives a uniform space-allocation of tank volume for each of the phases, and allows room for an earthed metal conductor between phases without reduction of phase-to-earth clearances in a given tank volume. The vertical round tank tends to cramp up the phases, as Fig. Q shows, because of the waste volume over and above the required clearances to the tank walls on the middle phase, and owing to this, rather than for the reason of bad distribution of stress also suggested by Mr. Grove, the earth between phases may have to be cut out. Again, it is not possible always to resort to vertical insulation only, because the plunger bars supported by insulating rods must be braced to withstand the mechanical forces between phase conductors during the passage of short-circuit current, and this introduces a horizontal insulating surface, which may be less than that of the usual rectangular-tank design owing to the narrowed centres for an equal tank volume. Metal for metal, however, the round tank is stronger, or, in other words, the rectangular tank of equal strength must be heavier in metal. Mr. Wilkinson prefers the round type, because some inferior old types of rectangular shape have burst under short-circuit tests; but the same thing applies also to round tanks when they are not strong enough.

The most efficient use of the round shape for circuit-breaker tanks is when the axis of the cylinder is horizontal, and not vertical, as advocated in the discussion. This is also illustrated in Fig. Q, which shows how the rectangular section of the horizontal cylinder across the plane in which the arcing contacts lie allows, as in the rectangular tank, not only for an equal clearance on all three phases, but also for an earthed attachment and metal barrier-rib between phases, for which there is no equivalent facility in the circular section of the vertical cylinder.

(*h*) *Tank Pressures.*—This brings me to Mr. Ferguson's statements about tank pressures. Hydraulic pressure-testing of circuit-breaker enclosures is a fundamental requirement, and at this stage of switchgear progress

it may seem surprising to some users that it should be necessary to mention the point at all. In some designs of circuit breakers, however, a hydraulic test may be difficult to make, because the gasket joint between the tank and the top-plate, although thought to be quite good enough for switching-service, would leak too much to allow the requisite high steady pressure to be attained. Mr. Ferguson's machine would be very helpful here; but I prefer to use a tight, machined, flanged joint, which is cleaner, as well as flame-tight in service, and allows for hydraulic pressure-testing by the usual process of injecting pressure by means of a force pump. Mr. Ferguson's suggestion of tank type-testing by exploding gunpowder has been referred to at Institution discus-

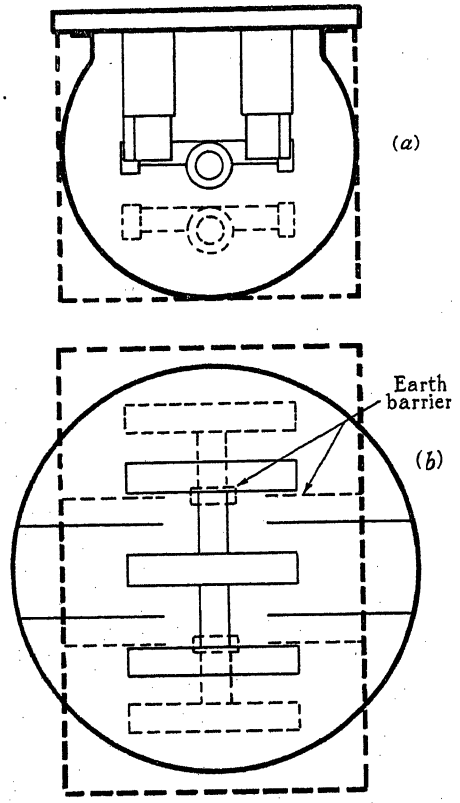

FIG. Q.—Comparison of circular and rectangular tanks:—
(a) In vertical plane.
(b) In horizontal plane.

sions in the past, and was in fact the only means available 20 years ago when my Company originated the strong enclosure as a simple solution of the breaking-capacity problems with which we were then faced on the North-East Coast.

Referring to Fig. 38, Mr. Ferguson says that there is no proof that the impulse pressure of 950 lb. per sq. in. was safe on a tank made for a steady hydraulic pressure of 150 lb. per sq. in. The proof is that the tank withstood the test without permanent distortion; the records are available among many others of similar occurrences. The tank was the ordinary commercial article; and, should doubt still exist, Mr. Leeson's records of explosion tests, the first of which were made in 1920, confirm authentically a high ratio between the momentary impulse pressure and the steady hydraulic pressure.

(*i*) *Air-cushion.*—Mr. Ferguson may feel satisfaction with lower tank pressures under test conditions, and these he doubtless secures, when plain contacts are used, by means of a large air-cushion and a domed top-plate. On the other hand, I prefer comparatively small air-cushions, in order to produce the very result he wishes to avoid, namely a high internal pressure, the reason being that all the pressure available is necessary, particularly at low fault-values, to suppress the arc quickly, and incidentally to eliminate the risk of secondary explosions of large volumes of gas. Experiments made at Hebburn on circuit breakers with air-cushions of about one-third of the total enclosed volume show that the arc may continue for twice or thrice as long as with more normal air-cushions, and that the stress is actually more severe because it is sustained over a longer period of time. A brisk conflict, firm and unyielding, inflicts the least disturbance on the system. Indeed, the main virtue of boxed contacts of the explosion-pot or baffle type, when they are themselves strong enough to stand the strain, is that they keep up the pressure on the arc. The unyielding tank, backing up the oil walls surrounding the arc, does the same thing, but from a greater distance.

(*j*) *Mr. Ferguson's other questions.*—Replying to Mr. Ferguson's other questions in detail, and in the order in which they were raised, I would say: (1) The test-pressure record shown in Fig. 38 was taken, as I said at Manchester, with a Collins micro-indicator. This is of British make, and I know of none more accurate or more reliable for practical service testing. (2) The pressure record shown in Fig. 38 was obtained on Test No. 257 (page 327), the power broken being 180 000 kVA, and the rating of the circuit breaker 100 000 kVA. (3) Assuredly I should be in favour of allowing purchasers to examine curves of performances. (4) A long series of tests was taken on the 100 000-kVA circuit breaker at and below normal rating. They were easily performed, and presented no item of sufficient interest to be worth space in the *Journal*. Certainly none was omitted to cover defects. (5) It is true that one of the many tests, namely No. 100, resulted in a damaged tank at 133 per cent of normal rating. The cause, a mechanical defect after 14 tests, is explained on page 323, and it must also be noted that these circuit breakers, fitted with plain contacts and strong enclosures, stood well up to 240 per cent of their rating. (6) As to the maximum breaking capacity advocated for hand operation, the confidence that one would have in operating a circuit breaker direct must depend upon the strength of the enclosure, its competence to withstand sustained arcing, its condition, and the chance of its never being closed on a short-circuit greater than its making capacity. In the ordinary operation of a circuit breaker there are no risks, because it would not be opened at a time coincident with the breaking of short-circuit current; and therefore direct operation has been used for circuit breakers of quite large capacity, up to, say, 250 000 kVA or even more. As a general rule, however, I have found it reasonably economical to have remote operation for circuit breakers of 75 000 kVA

rating and over. It is really a matter for the user to determine on the basis of his operating conditions and on considerations of economy. (7) There is a mass of information available on the tests recorded and other tests; and the only intentional omission is again due to there being a limit to the amount that can conveniently be included in the *Journal*, bearing in mind the necessity to keep the data within the limits of general interest. An indication of arc lengths is given in the record of arcing periods in half-cycles, and a typical pressure curve is shown in the paper.

(*k*) *Failures.*—In support of the paper, Mr. Ferguson showed " what breaking capacity is " by putting on the screen lantern-slide illustrations of experiences as a result of which buildings were destroyed owing to the use of inefficient oil circuit-breakers; presumably the tanks were too weak to withstand the operating stresses. But it must not be thought that such explosions are brought about only by oil circuit-breaker troubles. On the contrary, there are records of destruction of buildings occasioned by arcing outside of oil circuit-breakers; and thus, although oil may be contributory, and may have the effect of prolonging a fire, it does not follow that it must be looked upon as the sole cause of explosions. I have yet to learn of any destruction of buildings occasioned by circuit breakers operating on short-circuit within their rating, when the strengths and dimensions of their tanks have been such as were recommended in my earlier papers and discussions. These were illustrated on a slide shown during the reading of the present paper, and are reproduced here as Fig. R. In my opinion, what has to be feared most is a failure of insulation causing sustained arcing, and this is more likely to occur on exposed insulators than on insulators immersed in an insulating medium in metal-clad chambers. At Manchester, Mr. Ferguson cast doubt upon the reliability of a large proportion of the circuit breakers at present in service, and Mr. Wedmore says that " there never was a time when so many supply engineers were uneasy as to the rupturing capacity of their switchgear." I hold no brief for the majority; my only claim is that the tests recorded in the paper show that a typical British design of plain commercial form does perform satisfactorily with " reasonable consistency."

(*l*) *Factor of Safety.*—Mr. Ferguson and Mr. Blandford ask what factor of safety I would suggest for rupturing ability. (I notice that there is no reference to " making.") A safety factor of $1\frac{1}{3}$ to 1 without permanent distortion should suffice; but this is a very wide question, which cannot be as easily dealt with as can that of the factor of safety of an ordinary mechanical structure. I suppose it depends upon the degree of permissible injury to the circuit breaker. I think circuit breakers should withstand double their rating on breaking without damage of a kind that would endanger human life. I say this not because I fear they may be so badly selected as to be used where the vicinity short-circuit is likely to attain this overload value, but because they may be subjected to unforeseen sustained arcing conditions, to meet which some such precaution is necessary. The factor of safety on " making " circuits involves consideration of the excess of the maximum making-current over the normal breaking-current, owing to the time factor introduced by the decrement of the short-circuit transient. Personally, I think it dangerous to grade down required ratings on the strength of the time-limit factor, but a circuit breaker selected on the basis of a 1-second time-decrement might have to " make " up to as much as 6 times its breaking current, depending upon the reactance of the generator. On the curve recommended in the paper (page 319), namely Fig. 2 of B.S.S. No. 116—1929, the maximum asymmetric making-current would be greater than the breaking-current; and, given certain coincidences of faults, a circuit breaker may be called upon to separate its arcing contacts when carrying a current of this higher value.

(*m*) *Effect of Power Factor.*—Replying to Mr. Grant's comments on the effects of power factor, my conclusion that the demand upon a circuit breaker is greatest at

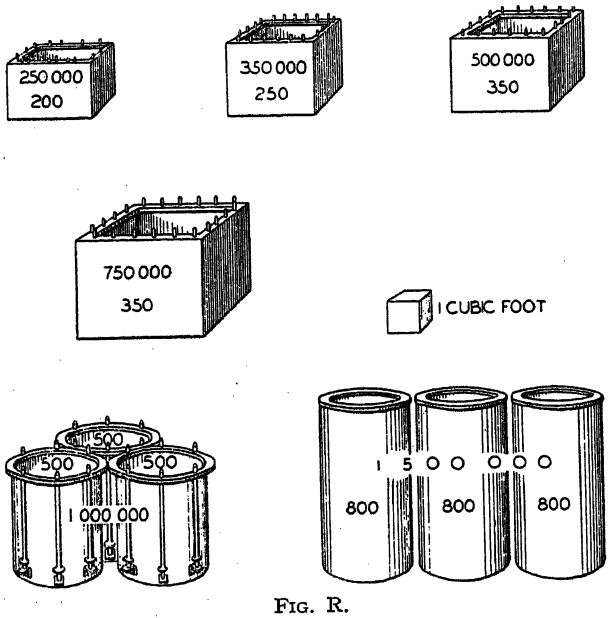

FIG. R.

Numbers represent rated kVA breaking capacity of complete circuit breaker, and pounds per square inch hydraulic test-pressure of individual tanks.

a low power factor is based not upon a few tests, but upon a large number made at Hebburn on circuit breakers of different sizes at power factors varying between 0·1 and 0·5. These show very conclusively that the nearer the power factor is to zero, the greater is the severity. This seems to be in accordance with the effect to be expected from the change in the magnitude of the voltage at zero current. Mr. Crocker asks about ratings for a vicinity short-circuit of 300 000 kVA at 0·5 power factor (presumably this is the short-circuit power factor and not the normal-load power factor). Considerable easement should be expected from the 0·5 power factor as compared with ratings determined upon a 0·1 power factor, in addition to whatever benefits may accrue from field service being lighter than test service, and it is reasonable to suppose that a circuit breaker of smaller rating, with a proved factor of safety, would serve the purpose well.

(*n*) *Earthing on the Test Plant.*—It is apparent that the proposal in Appendix I (page 320) is not clear to

Mr. Coates. It is not to be understood as meaning that it is British practice to insulate the neutral point below 66 000 volts. The contrary is known to be true, but insulating the neutral point on the supply side of the test circuit for the purpose of the test covers also the prevalent practice of earthing below 66 000 volts through a "comparatively high resistance," and in addition makes the test conditions more severe than actual service conditions (see Mr. Leeson's Fig. D). Mr. Ferguson does not favour tests with the neutral earthed, because an earthed neutral greatly relieves the stress. The Appendix agrees with this view, but makes an exception for voltages of 66 000 volts and upwards, because this complies with the practice in service on the British grid.

Stress Limitation.

(*a*) *Types of Contacts.*—Mr. Trencham is disappointed that the progress of circuit-breaking devices has not been more fully treated. He was not present at the reading of the paper, or he would have seen the series of diagrammatic representations of the plain, boxed, and blast devices shown on the screen. These are reproduced here (Figs. S to Y) as a brief bird's-eye record of the various devices known when the paper was written. Of these, for very large currents, and in view of the need for making as well as breaking, the plain contact has much in its favour for simplicity and all-round general service, particularly when some form, such as that shown in Fig. V, affords discrimination between making and breaking, the make being on a separate anti-chattering contact at close centres, and the break on ordinary heavy contacts at wide centres. This reduces the combined electromagnetic and thermo-explosive kick-off forces on making, without interfering with the use of these forces to the full for breaking. I suggest that to make 250 000 peak amperes on a 6 600-volt circuit would be difficult with circuit-breaker contacts of the boxed class, but it has been proved by Test No. 419 (page 327) to be possible with plain contacts. The Grant quenched-arc type of boxed contact, although at first it showed promise on lower-power tests, was unsuccessful at higher powers. (This answers a question raised by Mr. Stedman at Middlesbrough.)

My reply to Mr. Grant is that at the time of writing the paper, information about the "cross-jet" contact* had not been published, and the results of the most recent experiments with the E.R.A. "baffle" contact,* of similar kind, were not officially accessible to me. These contacts have side openings to direct turbulent oil and gas across the path of the arc. Since the paper was written tests made at Hebburn on a device similar to the "baffle," to which the name "turbulator" has been given, go a long way towards showing how to meet the demand for circuit breakers, in accordance with Mr. Wedmore's forecast, having two to three times the present breaking capacity without increase of dimensions, presuming that outside dimensions only are in question. These tests were made on an existing 250 000-kVA circuit breaker with the addition of special boxed turbulator contacts, and were carried up to 500 000 kVA at 11 000 volts. After a few failures a correct design of box was arrived at, and the 2 to 1 margin over rating was secured without any sign of distress. Table B describes briefly the results of representative comparative tests on the 250 000-kVA circuit breaker with turbulator contacts and on another of the same rating with plain contacts.

TABLE B.

kVA broken at 11 000 volts	With turbulator contacts			With plain contacts		
	Arcing period, in half-cycles	Total length of arc	Steady pressure on tank-sides	Arcing period, in half-cycles	Total length of arc	Steady pressure on tank-sides
		in.	lb./sq. in.		in.	lb./sq. in.
160 000	2·0	2·13	15	4·5	5·50	100
273 000	2·0	2·50	45	4·0	4·75	125
350 000	1·0	2·00	40	1·5	3·25	150
500 000	0·5	1·00	40	Not tested at this value		

The recovery voltage during the tests was of the order of 80 to 85 per cent of the line voltage.

(*b*) *Limits of "Make."*—The rating is incomplete, however, without the "make" performance, and to the requisite greater cost of the contact boxes there must be added the cost of improved mechanism at those voltages where the limit of the existing mechanism is the maximum current carried when making a short-circuit corresponding to existing ratings. With the same disposition of conductors, an increase of 2 to 1 would increase the "make" kick-off forces in the ratio of 4 to 1, and a trebling would imply a 9 to 1 increase. This may be possible with some existing types, but if the design is already within fine limits, the increase of breaking capacity by the mere addition of special contacts does not accomplish everything, nor does it represent the only extra cost. Although the addition of such arc-control devices, when they are applied under suitable conditions, does increase the margin in breaking capacity, we have still to ascertain the limits beyond which such devices, taking into account circuit-making as well as circuit-breaking, may introduce complications in design tending to produce mechanical weakness and possibly dangerous sustained arcing.

Time is required to obtain all the test data necessary

* British Patent No. 366998.

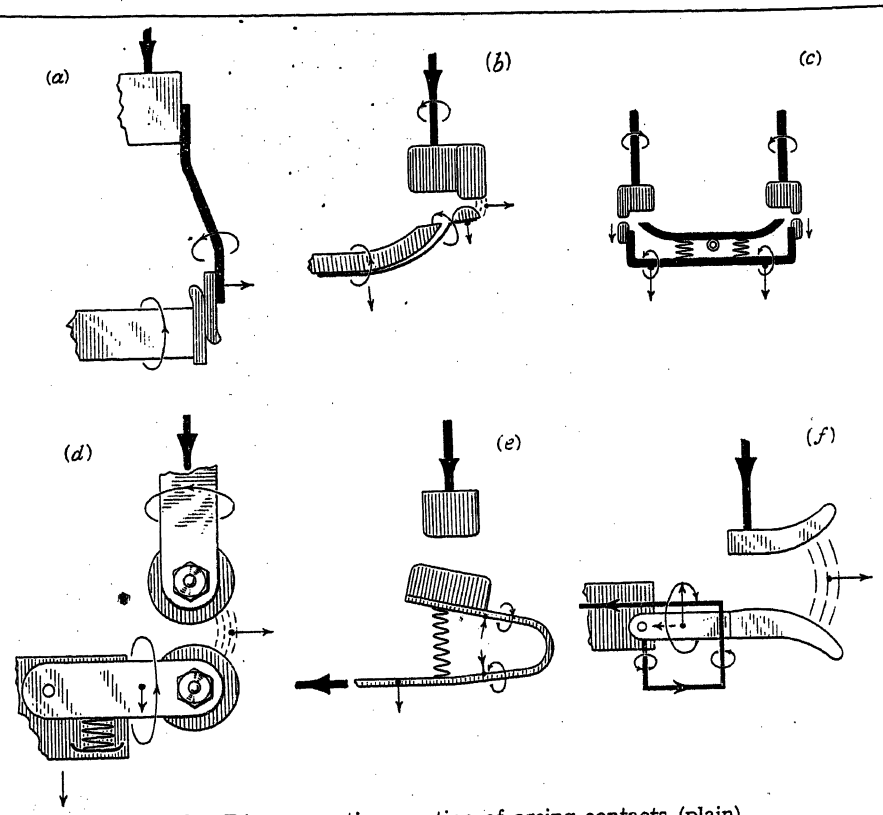

FIG. S.—Diagrammatic operation of arcing contacts (plain).

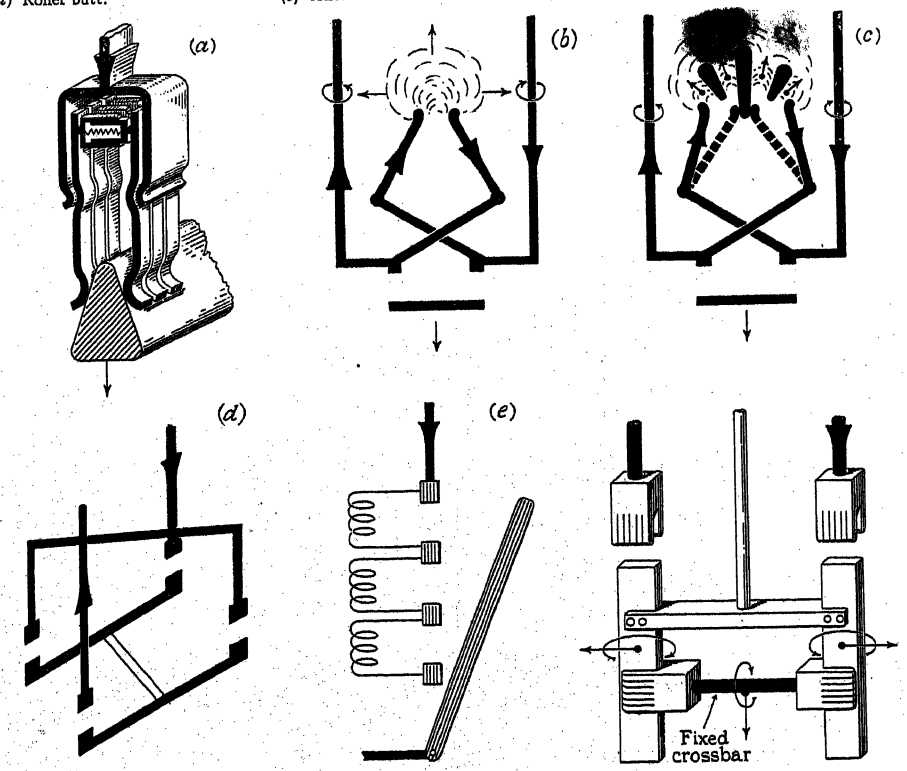
(a) Plain finger sparker. (b) Plain leaf butt. (c) Butt.
(d) Roller butt. (e) Anti-chatter butt. (f) Anti-chatter butt (with arcing horns).



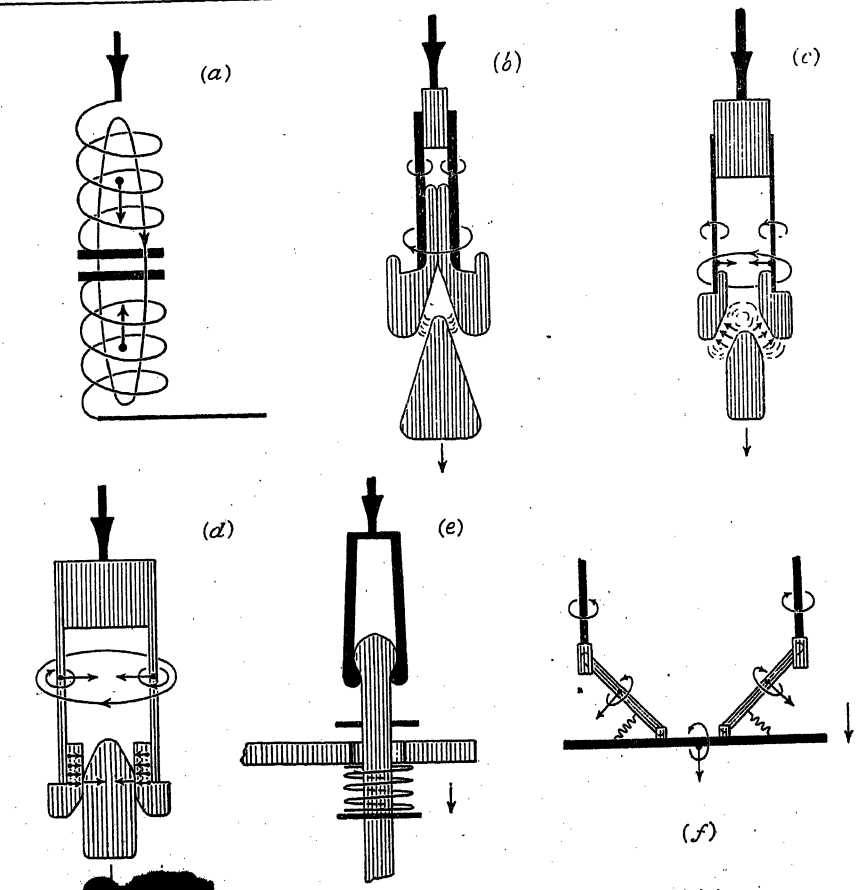


FIG. T.—Diagrammatic operation of arcing contacts (plain).

(a) Dashpot finger (multiple point). (b) Vertical blowout (single break). (c) Vertical blowout (split arc).
(d) Multi series break. (e) Reactance (resistance) break.

—Diagrammatic operation of arcing contacts (plain).

(a) Solenoid contact (anti-chatter).
(b) Wedge finger.
(c) Self-grip finger (anti-chatter).
(d) Steel self-grip finger (anti-chatter).
(e) Snap-pin contact.
(f) Snap-blade contact.

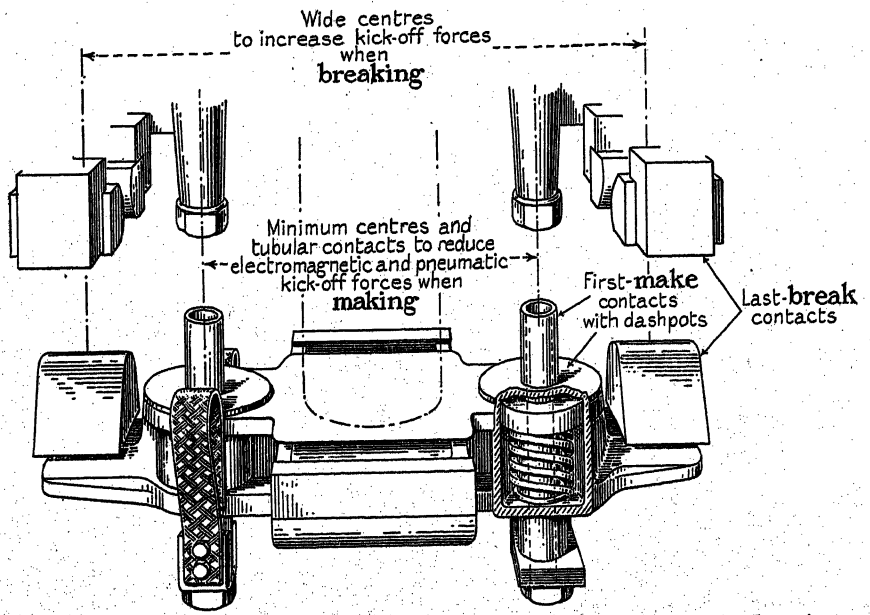

FIG. V.—Make-and-break discriminating contacts (main contact not shown).

to determine the safe limits in making and breaking current, and to show how to avoid the bursting of boxes, the harmful effects of which would obviously far more than counterbalance any intrinsic advantages of the boxes themselves. Meanwhile it is safe to say that the present explosion-proof tank enclosure must continue to be used, not only as a second line of defence against accidents to the more crowded inside parts, but as an aid to breaking by maintaining the high pressure required in the immediate neighbourhood of the arc for the shortening of the arcing period.

So far I have found that, for existing ratings of the order of 1 000 000 kVA and upwards for normal generating-station service, contacts of the plain type have the advantage of the simplicity for which Mr. Trencham calls, and, moreover, they embody this desirable feature to an extreme degree. In comparison with the multitude of alternative contacts and blasts, nothing can be simpler or cheaper to produce and to maintain for metal-clad switchgear than plain contacts in robust metal tank-and-top-plate enclosures. That this is so is especially clear when it is remembered that these enclosures are still required, no matter what form of intricate contact may be devised with the object of increasing the margin of safety in breaking capacity. Even if it is possible, by the addition of a boxed-contact device, to add 50 per cent to the test-performance, the rating of the circuit breaker should still be of the order of 1 000 000 kVA, since some risks have been introduced by the additional devices.

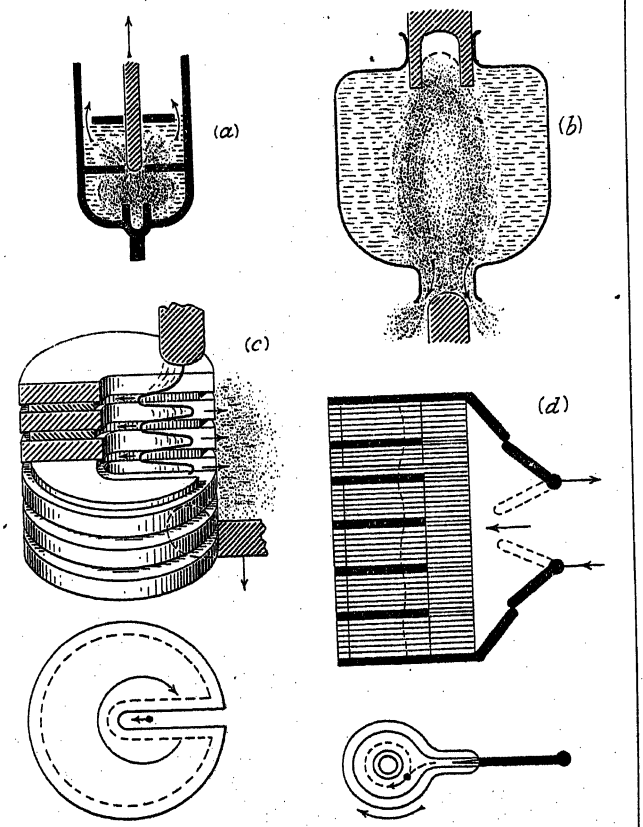

FIG. W.—Diagrammatic operation of arcing contacts (boxed).
(a) Baffled explosion pot. (b) Plain explosion pot.
(c) De-ion grid. (d) De-ion air break.

(c) *Oil-less Circuit Breakers.*—Mr. Rissik deals with circuit-breaking on the "expansion" principle, in accordance with which de-ionization occurs in a saturated vapour. My endeavours to procure a circuit breaker of this kind for test have not been successful, and hence my knowledge of the operation of expansion circuit-breakers is no more than is given by published information, in which, incidentally, short-circuit current-making characteristics are not described. It would appear that for large currents it is the practice to have a separate air-break current-switch in parallel with the expansion device. This, with its connections, and with the choke devices found to be necessary for current-sharing, adds to the number of bare conductors and insulators; and it also tends to delay fault-clearance. Moreover, no saving in cost over that of ordinary oil circuit breakers has apparently been made as yet.

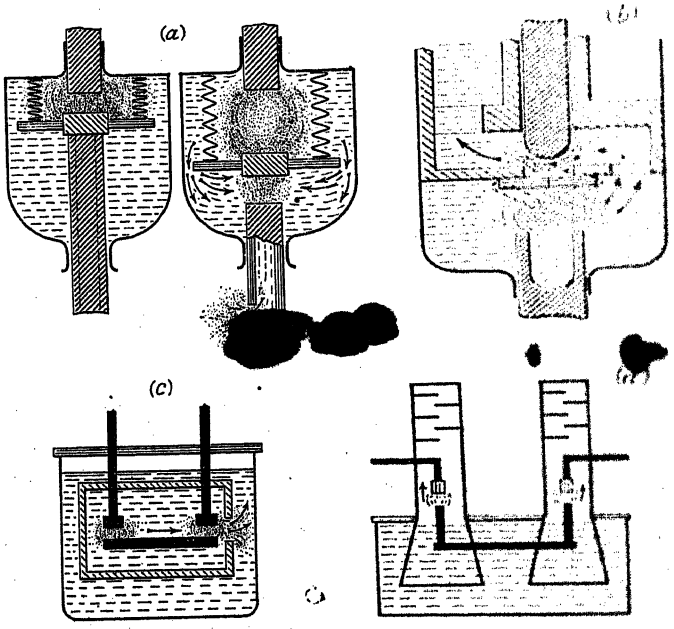

FIG. X.—Diagrammatic operation of arcing contacts (blast).
(a) Oil-bast explosion pot. (b) Gate oil-blast.
(c) Oil-blast baffle. (d) Semi-immersed.

It has been said that the degree of expansion created by the current must not be less than a definite minimum, below which it may be insufficient to extinguish the arc by the expansion process. Considerable attention appears to have been given to this subject. One interesting proposal* for dealing with it was to use a second chamber acting as a water-resistance switch in parallel with the expansion chamber. If this were adopted, the likeness to the old water-break switches would be more striking, since over a larger range the current would be broken by means of a plain water-break.

In my opinion the expansion type, like the air-blast type, will not make progress in its present form because security of insulation is an even greater primary consideration.

* British Patent No. 364345, accepted 7th January, 1932.

tial than perfect circuit-breaking. The insulation has to withstand stress during all the time that the circuit breaker is in circuit, whereas the circuit-breaking device itself may operate only very infrequently. Complete immersion in oil or compound is an invaluable preservative in metal-clad construction, whereas the introduction of moisture is the very antithesis of the durability of insulation. The attempt in Germany, first with air-blast circuit breakers, and then with expansion circuit breakers, to remove troubles that it may be thought can arise from oil, may itself lead to running into more serious trouble because of exposed conductors and insulation.

that surface I would expect them to melt down immediately on making circuit. Metals that will not weld together are of course chosen.

Saving Switchgear.

Mr. Highfield refers to the question of dealing with 750 000-kVA short-circuits on existing 50 000-kVA switches. This is indeed a serious problem, and I do not know how it is going to be solved. Some form of group-switching (page 304) may be used to meet it. The conditions of such situations will be made clearer by a detailed study of the vicinity short-circuit at each switching-centre on the system, and of the easements

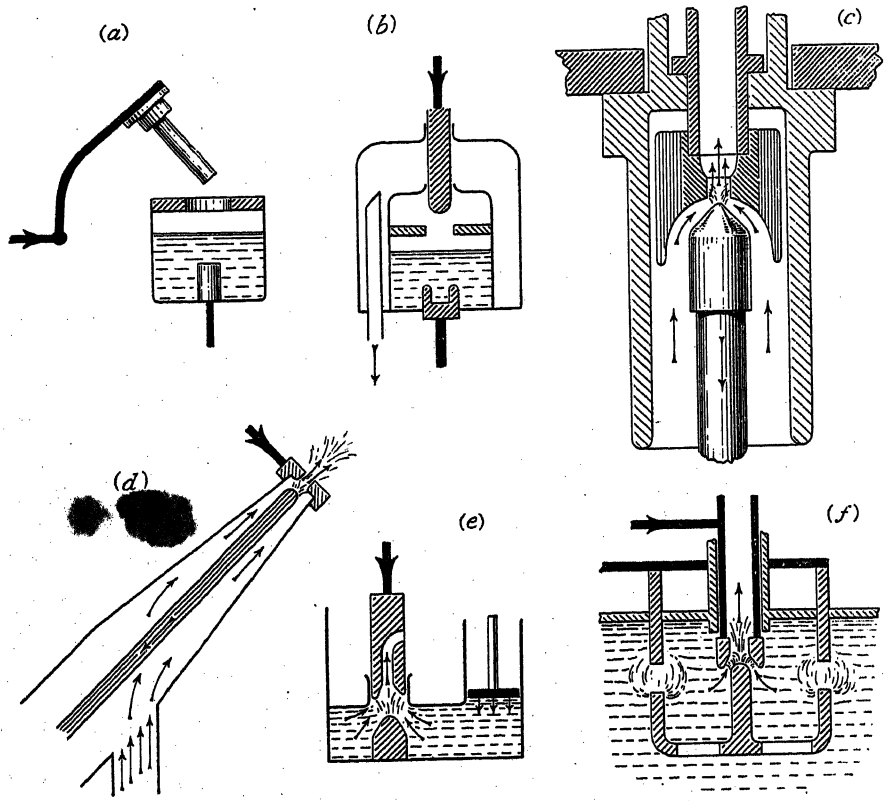

FIG. Y.—Diagrammatic operation of arcing contacts (blast).

(*a*) Old water break. (*b*) Liquid (water) expansion switch. (*c*) Controlled air blast.
(*d*) Open-air blast. (*e*) Impulse oil breaker. (*f*) Oil blast.

(*d*) *Multi-breaks.*—Mr. Cranmer asks about the performance of multi-breaks. These are included in the plain-contact class, and for high-voltage working probably represent by far the greater proportion of British practice to-day. Their function, in addition to increasing the speed of break, is to bring about an increased efficiency in the utilization of the oil volume; and their performance is satisfactory. The future may settle the present rivalry between multi-break contacts and some form of boxed contact for high-voltage service, in which the problems of heavy current are not so acute as at lower voltages.

(*e*) *Steel Arcing-Contacts.*—I have not come across the difficulty found by Mr. Grant, that globules on steel arcing-contacts cause incipient arcing on heavy-current circuits. The globules are generally away from the contact-making surface; but if any were to appear on

to which I have already referred. The fuse is an economical device in some places of lesser importance, when a small system is linked up with a large one, because a small fuse has the characteristic of limiting the amount of current that it will pass instantaneously. If the fuse is small enough, and the vicinity short-circuit is large enough, the fuse will blow before the first wave of the short-circuit transient has time to reach its maximum peak value. As another solution, where maintenance of supply is of prime importance, Mr. Highfield might find some scope for the "synchronizing-at-the-load" system (Fig. 40, page 303) as a means of reducing the required breaking capacity of the main circuit-breakers, since the load itself is used as a limiting reactance. I would also refer him to the "secondary network" mentioned by Mr. Trencham, which seems to be very much to the point.

Mr. Kidd claims that the credit for the idea of the single-switch substation attributed in the paper to Mr. Beard belongs to a Manchester engineer. The paper refers to a development, illustrated in Fig. 39, of the particular form of substation introduced by Mr. Beard, and called at the time "single-switch." The fault lies in the fact that the title is too general. There are obviously many ways of effecting economy in cutting down the number of circuit breakers, but the scheme referred to by Mr. Kidd is different in principle from Mr. Beard's, in that the circuit breaker is used for group control of the transformer circuits, whereas Mr. Beard uses it as an automatic protective device for sectionalizing a ring main. As a still earlier item in the history of switchgear connections, also in Manchester, Mr. Kidd will probably remember a single-switch application where a number of high-voltage feeder circuits were closed and opened through a single water-break resistance switch.

Safety of Men Working on the Line.

I am in full agreement with Mr. Crocker on the need for simplicity, and for greater care on the part of the manufacturer for the convenience and safety of operators. A multiplicity of types must be a great handicap, and earthing devices have not always been tried out sufficiently by designers to avoid taxing the patience of the users. It is with this in mind that alternative designs have been recorded in the paper.

Fault-Current Limitation.

Mr. Buist refers to the ohmic value of earthing resistors. When applied to circuits working at voltages of the order of 6 600 volts they are usually of low resistance, and I agree that, unless the earth-plate contact-resistance is taken into account, erroneous values for the protective-relay settings will be obtained. In comparison with earthing resistors applied to circuits of voltages of the order of 33 000 volts, for which resistances of about 19 ohms may be used, to pass currents of approximately 1 000 amperes, the earth-plate resistance can usually be neglected, since it is small compared with that of an earthing resistor. To overcome the uncertainty introduced by the earth-plate resistance in networks at voltages of the order of 6 600 volts, the earthing resistor should have a slightly smaller resistance than the total value aimed at, so as to allow for the resistance of the earth plate. The earthing resistor must be such that the earth-current passed on the occurrence of a fault is equal to at least twice the fault-setting of the protective relays on any part of the system, thus giving a factor of safety of 2.

Tripping Batteries.

In reply to Mr. Shipley, even in the tropics the renewal of the electrolyte should not need to be more frequent than once every two years. It is probable that the infrequency of the renewal is contributory to the trouble he describes. Nevertheless, it seems weak to change a type because of operators' errors in renewing with acid instead of with alkaline electrolyte. If such mistakes can be made now, is it not just as likely that alkaline electrolyte would be put into the acid cells, if they were adopted? I have heard of natives using starch for puddings.

I am glad to have Mr. McKinnon's correction on the construction of the nickel-cadmium battery,* and his confirmation of the possibility of using a trickle-charger for this type. It is to be noted that Mr. Grant finds the alkaline battery desirable in many ways.

Grid-Control Rectifier.

Mr. Taylor asks about a grid-control rectifier as a switch, and his question raises a new consideration of power-distribution problems. I understand that in place of each circuit breaker there would be a valve to carry the power current through a grid-controlled electron stream. Although this is an interesting thought, which may be realized in the future, the difficulties of carrying present power loads in this way make it impracticable for the time being. Presumably the circuit-breaking on this system would be done on the high-voltage side by a suitable control of the filament or grid circuit. Otherwise, I should say that switching unidirectional high-voltage current would be much more difficult than switching a plain alternating current.

Bakelite in the Tropics.

Mr. Orchard asks about reliability of bakelite insulation under semi-tropical conditions. Porcelain is frequently preferable, on account of its better surface durability; but a large number of bakelized-paper insulators have been supplied to tropical and semi-tropical countries and are giving satisfaction when immersed in oil or compound. When continuously exposed to a humid atmosphere, the surface of bakelite may require special treatment.

Cleaning Orifice Insulators.

Mr. Mellonie suggests a fitting to clean orifice insulators when they are alive. Such devices require great caution, and I consider it definitely preferable to leave cleaning alone until the conductors can be made dead and earthed. The trouble is that, however safe the fitting might be made, some person doing the operation would be only too likely to put his hand into the orifice in a moment of forgetfulness, perhaps to remove something that the fitting had left behind or that had not been cleaned away.

Automatic Isolation of Faults.

Limitation of Damage.

Mr. Winfield says that with modern machines it is now preferable to trip the main field-switch simultaneously with the main circuit breaker, instead of immediately after, as stated in the paper (page 308). I would welcome confirmation of this from the makers of generators.

Present-Day Practice.

One unusual feature of the discussion, perhaps satisfactory to the reader, is that no additional protective system has been put forward. This indicates that the subject is now written up to the point of saturation;

* Incorrectly referred to in the advance copies of the paper as "nickel-iron."

and it was reasonable to expect this state of affairs, seeing that the paper follows so closely on the full treatment of the subject in the recent discussion before The Institution, initiated in the paper by Mr. T. W. Ross and Mr. H. G. Bell.* The innovations of the last few years have now to be digested in practice; and I suggest that in the process of elimination of the unsuitable and protective system has been imported from abroad, and that the reactance (ratio-balance) system is "theoretically more perfect." The British developments introduced include: (*a*) Reactance instead of impedance as a basis of measurement; (*b*) instantaneous operation on faults over 70 to 75 per cent of the feeder length; and (*c*) a time-distance characteristic especially shaped to

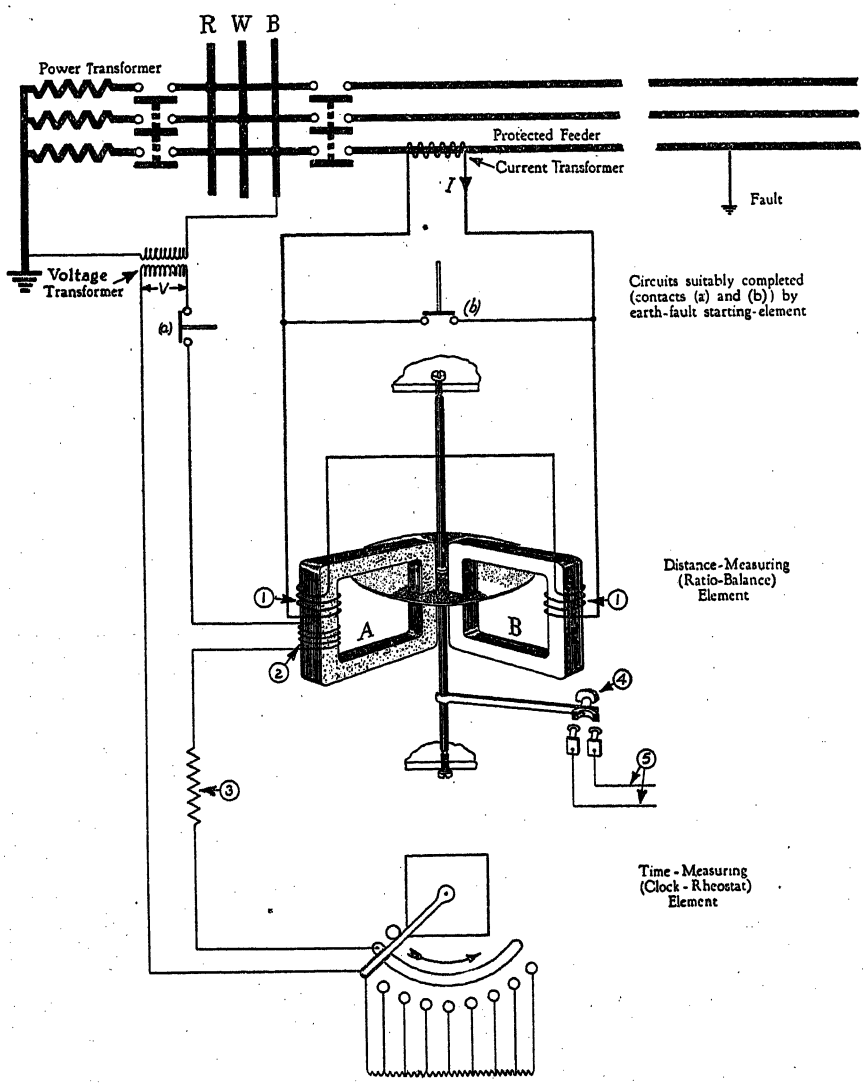

FIG. Z.—Diagram illustrating the principle of the time-distance discriminating unit of the reactance-type "ratio balance" protective system.

(1) Current coil. (2) Voltage coil. (3) Resistance. (4) Stop. (5) Trip circuit.

of selection for adaptability to situations and conditions, there will be many incidents and some "grief," and that an authorized and impartial body should collect, analyse, and study the experiences, in view of the great importance to the future reputation of electricity supply of continuity in all parts of the country when the whole national system is interconnected.

We have it on Mr. Ross's own frank admission that the experience of the impedance type of time-distance give an appropriate margin of time for faults on adjacent feeders. Mr. Ross, after referring to (*b*), asks, in effect, whether it is worth while to have the "theoretically more perfect" system for the sake of the remaining 30 to 25 per cent of the length. My answer is "Yes," because this is the most critical part for accurate discrimination. If the two systems are properly designed for their respective purposes, one is no more complicated than the other. Indeed, the main elements of the two systems, namely the time-distance discriminating

* *Journal I.E.E.*, 1930, vol. 68, p. 801.

elements, could hardly be distinguished from each other at a first glance if both were made by the same manufacturer, because the difference between them is merely in the method of utilizing the magnetic fields produced by the current and voltage coils. In the impedance system, each field provides its own torque, and these are put in opposition to each other; and in the reactance system illustrated in Fig. Z, in which the resistance-component of the impressed voltage is cancelled out by the very simple device of having a current coil (1) on the same limb as the voltage coil (2), the two fields co-operate to produce a single torque. The removal of the current coil from the limb referred to, the addition of shaded pole-tips, and the separation of the two magnetic fields for the purpose of a mechanical balance instead of magnetic co-operation, would make the reactance relay into an impedance relay. The difference between the two forms cannot rightly be described as a complication; indeed, if anything, the reactance relay is the simpler. With particular reference to Mr. Ross's impedance system, there is, in fact, in respect of actual total numbers of elements of all kinds, for equivalent service, nothing to choose between it as a whole and the ratio-balance system, which embodies the two advantages of a null method of distance measurement and accurate timing by means of a clock common to a group of elements protecting a feeder end, Mr. Ross's substitute for which is the less accurate device of an induction disc operating through a torsion spring in each time-distance discriminating element.

Mr. Ross suggests the possible need for additional "rejectors" (or high-frequency chokes, as they are called at B in Fig. 56) on the superimposed interlock system of protection, presumably because he fears that the signals may be short-circuited by the other lines. These may be necessary in some applications, but tests so far made on 66 000-volt lines and on 100 miles of 132 000-volt line have been satisfactory with rejectors on one line only, as shown in Fig. 56. Interference between adjacent sections is provided for by the use of different high-frequency carrier currents. To point out the dependence of the system upon the life of hot-cathode valves is perhaps a natural criticism; but Mr. Ross must not judge from ordinary domestic wireless experience. Wonderful as are the improvements that have been made, and great as are the future steps towards perfection that may be expected in this service, the valves used for it are comparatively of a low grade, whereas, to ensure reliability, the valves for protective gear, like those used in the valve repeater stations of the Post Office, are selected from the pick of all production. Reliability of operation is further obtained by provision for easy testing for deterioration of the valves and other apparatus, by periodic replacement, and by an automatic alarm in the unlikely event of an accidental failure.

Of Appendix III it has been said that the arrangement of electrodes used in the test does not correspond to practice, both because the gap was horizontal and because it was too long. But faults may occur between lines as well as from lines to framework, and, further, wind tends to elongate the arc, and the metal vapour from the fuse used to initiate the arc is not present in service. Hence the tests carried out are representative of average conditions. In addition, I think that Mr. Ross and Mr. Cranmer are not correct in assuming that the length of the arc remains the same as the distance between the initial flash-over points. In flash-over tests made with post insulators, an arc at only 20 000 volts travelled 14 to 15 ft. almost instantaneously along a neighbouring earthed rail, and what appeared to be metal from the live conductor was actually deposited on the burnt splashes of the rail at that distance away. Mr. Paul Ackerman, as a result of tests made in Canada, refers to the possibility of an arc of 1 000 amperes at 110 000 volts having a critical length of 370 ft. It occurs to me that Mr. Ross and Mr. Cranmer must be accustomed to think in terms of a voltage flash-over test with comparatively small power behind it; but the behaviour of an arc with a power system behind it is very different. It floats out and waves like a flag, and simultaneously with its fading away when it reaches great length another arc may instantly establish itself across the post insulator and follow a similar course. Tests have not been made with an actual chain insulator; but, judging from tests on vertical post insulators that have been made, the shape and type of the insulator, and its position, do not affect the resistance of the arc once it has been established. Mr. Cranmer raises the question of current values. The deductions of the paper (page 328) are based upon currents of the order of 500 amperes. If they were based upon the 200 amperes suggested by Mr. Cranmer, Fig. 76 shows that the errors of impedance protection given in the paper would be greatly increased. Mr. Wedmore suggests that the presentation would be simplified if the results were expressed in terms of voltage-drop per unit length of arc; but the difficulty is to measure with any degree of accuracy the length of an arc waving about violently in the air.

Mr. Ross asks how the R.M.S. values shown in Appendix III were deduced from the oscillograms. The test-circuit contained a large amount of impedance in series with the arc, inserted for the purpose of keeping the current in the circuit constant even when the arc-resistance varied, so that the distortion of the current wave-form was negligible. The slight distortion present in the voltage wave-shape was not taken into account in calculating the R.M.S. values, but the effect of neglecting the harmonics is very small, since they have to be added vectorially to the fundamental: a 20-per-cent harmonic affects the R.M.S. value by 2 per cent only. Further, the design of the ratio-balance (reactance) relays is such that the effect of wave-distortion on their operation is negligible in practice.

I have noted Mr. Ross's claim of satisfactory operation for impedance protection in Scotland. Future results, added to experience of operation with his type of protection in South-West England, where the arcing loads may be lighter owing to the greater distances of lines from large power stations, will be a deciding factor in this controversy of impedance versus reactance measurement.

Mr. Ross raises an interesting point about the possibility that the direct-current component of asymmetric

short-circuit faults may cause inadvertent tripping on Merz-Price balanced-voltage systems; but an asymmetric current entering one end of a sound section leaves it at the other end, and, whether or no there are direct-current impulses, the experience of a very large number of heavy-current balancing tests with the equivalent of very long and very short pilots shows that, if present, they are ineffective. The only abnormal frequencies that may cause inadvertent operation are those that do not pass through both ends equally, and the effects of these, when existing, are removed by tuning. I agree on the acid test of service, and hence I would stress the country's need for an impartial observation of results, because I feel that the issues involved are too great to leave entirely in the hands of competitive manufacturers.

Mr. Wilson, in his references to protective systems, deals particularly with the possible changes that we may have to make to get back to the starting-point such that all the high-frequency currents do pass through the restraining coil, it seems to me that their effect must be to increase the restraint on the operation of the relays under both healthy and faulty conditions, because the mechanical balance upon which operation depends cannot differentiate between frequencies. In a healthy section this increased restraint is necessary for stability; but unfortunately the same increased restraint will exist in a faulty section, with the undesirable result that the normal-frequency fault-current for tripping must be greater to an unknown and variable extent. This would mean that the McColl system does not comply with two fundamental requirements of protection, namely that high-frequency out-of-balance currents shall not adversely affect the stability of healthy sections, and that in a faulty section they shall not increase the normal-frequency tripping fault-current.

I, too, believe in the possibilities of split-conductor protection when applied to parallel feeders. If an

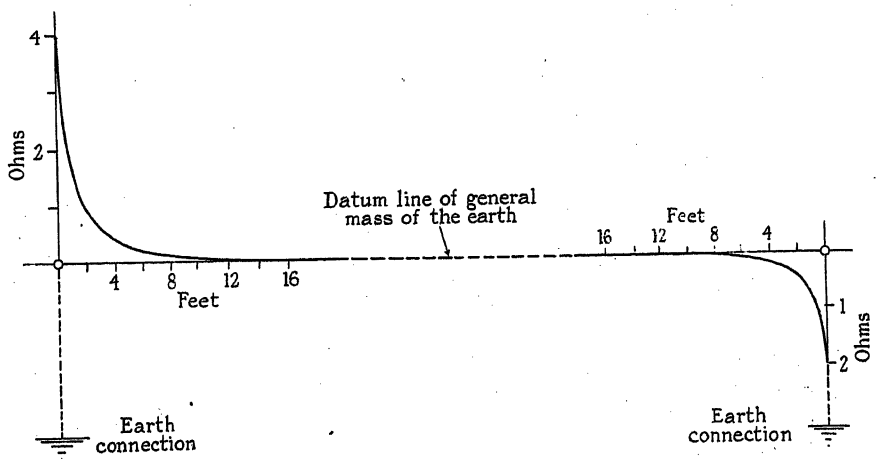

FIG. AA.—Diagram illustrating resistance-distance characteristics between two earth connections.
The ordinates represent the resistances between the points at which they are measured and the general mass of the earth.

of instantaneous release on account of the risk that plant may run out of step even with a small time-lag. He is hopeful of the carrier-current or superimposed interlock system, and suggests that the Kapp-Carrothers (duplex) scheme is of a similar type, and should also meet the conditions; but I understand that, so far, a similarly economical and practical method is not available for the transmission of signals by superimposed high-frequency currents with the duplex system.

Mr. Wilson claims that the McColl bias system of feeder-protection without tuning complications is quite unaffected by high-frequency surges, and that other vagabond and harmful currents all pass through the restraining coil of the relay, and hence stabilize the system instead of tending to make it trip. It is not clear that all the high-frequency currents will flow entirely through the restraining coil, and so conveniently avoid energizing the operating coil. It seems possible that the distribution of the high-frequency current through each coil depends upon the capacitance of the pilot wires, that is to say, upon their length, and it would appear that the pure McColl system must be subject in some circumstances to inadvertent tripping of healthy sections. If, however, the conditions are existing system has to extend the carrying capacity of its mains, nothing could be simpler, and at the same time more economical, than to put a new main alongside of the existing main, and to join them both up to the busbars through one panel. I think that new ring mains, as long as they are comparatively unimportant, might be protected by some time-class system, but when they become sufficiently loaded to warrant additional cables the reinforced sections could be cheaply and thoroughly well protected by split-conductor equipment.

Safeguarding Telephone Systems.

Mr. Bartholomew emphasizes the desire of the Post Office for the protection of its cables from the results of faults on power systems. He asks how the proposed figure of 50 yards was arrived at, and wishes to have details of tests. The 50 yards from the power-station earth plate, which should be on the outskirts of the building, was an empirical distance selected with a view to obtaining a piece of ground likely to give the necessary clearance from any other earthed metal in contact with the power station. Distance and resistance measurements, as shown in Fig. AA, have been made

between two dissimilar earths. Actually the potential difference between the ground surrounding each earth-connection and the general mass of the earth falls very rapidly in the first two or three feet, and becomes negligible within three or four yards.* The power tests mentioned in the paper are those referred to at the end of Appendix IV, which showed that the proposed precautions are adequate from the point of view of protecting relay apparatus from the effects of short-circuits on the associated high-voltage current transformers. Care is essential to avoid short-circuiting the fault-current paths by the lead sheaths of small cables, and it is valuable to have a record of Mr. Bartholomew's experience and conclusions. A case of trouble on pilot wires occurred in France owing to defective earthing, and damage to plant happens because of short-circuits initiated by lightning. Mr. Shipley's experiences in the tropics are a valuable contribution to this subject, owing to the greater prevalence of lightning there. Mr. Cox will note that his point about placing the spark-gap close to the switchgear is already provided for in the diagram, which reads: " Earthing device near switchgear."

Remote and Automatic Control.

Power-Station Control Boards.

Mr. Kidd's interesting ideal for future control boards is, I think, generally in line with the trend of examples shown in the paper, which are mainly based upon work actually in use or in hand. I am not so sure as he is that the telephone type of control switches and cables is sufficiently substantial; but the reduced space-factor must be a considerable aid to operating engineers, and will advance reliability so long as connections are not so close together that the operation of the controls or maintenance and cleaning work leads to inadvertent operation or signals. Referring to vertical-scale illuminated instruments of the shadow type in a row, I do not, of course, mean to suggest that they can do more than supplement the customary summation instruments.

Tandem and Radial.

Mr. Cox confirms the paper in the prospects of converting central-control indicating systems into complete operating control, but he prefers to use adapted telephone apparatus. Such equipment may be more flexible, as he says, but only in the " meccano " sense, in that it consists in the main of a multitude of standard telephone parts, whereas the alternative centrovisory-control apparatus has been specifically designed on the basis of mechanical units for its individual operating features, and possesses all the flexibility it needs for its essential purpose, which is the control of power systems. It is not correct to claim generally that a combination of telephone parts is speedier in its operation. Indeed, in some cases it is slower, owing to the cumulative number of individual impulse operations making up a given total indication or operation. In eliminating multitudinous relays operated by chains of impulses by the substitution of fewer mechanisms, centrovisory control aims at simplicity and reliability, and its circular system-diagram enables a large number of circuits associated with any one station to be indicated clearly in a minimum useful width of control panel. Mr. Ross also thinks that centrovisory control is less flexible than the combination of mass-produced telephone parts that performs the same functions. In reply, I would say that, so long as it can be made in sufficient quantities to be economical, it is refreshing to get away from the monotony of the telephone devices. As to the diagram, it is as simple and rational as the face of a clock.

Except possibly for railways, the radial system is more in conformity with normal geographical location, particularly in relation to central control. The continuity of full service is of great importance, and a breakage of a pilot in a tandem-controlled system would appear to dislocate the control to a much greater degree than in a radial system. For instance, seeing that the most likely location of a break or disconnection is in the more densely built-up areas of the kind to be found in the neighbourhood of control stations, the entire tandem system would be jeopardized by such a fault or break in the pilot.

Furthermore, although I agree with Mr. Cox about extended use on circuits of smaller powers, I suggest that there is likely to be considerable congestion of messages on a 2-pilot tandem system such as he has proposed, comprising 30 stations each with 10 operations. I am greatly interested in Mr. Winfield's remarks on the tandem system of pilot control. It is obvious that congestion of signals and the accompanying heavy duty on the telephone equipments cause wrong operation, which can only be avoided by the radial system upon which centrovisory control is based.

The Mimic Measurement of Vicinity Short-Circuits.

I am obliged to Mr. Smail for the analysis he has given of the requirements of a calculator suitable for the grid, and I would explain further that the two separate types of faults to which he refers are dealt with in the calculator shown in Fig. 66 by having the removable links constructed with concentric fittings in such a way that there are actually two distinct circuits, which represent the earth-fault and phase-fault conditions described by Mr. Smail.

Mr. Grant visualizes mimic calculator boards that will measure all characteristics and phenomena at any point of the system, including the change of impedance during the decrement period. These can be furnished; it merely needs someone to come forward who is prepared to pay the cost. In the meantime, the reproduction of impedance by ohmic resistance with direct-current power supply seems to suffice, and at times, I fear, to exceed users' ideas of price; and, after all, the information about resultant impedance thus obtained is a very great step in advance.

In conclusion, I would thank all those who have taken part in the discussion, including the Middlesbrough and Dundee members, the reports of whose remarks are, unfortunately, not available. There have been over 250 points raised in the discussion alone, and whether they have been super-critical, or due to mistaken reading, or constructive, they have all helped to show the need for a better understanding of the problems, and therefore they have all served a useful purpose.

THE PENETRATION OF ALTERNATING MAGNETIC FLUX IN WIRE ROPES.*

By T. F. WALL, D.Sc., D.Eng., Member, and C. H. HAINSWORTH, M.Eng., Associate Member.

(*Paper first received* 13*th January*, 1931, *and in final form* 19*th January*, 1932.)

SUMMARY.

When a wire rope is arranged in a laminated magnet yoke and magnetized by alternating current in accordance with the arrangement of magnetic circuit which has been described in a previous paper,† it is of importance to know how the magnetic flux becomes distributed across the section of the rope. In order to obtain some experimental data on this question, a sample of wire rope was constructed with a built-in search coil surrounding each layer. By an examination of the oscillograms obtained from these search coils the flux density has been obtained for each layer of the rope for two values of the a.c. supply frequency. By means of ballistic tests the flux density has also been obtained for each layer when the wire rope is magnetized by direct current.

INTRODUCTION.

In a previous paper† one of the authors gave an account of the principle of action of an electromagnetic apparatus which was designed in the Electrical Engineering Department of Sheffield University for testing for mechanical flaws in wire ropes, the excitation of the testing magnet system being obtained by means of alternating current. The form of magnetic circuit which is used in the rope-testing apparatus as described in the previous paper will be understood by reference to Fig. 1, which is reproduced from that paper. A ⊔-shaped laminated iron yoke is provided with an exciting coil, and tunnelled holes pass through the projecting limbs, the length of each of these tunnelled holes being large as compared with the diameter. The diameter of the rope under test is considerably smaller than the diameter of the tunnelled holes, so that there is a large clearance between the rope and the holes. Since the length of the tunnelled holes is large compared with the diameter, the flux density in the air-gap will be small and it is possible to obtain a high flux density at the section XY of the rope by means of a relatively small number of magnetizing ampere-turns. Typical proportions for the yoke and rope under test are shown in Fig. 1.

In the previous paper reference was made to the problem of the penetration of alternating magnetic flux

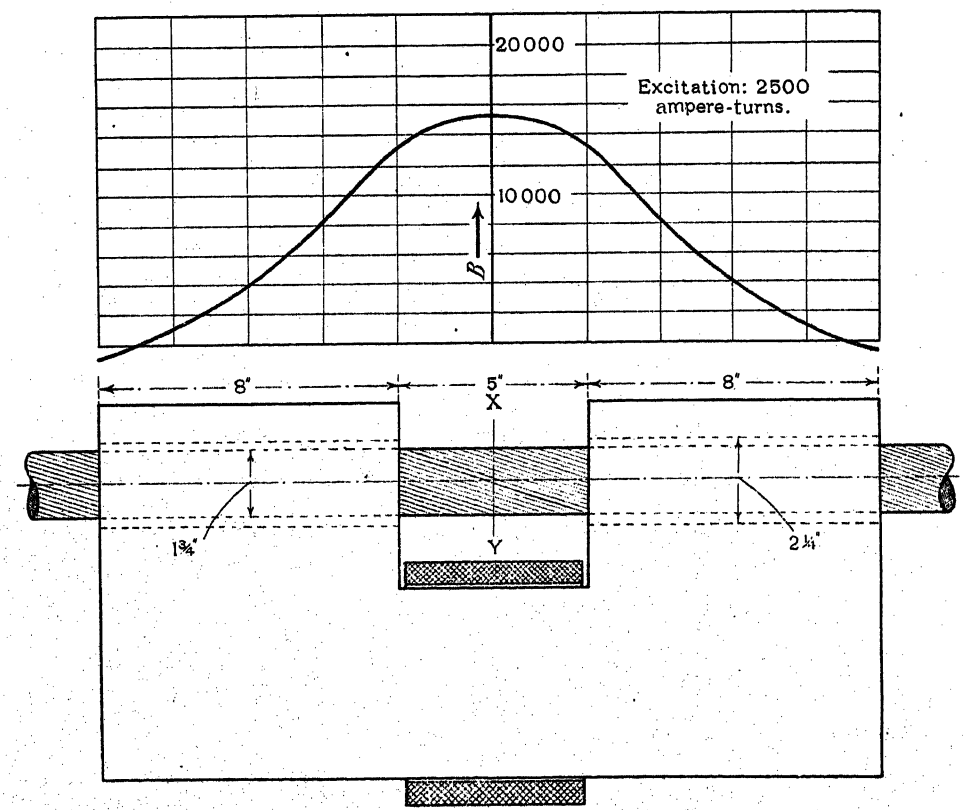

FIG. 1.—Magnetic circuit used in tests.

in the case of a composite structure such as a wire rope, and some test data were given showing the relationship between the total flux which was developed in a locked-coil type of rope and the excitation ampere-turns for an excitation frequency of 25 cycles and 50 cycles per second respectively, a comparison also being made with the total flux obtainable when d.c. excitation was used.

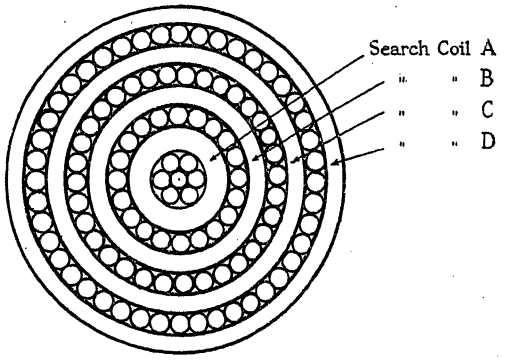

FIG. 2.—Cross-sectional view of completed sample, showing position of search coils.

All these tests were made with samples of rope as actually supplied for colliery winders, and the flux was measured by means of a search coil wrapped round that part of the rope in which the maximum flux density was developed. The flux measurements so obtained showed that, as compared with d.c. excitation, there was a distinct

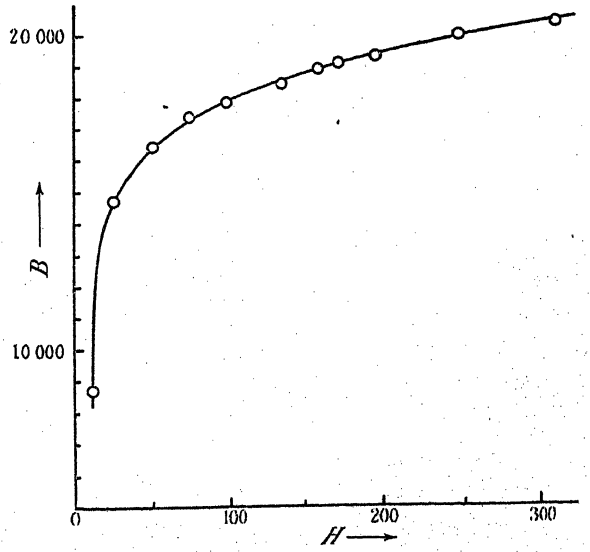

FIG. 3.—Magnetization curve of iron wire used in sample tested.

reduction of the total flux in a locked-coil rope unless the supply frequency was kept low. This reduction was most marked when the flux density was well below saturation value.

Now the information given by tests on a search coil which is linked with the whole cross-section of the rope does not enable any definite knowledge to be obtained as to how the total flux is distributed over the cross-sectional area. It is, however, of great practical importance to know something of the way in which the flux is distributed within the rope. In particular, such information is of considerable value in ascertaining whether there is any effect associated with a flaw which is characteristic of its depth. If such an effect can be found it will form the basis of a means for estimating the depth of a flaw in a locked-coil rope.

Whilst the mathematical theory of the screening effect of eddy currents has been worked out in full detail for thin laminated plates, the case of iron wires is a somewhat different problem and the screening effect of eddy currents in a compound structure like a locked-coil rope is a very intricate problem. It therefore appears hopeless to expect any generally useful practical assistance from a mathematical treatment. The problem is further complicated in the case of the electromagnetic testing

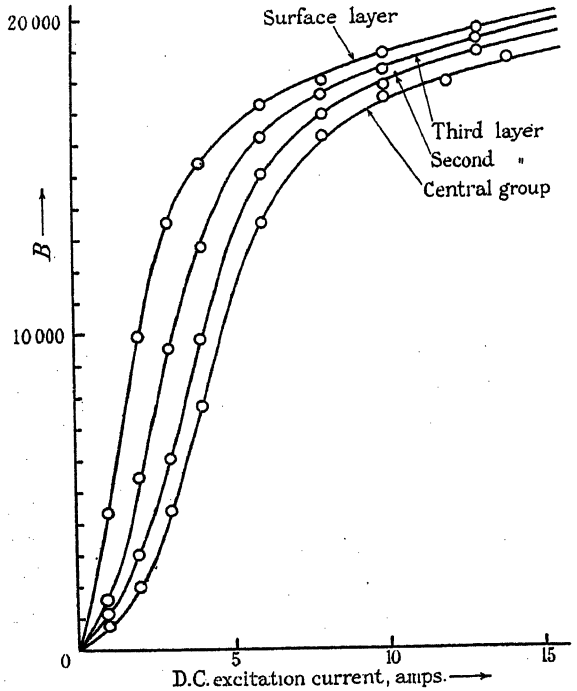

FIG. 4.—Ballistic tests.

apparatus under consideration because the flux enters the rope over an extended length, thus producing a cumulative effect at that part of the rope which is situated between the projecting poles (see Fig. 1).

The information which is required is a knowledge of the flux density in *each layer* of the rope as a function of the excitation ampere-turns. It is, of course, not possible to measure this flux density directly in an actual winding rope, as such a measurement requires embedded search coils embracing each layer. Some definite information as to the nature of the flux distribution over the cross-section of a locked-coil type of rope is, however, of such great importance in obtaining a complete knowledge of the action of the rope-testing apparatus that it has been considered desirable to build up a sample with embedded search-coils and to examine the flux distribution by means of ballistic tests and tests with alternating-current excitation at various frequencies.

The Experimental Sample with Embedded Search-Coils.

The experimental sample was made to be as nearly as possible an exact replica of a locked-coil type of wire rope, the layers of the experimental sample being not quite so close together as in the locked-coil rope, owing to the built-in search coils. The effects disclosed by the tests on the experimental sample must therefore be of the same nature as those which will occur in an actual locked-coil type of rope.

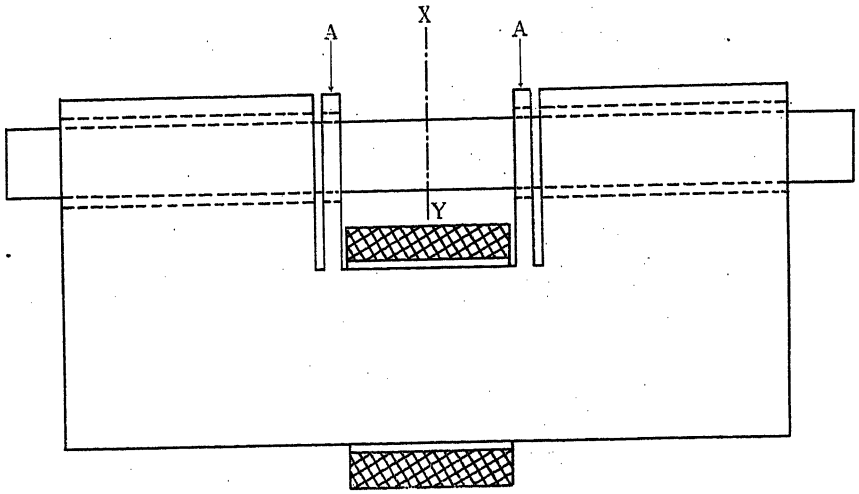

Fig. 5.

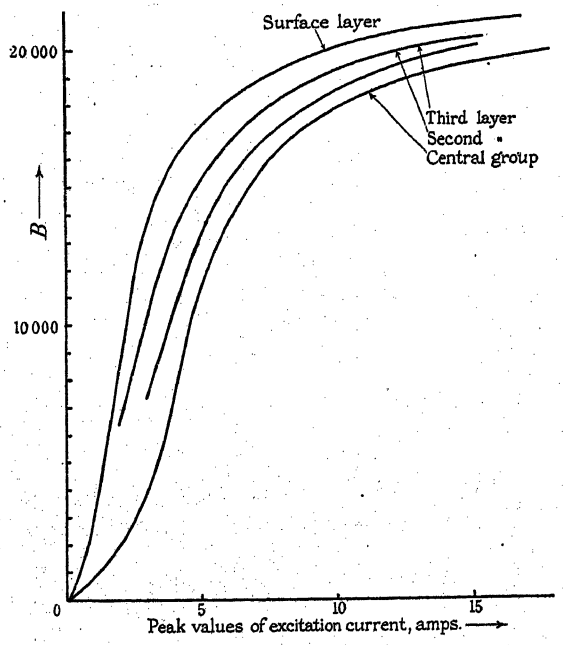

Fig. 6.—Excitation with alternating current at 18 cycles per sec.

Straight, mild-steel wire rods of $\frac{1}{8}$ in. diameter were used for this sample, each rod being coated with insulating enamel before assembly. A cross-sectional view of the completed sample is shown in Fig. 2. A first layer or central group of 7 wires was formed and a search coil (coil A) of 200 turns arranged to embrace this group. A second layer comprising 20 wires was then built up and a search coil (coil B) of 200 turns was wound embracing this layer. A third layer of 33 wires was then formed and a search coil (coil C) was wound on this layer. Finally a fourth layer of 44 wires was built up and the search coil D of 200 turns was wrapped on this surface layer. All these search coils were so arranged that their planes were all coincident and at right angles to the axis of the sample. The data of the area of the wires in each layer and also the mean area embraced by the respective search coils are as follows:—

First Layer or Central Group:
Area of iron wire = 0·57 cm^2
Mean area of search coil A = 1·55 cm^2

Second Layer:
Area of iron wire = 1·63 cm^2
Mean area of search coil B = 5·8 cm^2

Third Layer:
Area of iron wire = 2·69 cm^2
Mean area of search coil C = 12·4 cm^2

Fourth or Surface Layer:
Area of iron wire = 3·58 cm^2
Mean area of search coil D = 21·9 cm^2

The total cross-sectional area of the rope is thus 8·47 cm^2.

The general arrangement will be clear by reference to Fig. 2.

By connecting consecutive search coils in opposition in pairs, it is possible to measure the magnitude of the flux associated with each layer. By using search coil A alone the magnitude of the flux in the central group of wires is measured, and measurements with search coil D give the total flux through the sample.

In order to obtain the correct values of the flux density in the iron wires when the excitation is in the neighbourhood of saturation value, it is necessary to subtract from the measurement of the total flux that amount

which passes through the air space embraced by the respective search coils, and for this purpose it is necessary to know the magnetization curve of the iron wire of which the sample is built up. This curve has been obtained by arranging a group of the wires in a long standard solenoid and obtaining the B–H curve in the usual manner. The curve so obtained is given in Fig. 3.

(2) The Flux Distribution when D.C. Excitation is Used.

Tests made with d.c. excitation of the magnet system are useful as giving a standard of reference, since no such phenomenon as "skin effect" develops under these conditions. These tests were made with a Campbell high-sensitivity ballistic galvanometer, and the relationship between the excitation current and the flux density in the respective layers of the sample is given by the curves in Fig. 4.

The first noteworthy feature of these curves is that for a given value of the exciting current the flux density in each layer is different, being a minimum in the central group of wires and a maximum in the surface layer. Another important feature is that the shape in the neighbourhood of the origin is different for each curve. Both of these distinctive features are of great importance in considering the performance when a.c. excitation is used.

It is not at first obvious what the full explanation of these characteristic features of each layer of iron wires may be. Undoubtedly the main cause of the effects can be referred to the fact that the air-gap between the respective layers and the tunnelled holes in the magnet limbs is different for each layer, i.e. the air-gap associated with the central group is very much greater than that associated with the surface layer.

There is, however, another question which arises here, and that is whether the flux which enters the sample from, say, each band of 1 cm width of the surface of the tunnelled holes in the magnet limbs is distributed amongst the respective layers in the same proportion. Alternatively, does the flux which enters the sample from that part of the surface of the tunnelled hole which is near the inner flank of the magnet limb confine itself more particularly to any special layer? The answer to this question is of great importance and contains the clue to a method for examining the behaviour of each layer of an actual rope in practice, in which case, of course, it is not possible to make use of embedded search-coils.

A consideration of the results given in Fig. 4 suggests that the flux associated with the surface layer is more particularly the flux which passes through the inner slices, such as A, A, of the magnetic limbs as shown in Fig. 5, whilst the flux which is associated more particularly with the central group of wires passes across the air-gap further back towards the left-hand portion of the left-hand limb and the right-hand portion of the right-hand limb of the magnet system shown in Fig. 5. General considerations of symmetry also lead to the same conclusion as regards the magnetic circuits of the flux in the respective layers of a locked-coil rope.

The practical importance of this result is that it suggests a means for obtaining access to a flux band which is particularly associated with any one layer of the rope.

(3) Tests with A.C. Excitation at a Frequency of 18 Cycles per Second.

The frequency of the a.c. excitation for these tests was chosen sufficiently low to ensure that the skin effect would be small. In order to obtain the curves showing the relationship between the flux density in the respective layers and the excitation current, measurements were made of the induced e.m.f. in the search coils as follows: Coil A for the central group, coils A and B in opposition for the second layer, coils B and C in opposition for the third layer, coils C and D in opposition for the surface layer. By measuring the induced e.m.f. in coil D alone it is possible to determine the total flux through the sample; this gives a check on the measurements of the flux for the individual layers.

In order to deduce the magnitude of the flux from

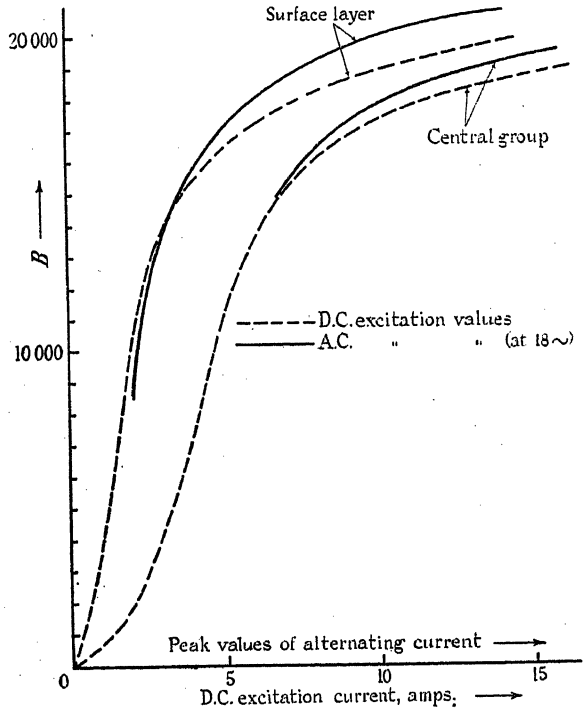

Fig. 7.

the R.M.S. value of the induced e.m.f., it is necessary to obtain the form factor of the e.m.f. wave. For this purpose an oscillogram of the e.m.f. wave was taken in each case and the form factor was then found graphically. From a knowledge of the R.M.S. value of the induced e.m.f. and the corresponding value of the form factor of the e.m.f. wave the maximum value of the total flux linked by any of the search coil combinations detailed in the previous paragraph was obtained. For values of the exciting current corresponding to saturation, correction was made for the flux in the air space which was linked by the search-coil combination, and in this way the flux densities in each layer was arrived at as a function of the exciting amperes.

In Fig. 6 the flux-density curves so obtained have been plotted with the peak values of the exciting current as abscissæ, and in this way a direct comparison can be

made with the corresponding curves given in Fig. 4 for d.c. excitation.

A comparison of the curves given in Figs. 4 and 6 shows that there is very little screening effect due to eddy currents and that the penetration is nearly as complete with a.c. excitation at a frequency of 18 cycles per sec. as with d.c. excitation. There is, however, one very prominent feature revealed by this comparison, viz. for the higher values of the exciting current the curve for a.c. excitation for any one layer lies distinctly above the corresponding curve for d.c. excitation. This effect is prominently seen in Fig. 7 in which the curves for the surface layer and for the central group are reproduced, the broken-line curves being the d.c. excitation values and the full-line curves the results obtained by means of a.c. excitation at a frequency of 18 cycles per sec. This implies that for high values of the excitation, the permeability of the iron rods is greater for a.c. than for d.c. excitation. This effect may be, at least in part, explained in the light of Ewing's experiments, in which he showed that when an alternating flux was superimposed on a magnetic specimen in such a way that this flux did not link the search coil, the hysteresis loop collapsed and the inward bend of the magnetization curve in the neighbourhood of the origin practically disappeared.*

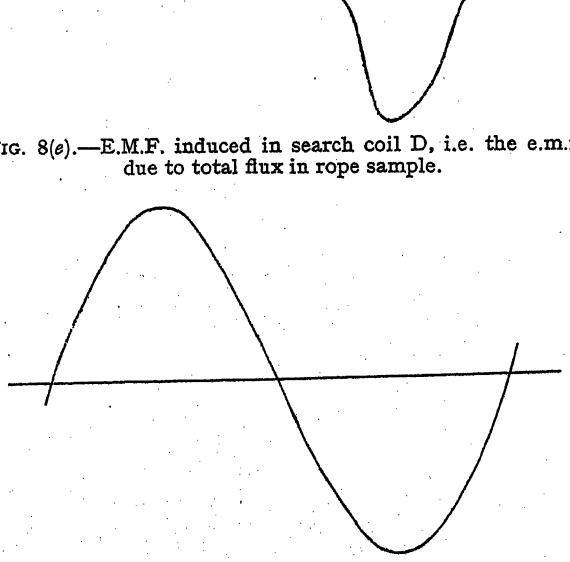

FIG. 9.—Wave-form of current in exciting coil of electromagnet.
Exciting current = 5·4 amps.
Supply frequency = 50 cycles per sec.

N. W. McLachlan† has shown that when the

* See also C. P. STEINMETZ: "Theory and Calculation of Electric Circuits."
† *Journal I.E.E.*, 1915, vol. 53, p. 818.

magnetization is produced by an alternating current of sine-wave form the permeability is greater than the permeability obtained when the magnetization is produced by a steady direct current.

(4) Tests with A.C. Excitation at a Frequency of 50 Cycles per Second.

A series of tests were also made with a.c. excitation at 50 cycles per sec. and the corresponding curves for the

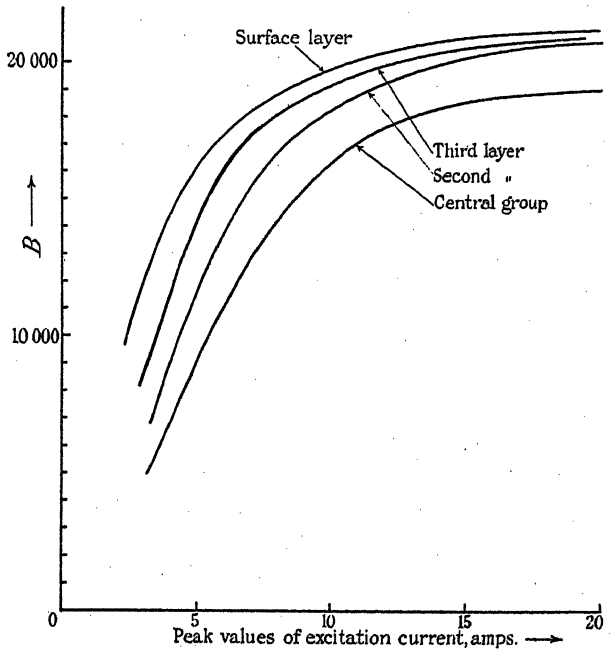

Fig. 10.—Excitation with alternating current at 50 cycles per sec.

several layers were obtained in the manner explained in Section (3). These curves are given in Fig. 10.

The difference between the wave-forms of the induced e.m.f.'s in the several layers is very striking. A representative set of oscillograms is given in Fig. 8, in which is also included the oscillogram obtained from the search coil D embracing the whole sample and thus giving a compound effect of the wave-forms of the fluxes in all the layers. These oscillograms were all taken with an excitation current of 10 amperes (R.M.S.).

An inspection of the wave-forms given in Fig. 8 shows that associated with each layer is a characteristic wave-form and that the wave-form given by the surface layer, for example, is widely different from that given by the central group.

In Fig. 9 is shown a typical oscillogram for the current wave; this is seen to be very nearly sinusoidal.

In Fig. 11 are reproduced, for purposes of comparison, the curves for the surface layer and the central group as given in Fig. 10. Also in Fig. 11 the corresponding curves for d.c. excitation are shown by broken lines. It is now apparent that there is a marked screening

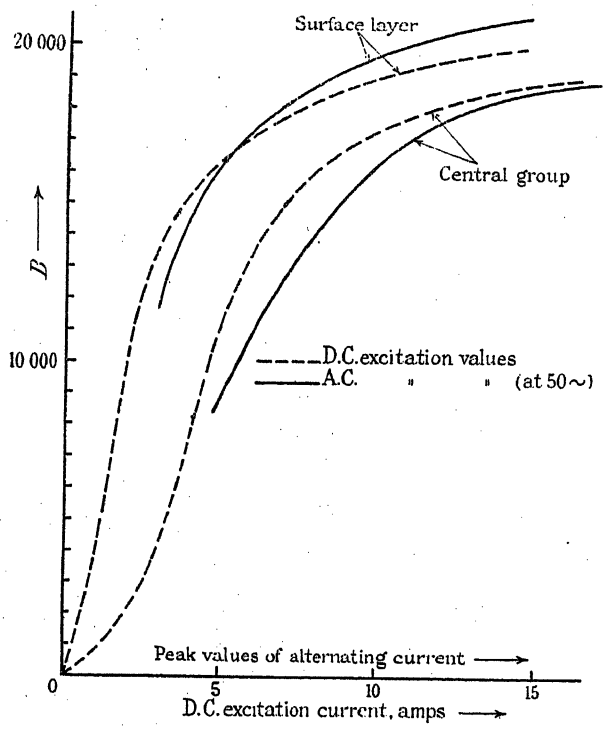

Fig. 11.

effect on the central group due to eddy currents at this frequency of excitation, the a.c. curve lying below the d.c. curve throughout the whole range of the excitation. For the surface layer, however, whilst the a.c. curve lies below the d.c. curve for the lower values of the excitation, the same effect as that noticed with 18-cycle excitation appears at the higher values of the excitation, that is, the a.c. curve lies above the d.c. curve. For the higher values of the excitation there will thus be two conflicting actions operating, viz. the tendency for the a.c. excitation to increase the effective permeability, and the tendency for the eddy currents to produce a skin effect and thus reduce the flux.

THE TECHNIQUE OF THE HIGH-SPEED CATHODE-RAY OSCILLOGRAPH.

By F. P. BURCH, B.A., and R. V. WHELPTON, M.Sc.

(*Paper first received 24th December*, 1931, *and in final form 5th April*, 1932.)

SUMMARY.

After an introduction in which the need for high-speed oscillography and the nature of the problems are explained, an equipment built for recording the "uncontrolled" surges of a 1 000 000-volt impulse generator is described. Attention is concentrated on the problems of discharge tubes, beam traps, sweep circuits, and screening. Examples of the oscillograms obtained are given.

(1) INTRODUCTION.

During the last 10 years electrical engineers have been forced to devote increasing attention to the momentary over-voltages to which their apparatus is subject. Such over-voltages arise from switching operations, the sudden development of faults, or, in the case of overhead transmission lines, from the inductive action of neighbouring lightning flashes, even in the absence of a direct hit. These disturbances are usually of extremely short duration—thousandths or even millionths of a second—but since the maximum voltage may be two, five, or even eight times normal they are often the determining factor in the design of the insulation. For example, when power is suddenly applied to one end of a cable or transmission line a wave of voltage travels along the line. On arrival at the far end this wave is doubled by reflection from the transformer or connected apparatus, and the whole of the double voltage is momentarily concentrated across the end-turns of the winding.

This fact has long been appreciated, and it has become the practice to reinforce the insulation of the end-turns, and sometimes to interpose a choke coil between the line and the transformer. But as a result of recent oscillographic researches it is now recognized that the concentration of voltage across the end-turns, lasting only a fraction of a millionth of a second, is not the whole story. The entire coil is "shocked" by the wave into an oscillation of somewhat complicated type which persists in general for some thousandths of a second, and imposes abnormal voltage gradients on the middle parts of the winding; and though these voltage gradients are not so great as the initial gradients at the end-turns, they may be equally dangerous because they last so much longer. For the longer the time of application, the lower is the voltage necessary to break down any insulator. These oscillations of the transformer winding are in some cases intensely aggravated by resonance between the line and the winding, and the use of a choke coil, instead of removing the danger to the transformer, may actually increase it.

From the foregoing example it will be realized that with the growth in the size of electrical undertakings, the insulation engineer is compelled to study in detail the mechanism of the production of transient over-voltages, their magnitude and duration, and the ability of insulation to withstand them, as well as the possibility of suppressing them by such devices as surge absorbers and lightning arrestors. A high-voltage laboratory must be equipped, firstly with an impulse generator to produce high-voltage transients, and secondly with a cathode-ray oscillograph capable of recording the variation of voltage with time in a single transient occupying less than a millionth of a second.

The small sealed glass oscillographs, using cathode voltages from a few hundred to a few thousand volts, which are to-day found in almost every electrotechnical laboratory, are admirably adapted to the study of *periodic* phenomena, even at frequencies of a million cycles or more, for a steady picture can be obtained on the screen by causing the cathode-ray spot to retrace continually in synchronism with the phenomenon under investigation. They do not, however, give sufficient intensity for the recording of a single transient lasting less than about 10^{-3} sec. For transients measured in microseconds (1 microsecond = 10^{-6} sec.) an instrument of a totally different type is necessary. The pioneer of high-speed single-transient recording was Dufour, who insisted on the necessity for a beam of high-voltage cathode rays, and took the important step of introducing the photographic plate into the vacuum. These expedients inevitably require a rather bulky apparatus with continuously running vacuum pumps.

The progress of cathode-ray oscillography up to and including the work of Dufour was described in a paper before the Institution by Prof. MacGregor-Morris and Mr. Mines in 1925.* Since that time high-speed instruments have been improved out of all recognition. German investigators have been chiefly responsible, notably Rogowski, who was the first to photograph travelling waves,† and has pushed the speed of recording very close to the limit imposed by the nature of cathode rays.‡

This paper is intended as a contribution to the technique of high-speed oscillography. The principal problems of high-speed recording are the following:—

(1) The problem of designing a discharge tube to provide a perfectly steady, intense beam of cathode rays.

(2) The choice of the method of obtaining a photographic imprint, i.e. whether the beam should fall directly on a film inside the vacuum, or should pass through a Lenard window on to a film outside the vacuum, or should strike a phosphorescent screen the light from which is recorded on a film outside the vacuum.

* See Bibliography, (1). † *Ibid.*, (2) and (3). ‡ *Ibid.*, (4).

(3) The problem of arranging that the beam shall be already moving over the film along the axis of time at the moment when the transient under investigation gives it a motion at right angles parallel to the voltage axis. This problem becomes especially difficult when the phenomenon under investigation is one of which the moment of occurrence cannot be controlled, e.g. a lightning disturbance. The earlier workers solved it by moving the beam continually backwards and forwards along the time axis, so that it was always ready to be deflected at right angles by the transient voltage. For certain very special problems this method is without peer, but the replotting of the records into ordinary graphs of voltage against time is a tedious matter. It has therefore become almost universal practice to sweep the beam once only across the film, so that an ordinary voltage/time graph is obtained directly. This single sweep must of course be initiated at the right moment, and therefore when the incidence of the transient is not under control it is necessary to arrange that the transient shall operate a relay which starts the time-sweep. Further, since even the swiftest relay has some time-lag, if the start of the transient is to be recorded it must first be brought to the relay, and then conveyed to the voltage deflection-plates of the oscillograph by an electrical line long enough to delay its arrival until after the relay has operated.

The methods adopted by different workers for solving these problems vary widely, and are in many cases ill-adapted to researches of a type other than that for which they were devised. The equipment described in this paper was built primarily for work with a 1 000 000-volt impulse generator.* For such work some American laboratories have so linked the impulse generator and oscillograph that the closing of a switch starts the time-sweep of the oscillograph, and immediately afterwards trips the impulse generator. This arrangement requires cumbersome and expensive high-voltage apparatus, and makes the oscillograph an integral part of the impulse testing equipment. The authors preferred to build an instrument capable of recording uncontrolled transients, and to treat even the artificial surges of the laboratory as "uncontrolled." This course provides an oscillograph which is cheaper and more convenient for impulse testing, as well as being applicable not only to a variety of laboratory problems but also to lightning and transmission-line investigations.

(2) General Features of Construction.

In general features the instrument is similar to those of Continental workers.† The authors adopted a vertical construction. Referring to Fig. 1, at the top is the discharge tube or source of cathode rays, which is here shown only diagrammatically, being described in detail later. From the discharge tube the rays pass through a 1-mm hole in the aluminium anode block into the main tube as a slightly divergent beam. The main tube is of drawn brass 17·8 cm bore and 145 cm long, supported in an angle-iron frame. Surrounding it about half-way down is the magnetic focusing coil, through which direct current is passed and adjusted so that the magnetic field causes the diverging beam of electrons to converge and come to a sharp point focus on the phosphorescent screen or photographic film. The focusing coil is shrouded with iron to confine its field. Inside the tube at the same height are diaphragms of aluminium backed with lead, so arranged as to limit the beam while allowing a free passage of air. Immediately below the focusing coil is a 4-pole electromagnet system by means of which the beam can be given independent steady deflections in two directions at right angles, and thus its zero position brought to any desired point on the photographic film. Inside the tube, below the position magnets, are the electrostatic deflection-plates. These are carried on a removable framework, and are inclined for maximum voltage sensitivity.

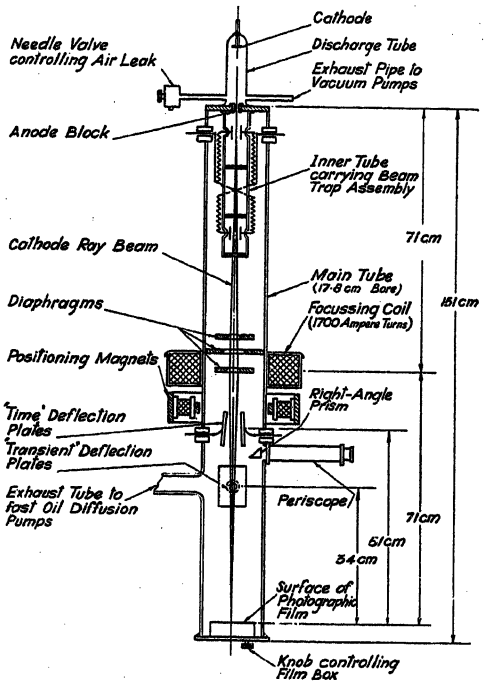

Fig. 1.—Diagrammatic sketch of cathode-ray oscillograph.

The upper pair is used for the time and the lower for the transient deflection. Contact is made to them by flat springs, from which leads are brought out through vacuum-tight insulating bushes. The photographic records are obtained by allowing the cathode-ray beam to fall on a film inside the vacuum; the film box is mounted on the lower cover-plate of the tube and accommodates standard 6 × 9 cm film on which 12 exposures of 6 × 6 cm are obtained. The film is normally covered by a lid coated on its upper surface with phosphorescent zinc sulphide. To open the lid, a shaft passing through a vacuum-tight cone joint is turned; turning in the opposite direction closes the lid and, if continued, winds on the film for the next exposure. The phosphorescent screen can be observed by means of a small telescope and right-angle prism.

In the upper half of the main tube, supported from the top cover-plate, is the beam-trap system, which is described later. The main tube is exhausted through a very short, wide pipe by two cascaded Metropolitan-

* See Bibliography, (5) and (6).
† See (for example) Bibliography, (7) and (8).

Vickers condensation pumps operating with " Apiezon " low-vapour-pressure oil. The very great speed of this pumping system (20 litres per second) enables it to maintain a vacuum of the order of 10^{-4} mm of mercury in the main tube, despite the continual leakage of gas from the discharge tube through the hole in the anode block. In the discharge tube a comparatively high gas pressure, 1 or 2 $\times$ 10^{-2} mm of mercury, is required for the production of the electron beam. Air is accordingly allowed to leak in continually through a needle valve and is removed by a separate oil condensation pump. In this way, by sweeping air through at a good rate, any bursts of gas which may be evolved from the walls of the discharge tube are quickly removed and thus momentary pressure-rises are avoided. The backing vacuum for all condensation pumps is provided by two cascaded pumps of the rotary vane type.

(3) Discharge Tubes.

These have been of the cold-cathode type exclusively, supplied through a series resistance from a rectifier set of which the maximum voltage is limited to 55 kV by the condensers available. The authors at first tried glass tubes 75 cm long, using the extra focusing coil and magnets, after Rogowski,* to bring the beam to a focus on the anode hole. The upper part of the tube was of 13 mm bore and 25 or 50 cm long, the remainder being of 25 mm bore. The cathode was a cylindrical aluminium rod 11 mm in diameter with a flat end, the sharp edge being rounded off. At first these tubes would run steadily for a few minutes only, after which sparking appeared near the cathode. This was soon found to be due to overheating. Oil cooling of the cathode, which appeared to receive about half the heat, made a great improvement, and the trouble was completely cured when a glass oil-jacket was added round the narrow part of the tube. Transformer oil, circulated by a small pump, was used. A sludge collected on the outer wall of the discharge tube near the cathode, but this did not appear to be detrimental; such tubes ran perfectly steadily for some hundreds of hours. A very high degree of polish on the cathode seemed to be unnecessary, and when flickering was observed this was always found to have been due to a leakage of grease through the cathode joint. To ensure perfect steadiness a series resistance of 1 megohm was found insufficient; a liquid resistance of at least 6 megohms was used. Silit resistance rods appeared to be satisfactory as long as there was no tendency to flicker, but when there was such a tendency they seemed to magnify it. The tube was run at about 1 mA, the voltage across it being 40 to 45 kV. At lower currents (0·6 mA) the cathode-ray beam began to become intermittent with a frequency of the order of 1 million cycles. A reduction of voltage increased the tendency to intermittence and reduced the frequency.

For the sake of compactness and simplicity, it is very convenient to use a metal discharge tube of the X-ray type and to dispense with the extra focusing coil. The authors accordingly tried a tube after the design of Messrs. Knoll, Knoblauch, and von Borries (see Fig. 2 of their paper).† But this tube would work for a few minutes only, after which a soft glow discharge broke out. The distance between the top of the metal anode tube and the cathode shoulder was increased or decreased, but without success; and no improvement was obtained by curving the Pyrex tube inwards into the space between the electrodes, or swelling it outwards away from the top of the anode tube. While these tubes were working, however, an excellent electron beam was obtained in all cases. It is probable, therefore, that the production of the beam is indeed wholly determined, as one expects and wishes, by the conditions inside the metal anode tube below the cathode face. The problem seems to be simply that of maintaining a sufficient creepage distance along the insulation, while at the same time restricting the space available for ionization in that neighbourhood. One solution, not, however, very simple to construct, has been given by Berger.* The authors were able to obtain a workable

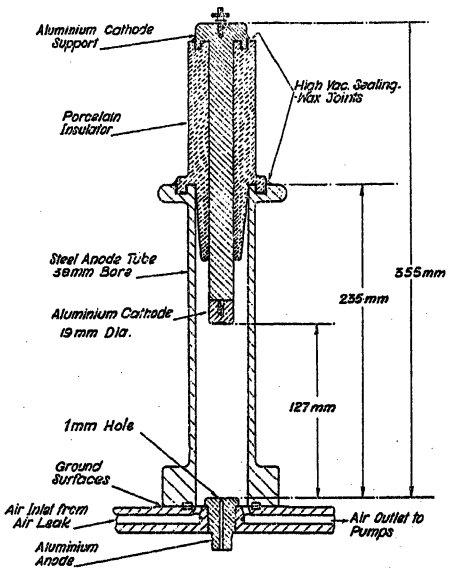

Fig. 2.—Metal discharge tube.

arrangement with the Knoll type tube by inserting below the cathode shoulder an insulated metal anchor-ring supported on a glass ring resting on the top of the anode tube. There were occasional flickers of green glow round the rings, but these did not appear to affect the current or the cathode-ray beam.† However, the very simple and robust design shown in Fig. 2 is completely successful. The distance from cathode to anode tube is now nowhere greater than at the cathode face, and the creepage distance along the porcelain insulator may be made as great as desired. This was suggested by Mr. J. M. Dodds, who gave great assistance in these experiments.

With these tubes oil-cooling of the cathode is unnecessary; water-cooling of the anode is desirable. With reasonably smooth surfaces, a slightly convex cathode gives as good results as a concave one, but if the central part (some 6 mm diameter) of the cathode face is dirty, or deeply scratched with a knife, the intensity of the beam is poor. Scratches on the sides do not matter.

* See Bibliography, (7). † *Ibid.*, (9).

* See Bibliography, (10).

† The authors' experiences with the Knoll type tube are confirmed by a recent paper of Dicks see Bibliography, (11)], who also adopted a floating electrode.

When the cathode is badly pitted, or if a small hole is drilled in it, the intensity of the beam is reduced.* A pointed cathode gave no beam at all. A truncated cone of 36° angle, terminating in a flat face 5 mm in diameter, seemed to give as good results as a concave cathode, but the current became unsteady above 2 mA. With these tubes the authors obtain a more intense beam than with the glass discharge tubes, but in addition to electrons the beam contains considerable numbers of atomic particles—the so-called "retrograde rays."† These, which were not appreciable with the glass discharge tubes, originate as negative ions, but can gain or lose charges in their passage through the gas. They thus pass as neutral particles through the charged beam trap, and reach the screen as a mixture of neutral atoms and positive ions. The deflections of the latter show that their energies approach those of the electrons; the former are distinguished from X-rays by the marked "fatigue" of the phosphorescent screen. To avoid undue fog the film must not be exposed to these particles for more than 5 minutes; they could of course be sifted out by giving to the electrons a magnetic deflection, by "filtering" the beam through a thin film of aluminium or Cellon, or by using the beam-trap arrangement of Norinder.‡

(4) Beam Trap.

In order to avoid fogging of the film, Dufour applied voltage to the cathode-ray tube only during the short time of photographing. This method has been developed and extensively applied by American investigators.§ The method used by Continental workers is, however, much to be preferred: the discharge tube is continually excited, and the beam is prevented from entering the lower part of the deflection tube by a trap from which it is released when required. In Norinder's ingenious trap system the transient voltage itself deflects the beam past a target which normally intercepts it; and where an oscillatory time-base is to be used this has many advantages. But with the single time-sweeping movement now almost universally employed it is best, especially for high-speed work, to release the beam by removing an artificially applied voltage which normally deflects it away from a central hole. The authors first tried to build a beam trap for use with a "Kipp" relay of the type devised by Gábor.‖ With a beam of appreciable angular divergence, however, the design of a low-voltage trap is difficult,¶ while if a high-voltage jump is required the design of a quick-acting "Kipp" relay is equally difficult. Having failed to produce satisfactory trapping at 300 volts, the authors decided to use a spark relay and a high-voltage trap. The latter has two stages, the plates being cross-connected to give zero deflection for a small voltage (Gábor). These connections are made by resistances, from the mid-points of which the external connections are taken. The pairs of plates are thereby prevented from oscillating "against each other" when the beam-trap is discharged. The plates of each pair are 19 × 50 mm, and are 19 mm apart. Measuring from the bottom of the anode we have at 5·9 cm the centre of the first pair, at 16·2 cm a diaphragm of aperture 3·6 mm, at 31·5 cm another diaphragm of 6·3 mm, at 37 cm the centre of the second pair, at 51 cm an 8-mm diaphragm, and at 70 cm the limiting diaphragm (6 mm). The trapping of electrons is believed to be absolutely complete at 1 500 volts.

(5) Time-Sweeping Circuits.

It was decided from the outset that the spark which released the beam from its trap and initiated the time-sweeping movement should be tripped automatically by the impulse under investigation, and not vice versa. The sweeping movement is of course obtained by the discharge of a condenser through a resistance or a saturated valve. In making their choice from the great variety of possible arrangements the authors were guided by the following considerations:—

(1) The circuit must be tripped by a conductively conveyed impulse of either polarity, as quickly as possible. The voltage and quantity of electricity necessary in the impulse should be as small as possible.

(2) It is most important that the time scale should not be distorted by currents flowing in the leads which convey the tripping impulse. Such distortion may arise either through inductive coupling of the trip and sweep circuits, or through impedance or a spark-gap common to both.

(3) For some kinds of work, tripping must occur even with quite a slow voltage-rise. In this case also the charge required should be small, and preferably should not alter the potentials of the sweep-plates before tripping.

(4) In high-speed work it is desirable that the sweep deflection-plates should be equally and oppositely charged with respect to the earthed metal tube of the oscillograph, otherwise the focus of a beam of large angular divergence is impaired.

(5) For the same reason the common potential of the beam-trap plates during the exposure should be that of earth.

(6) The spot must be prevented from retracing slowly over the film when the condensers recharge after the exposure.

In order to obtain amphipolar tripping the impulse must be made to affect the voltages across two spark-gaps simultaneously and in opposite senses. There are two types of circuit arrangement, according to whether the gaps are in series (Fig. 3*a*) or in parallel (Figs. 3*b*, 3*c*) with respect to the impulse leads. In these diagrams the various poles of the spark-gaps are supposed to be given the indicated initial voltages by connection through very high resistances to sources of the required potentials. The circuits as shown are suitable for a tripping impulse taking the form of a variation of the potential of a single wire with respect to earth. Such arrangements are the most generally useful; in special cases where the electrification of the trip circuit is initially symmetrical and must be maintained so at every instant of time, the symmetrical analogue of Fig. 3*c* or, better, that of Fig. 3*b*, must be employed. In these circuits the two spark-gaps are separated.

* In this connection see Rühlemann [Bibliography, (12)].
† See Bibliography, (13).
‡ *Ibid.*, (14).
§ See, for example, Bibliography, (15, 16, and 17).
‖ See Bibliography, (18).
¶ For this purpose Boekels [see Bibliography, (19)] puts one pair of plates above the 1-mm diaphragm, i.e. effectively in the discharge tube.

The series arrangement, Fig. 3(*a*), is distinguished by the fact that only one spark-gap responds, but it has the great disadvantage that during the passage of the spark the currents in the impulse lead flow to earth not only through the idle resistance and the spark-gap, but also through the sweep condenser C. The latter circumstance, in particular, not only introduces a small capacitative coupling between the sweep and trip circuits, but also makes it difficult to avoid a considerable magnetic coupling. Further, the sensitivity is low, since only half of the impulse voltage is applied to a gap carrying the full sweep voltage, and the impulse has to charge up the stray capacitance to earth of the condenser. In addition, when the gap XY responds requirement (5) is not satisfied.

When the gaps are in parallel with respect to the impulse lead the response of either gap throws overvoltage on the other, which therefore breaks down immediately afterwards. There are three possibilities, according to whether the sweep current flows through the gap which short-circuits the impulse, or the other, or both in series. The second alternative (Fig. 3*b* with the impulse applied to sphere X) has the advantage of giving very complete decoupling. The sensitivity is fair: the impulse has to charge up the stray capacitance of the auxiliary condenser C′; the full impulse voltage is applied to XY, but YZ receives a fraction $R/(R + r)$ only. Each gap carries a voltage equal to the sweep

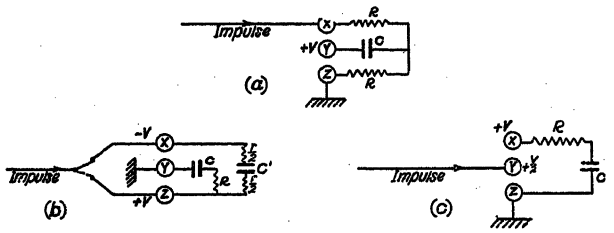

FIG. 3.—Amphipolar trip circuits.

voltage. The resistances $r/2$ must be included, to prevent oscillatory discharge of C′. When the sweep current flows through both gaps we have the familiar circuit of Fig. 3(*c*) in which the impulse current passes through one of the gaps. The full impulse is now applied to gaps carrying only half the sweep voltage. The stray capacitance to be charged is very small, and there is no shunting impedance, so that a steep-fronted impulse having a " tail " a few metres long will be doubled by reflection.

For a slow voltage-rise Fig. 3(*c*) is obviously the most suitable, and the authors accordingly adopted it. The importance of a symmetrical electrification of the sweep-plates was forced on them by preliminary experiments; with a beam of angular diameter 0·027 radian, a deflection of 2 cm, one sweep-plate being earthed, converted a fine spot into a patch several millimetres in diameter. Fig. 7 shows the effect with the beam stopped down to 0·009 radian; one plate was earthed and the potential of the other varied from zero at the beginning to 3·5 kV at the end of the record. In Figs. 8, 9, and 10 the sweep-plates were symmetrically electrified, with the result that the focus remained unimpaired by the sweep deflection. As regards the transient deflection, in electrotechnical work, of course, one usually wishes to work with one plate earthed, and all the authors' photographs have been taken in this way. That this does not give rise to appreciable loss of focus in their instrument is probably due to the fact that the transient deflection plates are closer together than the sweep-plates, and therefore the end-effects are less important.

Symmetrical electrification of the sweep-plates is not easily arranged if the condenser discharges through a valve, and therefore the authors preferred to use resistances. The complete sweep circuit, with which the oscillograms of Figs. 8, 9, and 10 were obtained, is

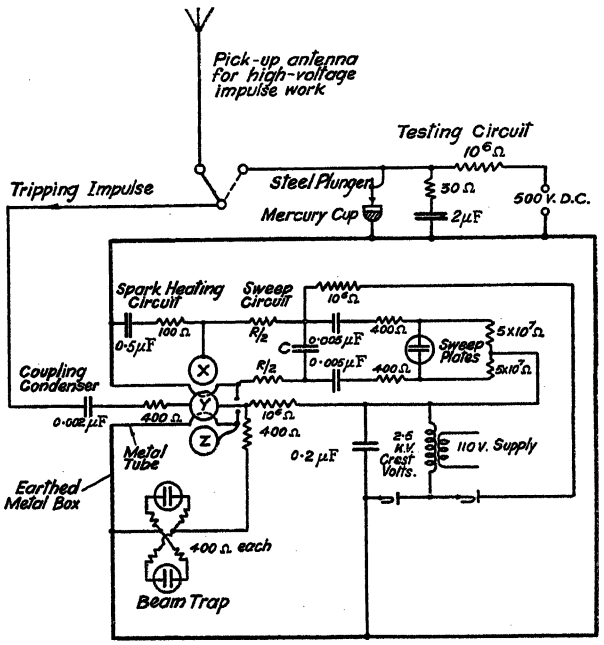

FIG. 4.—Complete sweep circuit.

shown in Fig. 4. As in Fig. 3(*c*), one pole Z of the gap is directly earthed; this is not essential, but was done to ensure the satisfaction of requirement (5). When the sparks occur, the common potential of the sweep-plates, which was previously 2·5 kV, jumps to zero. At the end of the exposure the plates have potentials + and − 2·5 kV. This plan makes it possible to arrange that the final position of the spot shall be a long way off the film, that is the time scale nearly linear, without the use of powerful opposed electric and magnetic deflections, which, the authors found, slightly impaired the definition at the beginning, even with symmetrical electrification.

The resistances in the sweep and beam-trap circuits must of course have such values that the discharge of these circuits is non-oscillatory. When this is the case, distortion of the time-scale can only arise from oscillatory currents flowing in the trip circuit. When the e.m.f. which provides the tripping impulse is non-oscillatory, only free oscillations are possible, and these can be prevented by including in the trip lead, close to the middle sphere, a resistance equal to the surge impedance of the lead. In practice, however, the tripping e.m.f. is often itself oscillatory, and, moreover, several

times stronger than is strictly necessary; and forced oscillations of course cannot be wholly suppressed. Since the oscillatory currents are superimposed on the sweep-current through one of the spark-gaps, they may, if of large amplitude, momentarily reduce the current through it to zero. The resistance of the spark then rises, and does not again become low until an appreciable quantity of electricity has passed. To guard against this, the well-known device is employed of passing through the spark-gaps, in addition to the sweep current, a large unidirectional heating current from an auxiliary condenser and resistance. But fluctuations in the resistances of the sparks seem to be less important as sources of time-scale distortion than inductive coupling between the trip and sweep, or trip and beam-trap circuits, and the authors were unable to obtain undistorted oscillograms until they took special precautions to reduce these mutual inductances. They could, of course, theoretically be made zero by a suitable disposition, but the authors preferred simply to make them very small by constructing the spark-gap as shown.

There is one case in which, although the tripping e.m.f. is non-oscillatory and of moderate magnitude, the suppression of free oscillations in the trip circuit is quite indispensable. This is when the impulse is conductively derived from a spark-gap, e.g. the 500-volt testing spark shown in Fig. 4. If resistance is omitted the current builds up, by repeated reflections at the ends of the trip line, to a very large amplitude, and then executes protracted quasi-stationary oscillations at the frequency determined by the capacitance of the coupling condenser and the whole inductance of the trip circuit.

Requirement (6)—no retracing—can be fulfilled in various ways. One of the simplest is to connect the sweep-plates across the resistance instead of the condenser.* This, however, is undesirable, since it immediately introduces into the time-scale any momentary fluctuations of the sweep current. Rogowski† uses a relay mechanism which retraps the beam by magnetic deflection. One way of dispensing with a relay, which the authors have used successfully, consists in connecting the beam trap across the spheres XZ; and using a rather small spark-heating condenser ($0{\cdot}05\,\mu$F.). With suitable resistances one can then arrange that the sparks go out when the potentials of the condensers have fallen to a value—say 2 000 volts—which is still sufficient to operate the beam trap. The authors prefer, however, the method shown in Fig. 4. The beam trap is connected across the spheres YZ, and when the sparks go out it recharges before the potentials of the sweep-plates have changed appreciably.‡

Much has been written about the time-lags of spark-gaps in responding to sudden applications of voltage, and the effect thereon of surface contamination. It has been stated§ that a sphere-gap freshly polished with clean carborundum paper will respond within less than 10^{-8} sec., even in the absence of ionizing radiations. The authors have not been able to obtain reliable results with this or any polishing method alone, but they obtain satisfactory results by the well-known device of irradiating the gaps with a quartz mercury lamp, when this is placed a few inches away. Response occurs regularly to a 500-volt impulse of either polarity with a time-lag which very seldom exceeds $0{\cdot}2$ microsecond. Some hundreds of sparks can take place before any adjustment is necessary. In high-voltage impulse work the tripping impulse is picked up by a small antenna. For testing purposes and for low-voltage experiments, the trip lead is connected to a steel rod and also through

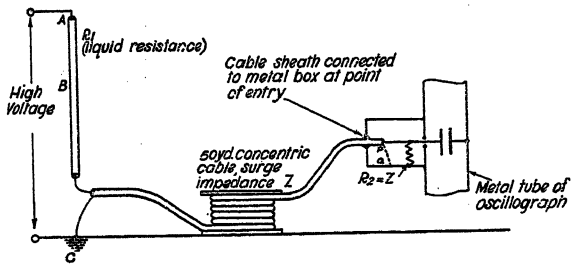

FIG. 5.—Resistance potential divider and screening arrangements.

a high resistance to a 500-volt supply. Plunging the rod into an earthed mercury cup then provides the tripping impulse, and may also simultaneously initiate a 500-volt transient in any desired apparatus connected between the rod and the mercury. The arrangement is shown in Fig. 4; it will be seen that a " heating " current is provided for the spark at the mercury cup.

(6) POTENTIAL DIVIDER.

The measurement of high-voltage transients of course requires a potential divider to tap off a few hundred volts

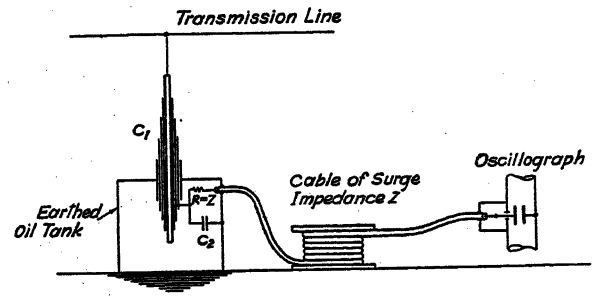

FIG. 6.—Simple potential divider for transmission-line recording.

for the oscillograph. Following Gábor, the authors connect the potential divider to the oscillograph by a rubber-insulated concentric cable which is long enough (50 or 60 yards) to delay the arrival of the impulse at the deflection plates until after the sweep circuit has tripped, thereby ensuring that the start of the impulse is recorded. For high-speed work with laboratory impulse generators, a resistance potential divider is usually satisfactory; but where the transient is superimposed on a power voltage, as in transmission-line work, condensers must be included. Fig. 5 shows Gábor's circuit for a resistance potential divider, while Fig. 6

* See Bibliography, (20). † *Ibid.*, (21).

‡ Boekels [see Bibliography, (19)] has also arrived at this principle. The modification which he adds to it in his Fig. 13 would be applicable even if the circuit contained only one spark-gap, and so represents yet another method, and he describes still another, due to Rogowski, in which the beam retraps itself by an arrangement of Faraday cylinders.

§ See Bibliography, (22).

shows the simplest arrangement for transmission-line recording. The division of voltage is effected by two capacitances C_1 and C_2 in series. C_1 may be a condenser bushing; C_2 is a low-voltage condenser having a very much greater capacitance than the delay cable. For transmission-line work at the highest speeds resistances and condensers must be used in combination; such an arrangement was given by Gábor. Improved potential-divider circuits have been discussed elsewhere.*

(7) Screening.

Since the oscillograph is situated only 6 yards from the impulse generator, very effective screening has been necessary. Indeed, the induced e.m.f.'s were at first so strong as not merely to distort the oscillograms hopelessly but even to break down the insulation of parts of the apparatus. The circuits have been enclosed in boxes of $\frac{1}{16}$ in. sheet steel, whereby also the magnetic fields of the control resistances are prevented from affecting the beam. A point in connection with the screening of the voltage-deflection circuit is worthy of special mention. Referring to Fig. 5, when the high-voltage applied to the potential divider, that is, the line integral of electric force down ABC, rises from zero and fluctuates in any manner, a wave enters the cable, establishing a potential difference between core and sheath which is a correct small-scale reproduction of these fluctuations. Independently of this, a wave also travels along the outside of the cable sheath; one may say loosely that both core and sheath together are raised in voltage by the fluctuating magnetic fields in the region between the cable and earth. If the deflection plates (and the resistance which shunts them in the circuit of Fig. 5) had no capacitance to earth, the currents flowing on the outside of the cable sheath would be of no consequence; it would be sufficient simply to connect the deflection plates and shunting resistance across the cable without any "earthing" of the sheath at the oscillograph or other special precautions. Actually, however, each deflection plate has capacitance to the metal tube of the oscillograph comparable with the capacitance between the two plates. In order to ensure that the voltage between the plates is determined only by the wave of voltage between core and sheath which is applied at the input end, it is therefore necessary that the cable sheath should in effect be made an integral part of the metal tube of the oscillograph, core and deflection plates forming a screened system, as shown in Fig. 5. How essential it is that this should be properly done is shown by the fact that it was found to be unsatisfactory to bring the sheath of the cable into the metal box in an insulated manner and then connect it to the box by a wire PQ a few inches long. This procedure introduced quite large spurious e.m.f.'s. So long as the screening is properly carried out, it is in practice immaterial whether or not the tube of the oscillograph is "earthed" directly, as well as through the cable sheath; such an extra "earth" cannot affect the correctness with which the line integral of force down ABC is measured, though it will, no doubt, slightly affect this line integral itself.

To check the efficacy of the screening the authors carried out various tests, notably one in which R_1 was disconnected from the cable and earthed, and the sheath of the cable at the potential-divider end was connected to the core and metallically sealed over it and also earthed. With a cable in which the sheath consisted of an open-mesh braiding, small residual e.m.f.'s

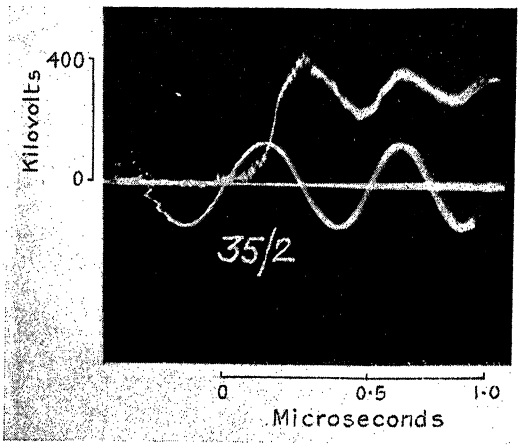

Fig. 7.—Impulse wave with oscillations. Loss of focus due to asymmetrical deflecting field.

remained, but these disappeared when lead-covered cable was substituted.

It is of interest to note that the authors were able to take undistorted oscillograms of the open-circuit wave of the impulse generator before the high-voltage circuit supplying the cathode was screened at all. No doubt

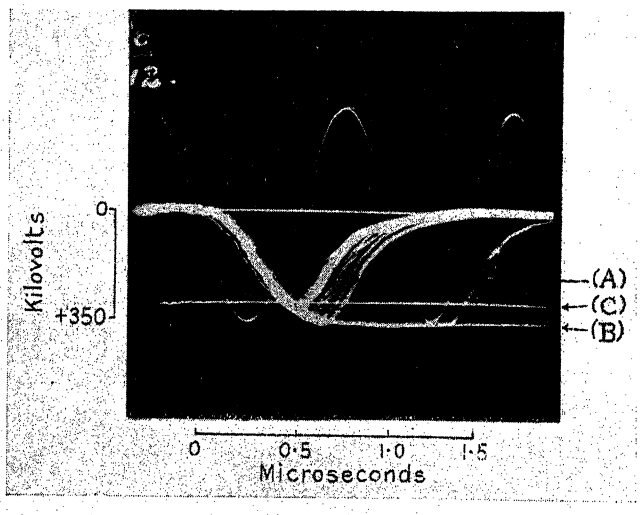

Fig. 8.—13 impulses applied to a sphere-gap set at 82 per cent spark-over.

the most violent induced e.m.f.'s had subsided before the transient had traversed the delay cable (0·4 microsecond).

(8) Performance.

Fig. 7 shows the voltage across a 75-cm diameter sphere-gap, opened too wide for spark-over, when supplied with a 350-kV wave from the impulse generator. It will be seen that the voltage rises above this figure,

* See Bibliography, (24).

reaching a maximum of 400 kV and oscillates. This is to be expected, and has been observed by others.* The wavelength of the oscillations, about 120 metres, is, of course, approximately four times the total length of the conductors forming the high-voltage circuit, plus a slight increase due to the capacitance of the sphere-gap. In Fig. 8 these oscillations have been suppressed

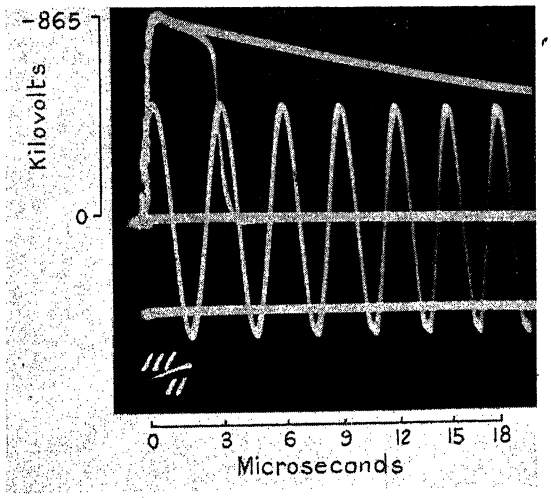

FIG. 9.—Impulse breakdown on a 31-in. point-rod gap.

by including resistance between the impulse generator and the sphere-gap. For this illustration the sphere-gap was first set so that it sparked over for 82 out of 100 applied impulses. Oscillograms of 13 successive impulses were then recorded on the same film. It will be seen that the gap did not always break down at the same

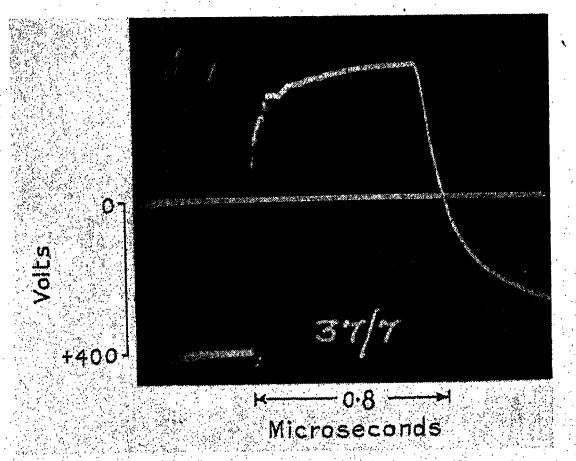

FIG. 10.—Cable discharge wave.

point on the wave, indeed in one case (A) breakdown was delayed until about 0·7 microsecond after full voltage had been attained, while in another case (B) spark-over did not occur at all. The line C is a voltage-calibration line. The coincidence of the wave-fronts in this photograph illustrates the regularity of behaviour both of the trigger-gaps in the impulse generator and of the spark relay in the sweep circuit of the oscillograph. Fig. 9 shows the behaviour of a 31-in. gap between a negatively charged point and an earthed length of channel iron. A 1 000-ohm resistance was included in the high-voltage lead to the point. Two impulses were applied, one of which caused breakdown after a lag of 3 microseconds, while with the other breakdown did not occur.

The application of the oscillograph to low-voltage work is illustrated by Fig. 10, which shows the discharge wave at 400 volts, of 60 metres of 3/·029 in. single-core lead-covered cable, i.e. the voltage at the open end when the other is suddenly short-circuited, the cable being connected to the mercury-cup switch shown in Fig. 4.

In ease and reliability of working the equipment is very satisfactory; over 1 400 oscillograms have been taken. The operator sits in a chair and has all the essential controls within easy reach. He has so little to do that the production of a completely automatic mobile recording instrument, an aim which has been kept in mind throughout, would present no real difficulty.

(9) ACKNOWLEDGMENTS.

The authors have great pleasure in thanking the Metropolitan-Vickers Electrical Co., Ltd., for permission to publish this paper, and Mr. A. P. M. Fleming, C.B.E., Director of Research, Mr. G. McKerrow, Mr. B. L. Goodlet, and many others of their colleagues, for their constant help and encouragement. Dr. T. E. Allibone, especially, gave a great deal of very valuable advice.

(14) Construction.
(15) Tie bank connections.
(16) Industrial development.
(17) Acknowledgment.

(1) INTRODUCTION.

Probably in no other country has the development of hydro-electric power advanced so rapidly as in Canada. The figures issued by the Bureau of Statistics for the year 1930 show that more than 6 million horse-power is now in use in the Dominion, compared with 2½ million horse-power in the year 1919. Further developments are rapidly taking place and big construction schemes, which will materially increase the existing horse-power harnessed, are now in hand. Projects which when investigated some 20 years ago were reported on as unfavourable are now being developed into big hydro-electric power plants and render practicable a constantly increasing area of possible development.

The amount of capital invested in Canada's hydraulic installations has been the subject of intensive study, and the Dominion Water Power Bureau states in its latest bulletin that this investment amounts to almost 1 390 million dollars. Of this amount, 1 168 million dollars, or over 84 per cent, have been expended on lands, buildings, plant, and equipment. This is greater than the capital investment of any other manufacturing industry in the Dominion. The total amount of power installed has grown from 890 000 h.p. at the beginning of the year 1910, to 6 125 012 h.p. In addition, we find that the capacity of central electric stations has grown from 586 502 h.p. to 5 214 336 h.p., and pulp and paper installations from 115 042 h.p. to 579 826 h.p. in the same period.

The capacity of the hydraulic installations of the Dominion now averages 617 h.p. per 1 000 of the population, a figure which places Canada in an outstanding position among the waterpower-using countries of the world.

(2) POWER PRODUCTION.

One of the foremost in the field of hydro-electric power production is the Southern Canada Power Co., Ltd. In the year 1914 the output of this company totalled 4 640 000 kWh, whilst the figures for the year 1930 show an output of 170 865 947 kWh, which is a typical example of the progress made by Canadian hydro-electric power companies.

The company owns and operates five power houses on its system, having an aggregate capacity of 60 000 h.p.; and undeveloped sites throughout the system allow for further development to the extent of 147 000 h.p.

The high-tension transmission lines of the company extend over 463·3 miles, and the distribution lines over 578 miles, the area of supply being approximately 6 000 square miles. The number of municipalities served is 118, and the number of consumers connected is 26 594. The rating of the installed motors amounted for the year 1930 to 45 602 h.p. In addition, the company operates its own telephone system, comprising 423·4 miles of telephone lines.

(3) POWER HOUSES.

The power houses are situated at various points throughout the system. Fig. 1 shows the location of these plants, together with details of the transmission lines and the municipalities served.

On referring to Table 1, giving particulars of the various power houses, it will be seen that the largest of the plants is situated on the St. Francis River at Hemmings Falls.. The capacity of this station is 36 000 h.p., and some details of its construction are given later.

Next in order, we have the Drummondville power house. This is also situated on the St. Francis River, approximately 3 miles down stream from the Hemmings Falls station, and its capacity is 18 000 h.p.

Then comes the Sherbrooke power house of 4 000 h.p. capacity, this station being situated on the Magog River at a point only a few hundred yards upstream from where this river joins the St. Francis.

The next power house is at Burroughs Falls, where a semi-automatic plant of approximately 2 000 h.p. operates under a head of 175 ft. This plant is the company's latest acquisition and was only brought into service during the latter part of 1930.

Finally, we have the Farnham plant of 800 h.p. capacity on the Yamaska River.

With the exception of the Burroughs Falls plant which operates under a head of 175 ft., the heads of water do

* The Papers Committee invite written communications, for consideration with a view to publication, on papers published in the *Journal* without being read at a meeting. Communications (except those from abroad) should reach the Secretary of the Institution not later than one month after publication of the paper to which they relate.

not exceed 55 ft., with the result that the speeds of the machines are low. The hydraulic works vary in design. Hemmings Falls and Drummondville have forebays in the immediate vicinity of the power houses, whilst Sherbrooke and Burroughs Falls are constructed with penstocks. At the Farnham station the water is brought to the machines by canal.

The four alternators at the Drummondville power house are of standard welded-steel design, and are equipped with Kingsbury bearings. Two of these alternators are of Canadian Westinghouse manufacture and are designed for 3 125 kVA at 2 300 volts, 3-phase, 60 frequency. The excitation for these machines is provided by a water-wheel-driven generator rated at 100 kW, at 125 volts. As a standby in case of breakdown, an emergency 150-h.p. motor-generator is also installed. These two alternators are connected to the 2 300-volt busbars, which in turn are connected to No. 1 transformer bank, which consists of three 2 300/48 000-volt 3-phase 3 000-kVA transformers, which feed the high-tension transmission line.

The other two machines are of Canadian General Electric manufacture and are designed for an output of 6 000 kVA at 4 000 volts, 3-phase, 60 frequency. The excitation for these machines is provided by direct-coupled exciters, rated at 100 kW at 125 volts, mounted on the top of the main shaft. These machines are connected to the 4 000-volt busbar which supplies the factories in Drummondville operating at this voltage. Connection is also made to No. 2 transformer bank consisting of three 2 000-kVA 4 000/48 000-volt 3-phase transformers, which feed a second high-tension transmission line.

The two transformer banks are housed inside the power house, and are of the water-cooled type. The control is effected on the high-tension side by remote-control, oil-immersed switches operated from the switchboard. The station itself is supplied from the 2 300-volt busbar through a separate transformer bank, and lightning protective devices are installed inside and outside the power house on the high-tension transmission lines.

The electrical equipment at Hemmings Falls consists of six alternators designed to give 6 000 kVA, 3-phase, at 60 frequency. Two of the machines were originally wound for a frequency of 30 cycles per sec., owing to the fact that they were used solely for supplying power to the Shawinigan Co. which was operating its system

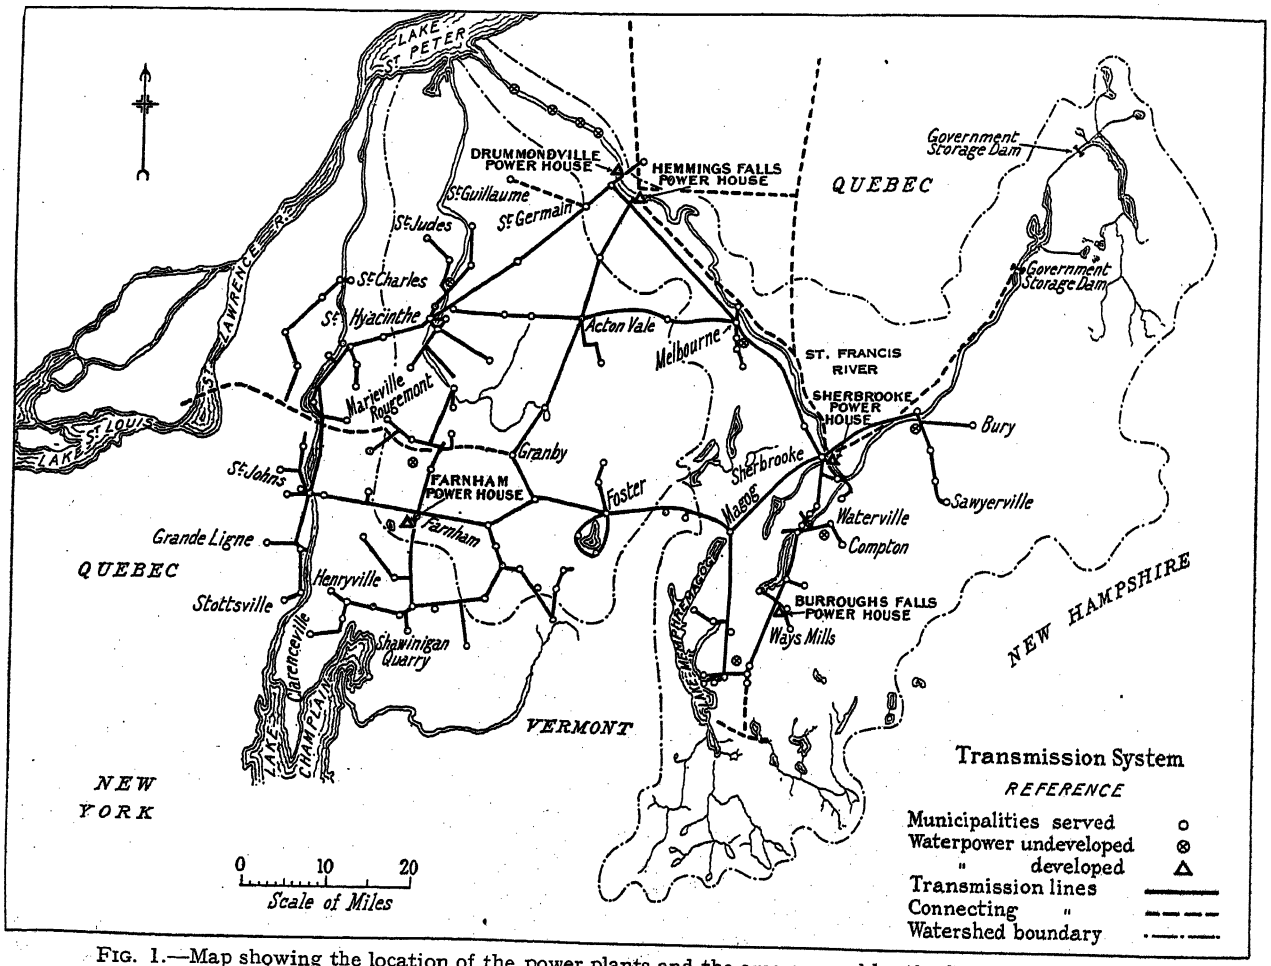

FIG. 1.—Map showing the location of the power plants and the area covered by the Southern Power Co.'s transmission lines.

at that frequency. The Shawinigan Co. has now converted its supply to 60 frequency, and on the completion of the tie bank with this company at Hemmings Falls, the two machines were rewound to correspond to the other four. Further details regarding this tie bank with the Shawinigan Co. will be found later in this paper.

(4) Automatic Power Station.

In September 1930 the Southern Canada Power Co. put into operation its new automatic installation at Burroughs Falls. This plant operates under a head of 175 ft. at a speed of 600 r.p.m., and supplies power at 2 300 volts, 3-phase, 60 frequency. The turbine is of the horizontal variety and was manufactured by Messrs. Morgan Smith & Co., Ltd. The generator, which is a standard welded-steel structure, is of Canadian General Electric manufacture, the governor mechanism being Woodward automatic and oil-operated.

The machine is set in motion by pressing a control button located on the switchboard. This sets the governor mechanism in motion, and, as soon as the machine reaches synchronous speed, the station operator parallels the machine on to the busbars. Thermo-couples are inserted at various points throughout the windings and, in the event of the machine becoming too hot, relays trip the generator switch; at the same time an auxiliary relay in connection with this shuts down the governor mechanism and the entire plant comes to a standstill. In addition to the thermo-couples in the windings, bearing temperatures are looked after in the same way. Over-speed and overload protection are also provided for, relays being incorporated in each of the circuits. As soon as the machine is tripped off the busbars owing to the operation of any of the protective devices, an alarm bell begins to ring.

The power house is a small, brick building on a concrete substructure. The dam is a gravity-type, reinforced concrete structure and is flanked on one bank of the river with an earth-filled dam having a concrete core wall. At its highest point the dam is 68 ft. high, exclusive of the height of the sluice-gate towers.

Out of a total length of 490 ft., 140 ft. is accounted for by the earth-filled dam, 55 ft. by the sluiceway section, and 90 ft. by the spillway, while the concrete wing walls and intake section make up the balance. Over 11 000 cubic yards of concrete were poured into the dam. The flood discharge capacity of the sluicegate and spillway is 8 000 cubic ft. per second, corresponding to 136 cubic ft. per sec. per square mile of drainage area.

The penstock intake has been placed 23 ft. below high water-level to allow a draw-down of 20 ft. from the pond. The head-gate is made of wood and is manually operated by means of a screw hoist and a reduction unit. Two 14 ft. × 20 ft. sluice-gates complete the hydraulic works at the dam. These gates are electrically operated by a single motor, which can be connected to the gear drive of either gate by means of a clutch. The motor is controlled by two push-button stations at convenient points. In addition, the gates are equipped with heaters to facilitate their operation during the winter.

Tests were carried out prior to the machine being put into operation, in order to determine the overall efficiency of the unit, also to make a check upon the friction loss in the intake and pipe line, and to establish curves for recording the permanent stream-flow.

Table 1.

Data Relating to the Power Houses of the Southern Canada Power Co.'s System.

Location, river, and h.p.	Head, ft.	No. of machines	Speed, r.p.m.	Prime movers	Make	Governors	Generators
Hemmings Falls, St. Francis River, 36 000 h.p.	55	6	150	Vertical turbines	Dominion Eng. Co.	Pelton	6 000 V 60 ~ 6 000 kVA
Drummondville, St. Francis River, 18 000 h.p.	30	4	150	Francis type runners	Dominion Eng. Co.	Woodward Pelton	(2) 2 300 V 3 125 kVA (2) 4 000 V 6 000 kVA 60 ~
Sherbrooke, Magog River, 4 000 h.p.	55	3	360	Horizontal turbines	Canadian Boving Co.	Lombard	2 300 V 60 ~ 940 kVA
Burroughs Falls, Nigger River, 2 000 h.p.	175	1	600	Horizontal turbines	Morgan Smith & Co.	Woodward automatic	2 300 V 60 ~ 2 000 kVA
Farnham, Yamaska River, 800 h.p.	26	2	277	Horizontal turbines	Swedish Boving Co.	Oil (Swedish Boving Co.)	2 300 V 60 ~ 300 kVA

The power of the turbine and generator was measured at the generator terminals by using a Weston calibrated wattmeter, which was connected to the switchboard instrument-transformers. The readings of the switchboard wattmeter, as well as of the ammeter and voltmeter, were recorded, the unit being run in parallel with the system throughout the test.

The head-water elevation at the dam was read on a gauge-board installed near the intake. The water-level at the turbine inlet was obtained from a pressure gauge which was connected to a brass pipe tapped into the penstock 6 in. upstream from the face of the butterfly valve, this being about 10 ft. upstream from the centre-line of the turbine. The area of the pipe at this point was 7·9 sq. ft., the pipe being 42 in. in diameter, and the butterfly wicket in the full-open position being 6 in. thick by 42 in. wide.

current. The distance from the upstream face of the trash racks to the electrode was found to be 2 198 ft. Inside measurements of the diameter of the wooden stave-pipe showed it to be within $\frac{1}{16}$ in. of 5 ft. average diameter, giving a total volume between the trash racks and the electrode of 43 000 cubic ft. The quantity of water flowing per second was obtained by dividing 43 000 cubic ft. by the time in seconds for the salt to pass from the intake to the electrode.

Water measurements were made at different gate-openings on the governor. Readings were taken of the head water, tail water, and pressure gauge in the penstock, with the unit shut down in order to establish zero readings; then the unit was started up and run at no load and normal speed, further readings of the pressure gauge and tail water being taken.

The unit was then paralleled with the system, and

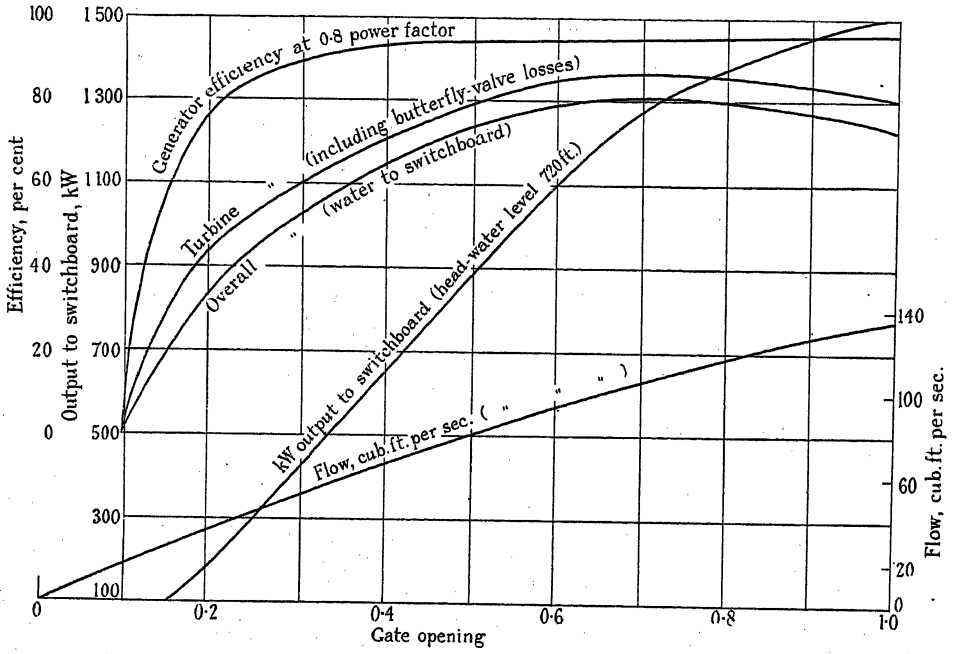

FIG. 2.—Curves showing turbine efficiency at various gate openings.

The quantity of water required for different loads was obtained by recording the time required for a dose of salt to travel down the wooden stave-pipe from the face of the racks to an electrode installed at the lower end of the stave-pipe, just upstream from the surge-tank. A specially-designed bucket containing the salt was lowered into the forebay, just upstream from the trash racks. This bucket was suspended by a rope, and at a given signal a second cord attached to pieces of 10-in. pipe forming the sides of the bucket was pulled, leaving the top and bottom of the bucket stationary and allowing the water to force the salt solution into the upstream end of the pipe.

The electrode consisted of two bars of $\frac{1}{4}$ in. × 2 in. strap iron, supported by insulators and spanning the 5-ft. diameter penstock, an electrical connection being brought out from each bar to a recording wattmeter. The instrument was connected to the 110-volt lighting circuit, with a fixed resistance in series to limit the loaded up to full or 10/10 gate. The bucket was then immersed in the water at a point approximately in the centre of the face of the trash racks, and at a given signal the release cord was pulled. At the same time the starting point was marked on the recording chart of the wattmeter, and readings were taken of head-water level behind the racks, also of the pressure gauge, the wattmeter at the power house, and the tail-water level. At full load it required about $5\frac{1}{2}$ minutes for the salt to pass from the intake to the electrode. Several readings were taken for different gate openings.

The turbine efficiency at the various gate openings is shown in Fig. 2. It includes the loss through the butterfly valve, as it was impossible to get a pressure-gauge connection downstream from the butterfly valve on account of the turbine casing being concreted in. The results show the efficiency, including the butterfly-valve loss, to be 87 per cent. The turbine is guaranteed to give 87 per cent efficiency at approximately 90 per cent

or full load, and also to deliver 2 000 h.p. to the turbine shaft under 165 ft. head. A rough estimate shows that the butterfly-valve losses are in the region of ½ to 1 per cent.

The total friction loss in the length of 2 549 ft. of 5-ft. diameter pipe, comprising 2 177 ft. of wooden pipe and 318 ft. of steel pipe, varies from 5·3 ft. to 0·6 ft. at different flows, this corresponding to a coefficient of friction of between 130 and 140 in Hagen and Williams' tables.

Lake St. Francis station is located 1 000 ft. downstream from the Allard dam at the outlet of Lake St. Francis. The drainage area is 472 square miles. The discharge is measured with a Price current meter, a steel cable being stretched across the river at this point. The gauge readings varied over a period of three years from 193 cubic ft. per sec. at elevation 89·8 ft. to 2 800 cubic ft. per sec. at elevation 94·8 ft. The section of the river at this point is about 150 ft. wide, and the river flow is controlled by the Allard dam.

Sherbrooke station, on the River St. Francis, has a drainage area of 2 626 square miles. Meter readings over three years show a variation in the flow from 763 cubic ft. per sec., for a gauge reading of 0·9, to 20 735 cubic ft. per sec. for a gauge reading of 14·65 ft. The discharge is partly controlled by the Allard and Lake Aylmer dams. The flow curve shows a flow of less than 8 000 cubic ft. per sec. Above that figure the curve is affected by the backwater of the River Magog, which flows into the River St. Francis about ¼ mile below the station.

(5) Hydraulic Works.

The biggest of the power plants on the system at the present time is that at Hemmings Falls on the St. Francis River. The works includes a regulating pond extending some 6 miles up the river. The use of this pond will be very beneficial and will affect future developments below it.

The tributary drainage area is 3 720 square miles and includes a number of lakes of considerable size which are available for storage purposes. Storage facilities have already been provided by the Quebec Government through the agency of the Quebec Streams Commission at Lake St. Francis and Aylmer. There are also privately-owned dams and outlets at Lakes Memphremagog and Little Magog. These, together with others at Brompton Lake and Lake Massawippi, have still to be developed, and it is expected that the St. Francis River will ultimately be controlled to the extent that there will be a reliable flow of 3 000 cubic ft. per sec. The positions of these lakes can be seen from Fig. 1. The flow-duration curve for the year 1925 showed that with the existing storage the flow is maintained at or above 3 000 cubic ft. per sec. during 307 days in the year.

The Hemmings Falls development was started in the year 1923. The power station is situated 2½ miles above Drummondville, at a point where a 15-ft. fall terminates a series of rapids, in which there is a total drop of 50 ft. in a 5-mile stretch of river. The river banks and bed were found to be very favourable at this point and a scheme was adopted consisting of a north wing wall, power-house section, sluice-way section, spillway, and a south wing wall, together with an isolated earth-filled dam. Records for 22 years prior to 1926 show that the flood flow of the St. Francis River was not in excess of 55 000 cubic ft. per sec. It was assumed that a possible run-off of 25 cubic ft. per sec. per square mile is a conservative estimate, and on this basis four 50-ft. sluiceways were provided at an elevation of 299 ft. above sea-level and, in addition, a spillway 507 ft. long, with crest elevation 314 ft. This spillway was provided with facilities for installing temporary flash-boards 5 ft. high, which would permit the head-race water-level to be raised to an elevation of 319 ft. during seasons of low flow. With water at this level, each sluiceway has a discharge capacity of approximately 20 750 cubic ft. per sec., and three or four sluiceways could easily handle the maximum recorded flow. The proposed water-levels were at an elevation of 314 ft. for the head-race and of 264 ft. for the tail-race, giving a gross head of 50 ft.

The spillway section was calculated to resist an ice pressure of 20 000 lb. per linear foot, acting on a line 1 ft. below the crest, plus a hydrostatic pressure corresponding to that condition. This requires a heavier section than is needed to resist water pressure up to an elevation of 321 ft., which would be equivalent to 2 ft. of water running over the top of a 5-ft. flash-board. For the sluiceway section, the crest of which is lower at the elevation 299 ft., the basis of design was water at the elevation 321 ft. with no ice pressure, but allowance was made for ice pressure on the sluiceway piers. These were calculated to resist the pressure transmitted to

Table 2.

Variations in Monthly Flow and Kilowatt Output.

Month (1930)	St Francis R.	Magog R.	Yamaska R.	Total	Daily av. flow	Output*	Daily average

* The total kWh output shown represents the total generated.

them by the gates, plus the direct pressure on the piers caused by water at the elevation 321 ft. In addition, they were to resist 20 000 lb. ice pressure per foot width of pier acting at the elevation 320 ft.

The sluiceway section between the piers and below the gate was calculated to resist the pressure of water up to the elevation 321 ft., or 22 ft. above the crest. The sections were all developed as gravity sections, but to overcome the uncertainties in construction, and unavoidable joints between batches, vertical reinforcing steel was placed near the upstream face. Since the positions and numbers of the horizontal batch joints could not be foretold, this reinforcement was made continuous.

Owing to the existence of seams of shale at certain points, two rows of $1\frac{3}{4}$ in. diameter anchor rods, running approximately 10 ft. into the underlying rock, were inserted at the heel of the dam to complete an efficient anchorage.

Between the first sluice-gate and the south end of the power house a log and trash chute with stop-logs was provided, 6 ft. in width, and with a bottom elevation of 310 ft., which corresponds to 4 ft. below the crest of the spillway. Below the log chute is a 7-ft. diameter regulating sluice, with its centre at the elevation 301 ft., and provided with an electrically operated pivot valve controlled from the power house. The idea of this is to provide a means of quickly letting through approximately 1 000 cubic ft. of water per sec. in the event of a sudden shut-down of the turbines at a time when, with sluice-gates closed and flash-boards in position, the plants lower down the river would be depending upon the flow of water through the Hemmings Falls plant.

The sluice-gates are of the Stoney roller type, 22 ft. high, with a clear opening 50 ft. wide. Four screw-hoists, with individual motors mounted on an overhead steel structure, operate the four gates. Automatic limit switches guard against over-travel when opening or closing the gates. The gates are provided with electric heaters to allow of their operation during the winter months, and a patent air-bubbler system has been installed for the purpose of keeping the ice sheet from bearing on the gates. This has proved effective, and, in addition, it also prevents the ice from forming in the vertical seal. The velocity of water at the racks is approximately 1·4 ft. per sec., and at the head-gate section 2·7 ft. per sec. The draught tubes are of the Moody spreading type with concrete cones provided with cast-iron caps. The tail race is 500 ft. long and has a minimum section of 1 845 sq. ft. below the elevation 264 ft. It is designed for a velocity of 4 ft. per sec. with water at that elevation and full load on all six units.

(6) Operation.

The entire system is controlled from the offices of the operating department in Drummondville, a building quite apart from the power house. A diagram showing every detail of the system is erected before the operator's desk. On this diagram, tags indicate the number of machines running at the various power houses, and which switches are open or closed throughout the system. Particulars of gangs working on the line are also posted on this board, with details of the work in hand.

* Miscellaneous revenue includes merchandise net profits, and earnings from investments, etc.

The system operator on duty has entire control of the system, and the operators at the power houses have to receive instructions from him before connecting a machine to the busbars, or taking one off. The loads at the power houses are telephoned to the operator hourly, and are plotted by him on a graph sheet. From this graph the system operator is able to observe the load, and as soon as it decreases by a certain amount he gives instructions over the system telephone for a machine to be taken off the busbars at one of the power plants. When the necessary switching has been effected, the power station operator will report to the system operator details of the switching which has been done. The whole operation is recorded on the daily log sheet which the system operator has before him.

Clearances for working parties to effect repairs on the line or other parts of the system which are alive, can be obtained only from the system operator. When a gang arrives at the site of the trouble, the foreman will ring through to the system operator and arrange for the clearance. When the line or apparatus has been made dead, the system operator advises the foreman of the working party. During the time that men are working upon repair jobs the line or apparatus is " tagged " to that effect upon the system operator's board and no switches are closed until the working party have reported all clear.

Operating costs, including maintenance, are given in dollars in Table 3.

(7) Maintenance.

Maintenance of substations is effected by a gang whose job it is to move any faulty transformers, and to repair bushings, substation equipment, and any other apparatus that becomes faulty, including power house equipment. The cost of maintenance can be seen from Table 3. The maintenance gang operates from the Drummondville plant department, and consists of a party of six men, including the driver of the equipment truck with which they are provided. Every necessary tool is carried, including what in Canada is called " hot line equipment," which enables insulators to be changed without interrupting the supply. Spare conductors, insulators, nuts and bolts, insulating material, rubber mats, gloves, etc., are all contained in specially designed compartments built round the body of the truck.

Maintenance of transmission lines is effected by patrol men who are alloted areas for which they are responsible. In the event of a faulty insulator being located, the patrol man immediately reports the matter to the system operator, giving the pole number and the condition of the insulator. He is able to report this from the field, as all he does is to climb up the pole, connect his test set, with which every patrol man is equipped, and ring through to the system operator. If possible the changing of the insulator is left until such a time that the least possible inconvenience is caused by shutting off the supply to that line; this is usually early in the morning or during Sunday, when factories are closed down. In cases of emergency, however, the matter receives immediate attention; the patrol man obtains assistance from the nearest local office, and with the least possible delay the insulator is changed.

Distribution lines are all under the supervision of the local staff for the municipality served, each town having its own office, with a manager and a staff for installation work, meter reading, and the care of the local distribution lines.

(8) Troubles.

Table 4 summarizes the causes of interruptions to the supply during the 12 months ended October 1930. It is obtained by multiplying the number of consumers affected, by the duration of the stoppage in minutes, and dividing by the number of consumers on the whole system. From this we get that the interruptions to the supply represented 0·23 per cent, or that the whole system was out for a period of 12·29 hours. Stated in another way, the operation was 99·77 per cent of perfection.

Table 4.

Interruptions to the Supply during the Year ended October 1930.

	Consumer-minutes / Total number of consumers
Lightning	296·5
Insulators	233·0
Conductors	57·3
Bushings	34·0
Bad operating	34·0
Line repairs, etc.	14·9
Transformers	13·5
Oil switches	13·5
Wind	12·1
Guy wires	6·1
Sleet	5·0
Trees	4·6
Unknown	3·6
Poles	3·4
Miscellaneous	6·0
	737·5 minutes

Most of the troubles experienced throughout the year were due to lightning. Faulty insulators account for the next biggest percentage of troubles; this may be partly due to the fact that the electric strength of some of the insulators may have been reduced owing to a flash-over during a storm. The condition of the insulators is carefully watched, both by patrol men and by linemen, and during the summer months a special insulator tester, which enables the insulators to be tested whilst the line is alive, makes a tour of the system, and weak insulators are marked down on a line report. At the earliest possible moment every insulator that has not passed the test is replaced. Usually the whole line is made dead and every available man on the system assists in the changing of insulators, thereby reducing the length of the stoppage to a minimum.

Each month a meeting of operatives is held at Drummondville. Each power house sends a representative, and all patrol men and members of the operating staff who are available must attend. The business is to discuss troubles, and anyone who has had any during the month states his case. The meeting is presided over

by the operating superintendent, and the entire proceedings are entered in a minute book, a copy of which is forwarded to the head office. Before the meeting breaks up, four demonstrations of resuscitation have to be given by members of the staff. There is thus no excuse for anyone in the employ of the company being unfamiliar with the correct method of performing this operation. Practices are held every week throughout the system.

(9) Substations.

The substations are nearly all of the outdoor type, the more modern ones having steel structures, whilst the earlier constructions are wooden. The transformer banks are usually mounted on concrete bases, although in some cases platforms have been built for mounting the transformers upon. Connections are made delta to delta, there being only one or two exceptions where the bank is delta to star, or star to delta. Substation construction follows standard lines, there being no unusual features. Transformers for outdoor-type substations are nearly all oil-cooled and range from 50 to 3 000 kVA capacity.

There are two exceptions in cooling practice, one at the substation at Sherbrooke, and the other at the switching station at Hemmings Falls. Both these stations have outdoor transformer banks, but in each case they are water-cooled.

The transformer bank at Sherbrooke was the first to be thus equipped, and this was done over six years ago; at that time the Southern Canada Power Co. claimed that it was the pioneer in adopting this practice in Canada. During the winter, temperatures as low as 40 degrees below zero are registered at Sherbrooke; this will give some idea of the conditions under which the transformers operate. This bank consists of three 1 250-kVA transformers, whilst the bank at Hemmings Falls consists of three 5 000-kVA transformers. The Hemmings Falls bank is used in conjunction with the Shawinigan tie, and is a quite recent construction, having been brought into operation only during the latter part of 1930. This bank is at present connected delta to delta, but later is to be changed to star to delta.

(10) Transmission.

The high-tension lines of the company are operated at three voltages: 306·7 miles at 48 000 volts, 42 miles at 22 000 volts, and 114·6 miles at 13 000 volts. The structures are mostly of the wooden variety, although steel towers are used, especially where the spans are long, e.g. at river crossings.

The Shawinigan Company's line, which runs from Three Rivers to Hemmings Falls, is suspended on steel towers the whole way, and where the line crosses the St. Lawrence River special arrangements have been made to vary the tension of the line, the extreme weather conditions making this necessary. In addition, as soon as the river opens up in the spring, heavy shipping traffic passes to and fro beneath this line. This line has been mentioned owing to the fact that through it the Southern Canada Power and the Shawinigan Co. tie their systems together. The height of the wooden structures varies between 35 ft. and 70 ft. H frames are also employed, but in this case only single circuits are carried, whereas a single-pole structure may carry either one or two circuits. Two types of steel tower are employed, the single circuit and the double circuit. The single-circuit tower usually supports the conductors in a horizontal plane at a height varying from 45 ft. to 69 ft. under normal conditions, whilst with the double-circuit tower the conductors are in a vertical plane at a height of from 60 ft. to 100 ft.

(11) Distribution.

Distribution transformers rarely exceed 100 kVA, the majority being between 1 and 25 kVA. For lighting service their spacing varies from 135 to 3 000 ft., the average being between 800 and 1 000 ft. Single-phase transformers are generally used for this service, with 2-wire or 3-wire secondaries.

For power loads the secondaries of the transformers are usually 3-phase delta-connected, and the secondary voltage is in most cases 220 or 550 volts. Distribution is also effected at 4 000 and 2 200 volts for power purposes.

Overload protection is taken care of by fuses, porcelain cut-outs and expulsion-type fuses being mostly employed.

Wooden poles are generally used, and vary in height from 30 ft. to 60 ft. Cross-arms are constructed of wood and are used almost exclusively. The standard dimensions for the arms are:

8-pin arm: $3\frac{1}{2}$ in. × $4\frac{1}{2}$ in. × 9 ft. 2 in., pins 12 in. apart, climbing space 30 in.
6-pin arm: $3\frac{1}{2}$ in. × $4\frac{1}{2}$ in. × 8 ft., pins $14\frac{1}{2}$ in. apart, climbing space 30 in.
4-pin arm: $3\frac{1}{2}$ in. × $4\frac{1}{2}$ in. × 7 ft. 7 in., pins $14\frac{1}{2}$ in. apart, climbing space $14\frac{1}{2}$ in.

Cross-arms situated vertically in the same plane are usually set 24 in. apart; where arms are set at right angles to each other a separation of 12 in. is usual.

Wooden pins and porcelain pin-type insulators are nearly always used, iron pins being employed only in special cases.

The conductors for distribution vary from 500 000 circular mils to No. 6, 4/0, and 2/0 American wire gauge for higher load densities, and No. 2 and No. 4 for the lighter loads. The conductors are generally medium hard-drawn, or soft-drawn copper, with triple-braided weatherproof covering. The configuration is generally horizontal, but where other wires of the same circuit are on another arm, the vertical spacing is almost invariably 24 in. Horizontal pin spacings are usually either 12 in. or $14\frac{1}{2}$ in., the $14\frac{1}{2}$ in. spacing being the most general, as this corresponds to the standard 4-pin and 6-pin cross-arm, the 8-pin cross-arm having a 12-in. pin spacing. For street-lighting circuits No. 6 triple-braided weatherproof wire is the most commonly used, but No. 8 conductors are also employed.

(12) Consumers.

The Southern Canada Power Co. serves altogether 118 municipalities, covering an area of some 6 000 square miles. The total number of consumers connected at the end of the year 1930 amounted to 26 594. Manufacturing concerns account for the biggest load. Drummondville has possibly the largest number of factories,

with Granby next; both these towns have a fair-sized population, and the domestic load is quite big. The growing popularity of electric cooking appliances, refrigerators, and washing-machines is increasing the domestic load, and in several areas new transformer banks have had to be installed to meet the demand. Small towns which at first only required a lighting service have had to have their substations increased in capacity for the same reason. Statistics are contained in Table 5. It will be seen that over a 4-year period there is only a 2½ per cent variation in the connections for the corresponding months.

(13) Tariffs.

General service.—10 cents per unit for first 500 units per month, 8 cents for next 500 units, and 6·66 cents for remainder. Minimum charge $1 per month; discount* 25 per cent; duration 1 year.

Residential service.—$2 per month, plus 4 cents per unit; or 60 cents per month, plus 8 cents per unit. Minimum charge $1 per month; discount 25 per cent; duration 1 year.

Commercial service.—$1 per month, plus 8 cents per unit for first 1 000 units per month, and 6·66 cents for remainder. Minimum charge $1 per month; discount 25 per cent; duration 1 year.

Cooking.—4 cents per unit. Minimum charge $1 per month; duration 1 year; discount 25 per cent.

Heating (Over 1 000 watts).—$1.34 per kW-month. Minimum charge $1.34 per month; discount 25 per cent; duration 1 year.

(*Under 1 000 watts*†).—10 cents per unit; discount 25 per cent.

Tank heaters.—$5.33 per kW-month; discount 25 per cent.

Power contracts.—The following are examples of the tariffs charged for power supplied to factories and consumers who use motors, etc.

Rating	Voltage	Contract	Remarks
Up to 2 h.p.	110	P6, P1‡	Available also for lighting, heating, and cooking.
2 to 10 h.p.	110	P6, P1	
5 to 10 h.p.	550	P6, P1	
10 h.p. (no minimum)	550	P1	
10 to 100 kW..	Primary	P1	
Over 100 kW..	Any primary	P1, P2	

Additional rates are also available for temporary connections, as shown under contract P5.

POWER CONTRACT P1.

Flat rate.

First kW of max. demand	$130 per annum
Second kW	$120 ,,
Third kW	$110 ,,
Fourth kW	$100 ,,
Fifth kW	$90 ,,
Each of next 5 additional kW ..	$80 ,,
Each of next 90 additional kW ..	$70 ,,
Each kW (100 kW minimum) ..	$72.50 ,,

* For payment within 10 days.
† This applies where added to existing lighting, or heating, or cooking.
‡ See below.

Alternative meter rate.

Service charge.	
First kW of max. demand	$8 per month
Second kW	$7 ,,
Third kW	$6 ,,
Fourth kW	$5 ,,
Fifth kW	$4 ,,
Each of next 5 additional kW ..	$3 ,,
Each of next 90 additional kW ..	$2 ,,
Each kW (100 kW minimum) ..	$2.25 ,,

Consumption charges, in addition to service charge:—
For first 50 hours' monthly use of max. demand, 5 cents per unit.
For next 50 hours' monthly use of max. demand, 2½ cents per unit.
For additional consumption, 0·6 cent.

Class A.—Power may be used at any time, charge as above.

Class B.—Power may be used each working day between the hours of 7 a.m. and 6 p.m., 20 per cent discount from above charge.

Table 5.

Number of Lighting and Heating Consumers.

No. of municipalities	Lighting consumers	Heating consumers		Date
		No.	Percentage of total	
89	17 948	2 578	14·4	Dec. 1927
99	19 279	2 982	15·5	Dec. 1928
106	20 781	3 205	15·4	Dec. 1929
114	21 783	3 265	15·0	Dec. 1930

Duration discounts.—Less than 5 years, net; 5 years and over, 20 per cent; 5 per cent allowed for synchronous and condenser equipment; 10 per cent allowed for payment within 10 days.

POWER CONTRACT P2.

Rate for service.

Fixed charge, $1.667 per month per kW of max. demand.
Meter charge, $1.67 per unit for first 50 units per month per kW of max. demand; $1.12 for next 50 units; and $0.883 per unit for remainder.
Discount, 10 per cent if paid within 10 days.

POWER CONTRACT P5.

Power rate.

Service required for one month or less.
$6 per h.p. of rated capacity of motor, payable in advance, plus $2.50 per h.p. per week or fraction thereof, for any service required in excess of 2 weeks, payable weekly in advance.
Service available 24 hours per day except Sundays and legal holidays.

POWER CONTRACT P6.

Fixed charge plus charge per unit.—Fixed charge, based on rated capacity of motor or other apparatus,

of $1.66 per horse-power per month, plus 5 cents per unit. 24-hour service except Sundays and legal holidays.

Consumer pays cost of making service available in this case. When 3-phase service is required an additional $25 is charged towards the cost of metering, plus 35 per cent overhead. All property belongs to the company.

(14) Construction.

All construction work is carried out by a construction gang. New switchgear and apparatus, including new transformers, are installed by this section. For big jobs the assistance of the maintenance gang is sometimes required. This is usually necessary only where heavy transformers have to be moved into position and the use of the equipment truck is required. A line construction gang deals entirely with the construction of new lines throughout the system. Buildings, dam construction, and similar work is handled by the Power Corporation of Canada, who place the work with sub-contractors.

(15) Tie-Bank Connections.

Early in 1931 the Southern Canada Power Co. and the Shawinigan Co. connected their systems through a set of 15 000-kVA transformers at Hemmings Falls. The transformers are at present delta-delta connected with a 50 000-volt connection on the Southern Canada side and a 66 000-volt connection on the Shawinigan system. Later the 66 000-volt connection will be changed to star, giving 110 000 volts. The station is one of the most up to date of its kind using outdoor equipment. The relay protection is all housed in a small brick building centrally located on the substation grounds. The control and metering is all taken care of by a system of conduits brought back to the power house at Hemmings Falls.

Interconnection is of great value both to the Shawinigan Co. and to the Southern Canada Power Co., since low-water conditions occur on the St. Francis River at a different time from those on the St. Maurice River, which is the source of supply of the Shawinigan Co. Interconnection also provides the Southern Canada Power Co. with ample capacity for all peak loads. At periods of high water the excess power on the St. Francis is disposed of to the Shawinigan Co., who find a market for it in electric boilers, or in the large chemical works at Shawinigan.

Additional linking-up is provided with the Montreal Light, Heat, and Power Co. through a Scott-connected bank of transformers of 5 000-kVA capacity, and several smaller connections are available in cases of emergency.

(16) Industrial Development.

Keen interest is taken by the Southern Canada Power Co. in encouraging new plants to start up in its area. For this purpose an industrial department is in operation, which deals entirely with this branch of the business. Over a period of four years this department has brought to the attention of manufacturers throughout the world the unequalled opportunities for economic production that exist in the district. As a result, 43 new industries have been started and give employment to more than 10 000 people.

(17) Acknowledgment.

The author is indebted to the Southern Canada Power Co. for the data contained in this paper.

DISCUSSION ON

"POLYPHASE COMPENSATED COMMUTATOR INDUCTION MOTORS."*

Mr. H. M. Clarke (*communicated*): The fact that the paper obviates the necessity of referring to the circle diagram of the simple induction motor is probably the reason why the author omits the following interesting comparisons. Referring to equation 7 (vol. 70, page 374), it will be noticed that

$$x_c = E_1/2X = E_1/2(x_1 + x_2) \quad \text{and} \quad y_c = kE_1 \cos\beta/2R_2$$

So far as x_c is concerned, the commutator has no effect and the chord of intercept of the x axis in Fig. 22 is the same as for the simple motor. Considering y_c, the case of the simple motor is obtained when k is zero; the centre then lies on the x axis. The size of the circle for the compensated motor only differs from that for the simple motor according to the variations of y_c. The locus of the centre of the circle is a line parallel to the y axis. Unless y_c becomes comparable with x_c, the size of the circle will be only slightly changed. The centre will move in such a way as to give an improvement in power factor, provided $\cos\beta$ is positive. Hence

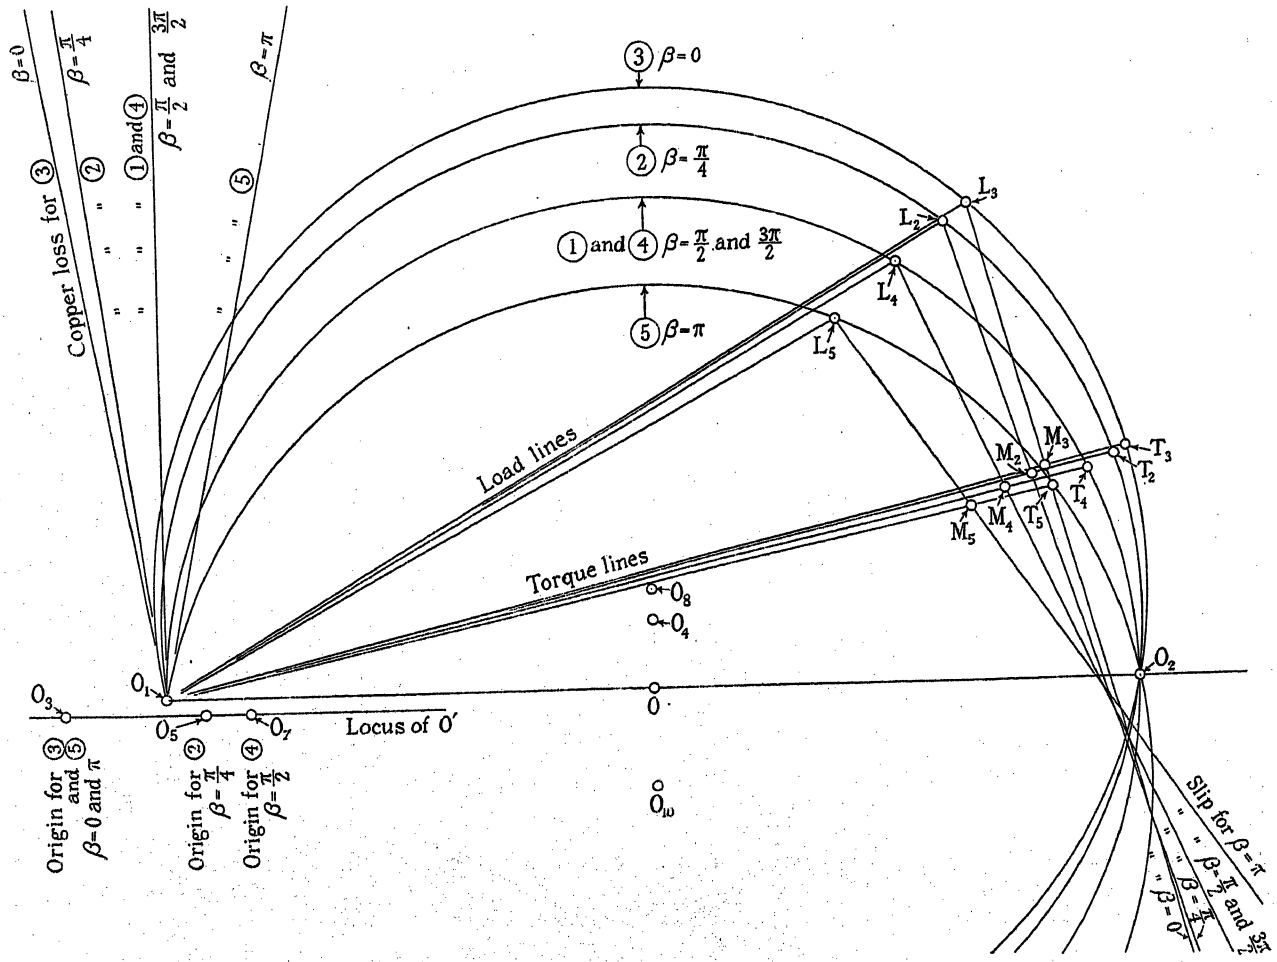

Fig. A.

a nest of circles can be drawn, all passing through O_1 and the other intercept on the x axis, say O_2, their centres all on the right bisector of O_1O_2 and displaced from the x axis according to the value of $kE_1 \cos\beta/2R_2$. As the author points out, the principal effect of the commutator is at O′, the centre of current vectors. The locus of O′ is a line parallel to the x axis and below it by an amount y_n representing the iron loss, just as it would be in the case of the simple motor. The x co-ordinate of O′ is displaced from O_1 by $E_1\left[(k \sin\beta/R_2) - b_0\right]$, or if the usual origin of current vectors for the simple motor be called O_3 (a point on the line $y = y_n$), the new origin O′ is on this line where O_3O' equals $kE_1 \sin\beta/R_2$. To summarize, take the origin of co-ordinates at O_1.

* Paper by Dr. J. J. RUDRA (see vol. 70, p. 365).

then all the circles pass through O_1O_2 with their centres on the line

$$x = E_1/2X \quad \text{at} \quad y_c = kE_1 \cos\beta/2R_2;$$

all the origins O′ lie on the line

$$y = -y_n \quad \text{at} \quad x = E_1[(k \sin\beta/R_2) - b_0].$$

By this means the lines of load, torque, and copper loss pass through the same point O_1 for all values of β. The variation of k may also be studied conveniently. Fig. A illustrates these points.

Another interesting point can be brought out with reference to equation 1 (page 369) and the expression $x_1(I_1 - kI_2)$ for the leakage-reactance drop in the primary. From equation 1 it follows directly that

$$I_1 - kI_2 = I_0 + I_2$$

Now $I_0 + I_2$ is the primary current for the uncompensated motor, and therefore the primary leakage-reactance drop of the simple motor is the same as that of the compensated motor. The author omits a construction for the slip. Referring to Fig. 8, it appears that the term $R_2/[(s + m)(1 + m)]$ is most convenient for this purpose. I think that

(Rotor input)/(Rotor copper-loss)

is equal to $(1 + m)/(s + m)$; this assumption certainly gives the correct result for the simple motor when m is zero. In that case, referring to Fig. 22 (page 377),

$$\begin{aligned}\text{(Rotor input)/(Rotor copper-loss)} &= r_1C_T/R_2C_R) \times (P_T/P_R)\\ &= (r_1C_T/R_2C_R) \times (\sin \mathrm{PO_1T}/\sin \mathrm{PTO_1})\\ &= a(\sin \mathrm{PO_1T}/\sin \mathrm{PTO_1})\end{aligned}$$

where $a = r_1C_T/R_2C_R$

Draw LM parallel to the tangent at T to cut O_1T in M. Join PT to cut LM in S.

Then

$$\sin \mathrm{PO_1T}/\sin \mathrm{PTO_1} = \sin \mathrm{MST}/\sin \mathrm{STM} = \mathrm{MT}/\mathrm{SM},$$

and $(1 + m)/(s + m) = a(\mathrm{MT}/\mathrm{SM})$

When $s = 1$, P moves round to L, and

$$(1 + m)/(1 + m) = a(\mathrm{MT}/\mathrm{LM})$$

Therefore

$$(s + m)/(1 + m) = \mathrm{SM}/\mathrm{LM}$$

When $(s + m)$ is zero, SM is zero, and P coincides with O_1. LM produced in both directions is the slip line, L is at $s = 1$, M is at $(s + m) = 0$, and the length SM is proportional to $(s + m)$.
